Previous studies investigated the seismic behaviour of offshore pipelines [7-9]. However, to the knowledge of the authors, the seismic studies of high pressure/high temperature (HP/HT) pipelines so far has been limited to buried and trenched pipelines [10]. A subsea HT/HP pipeline can undergo large bending stresses and strains due to lateral/upheaval buckling or free-spanning [11-14]. If the compressive strain in the pipe wall exceeds a certain limit, structural instability, in the form of local buckling/wrinkling may occur [15]. Periodic loading, such as flow-induced vibrations and earthquakes may cause fatigue cracks in this affected region [16]. In the current paper the seismic and thermal buckling responses of an unburied HP/HT subsea pipeline laid on an uneven seabed is investigated numerically. Structural responses of the pipeline under 17 recorded ground motions are considered in two scenarios:

(1) Scenario 1, where a controlled lateral buckle of the HP/HT pipeline is followed by the earthquake (EQ) input;
(2) Scenario 2, where the imposed EQ triggers the lateral buckle.

2 FINITE ELEMENT MODEL

Due to the lack of seafloor earthquake recordings, in the present study onshore ground motions are considered by neglecting the effects of the surrounding seawater layer on the pipeline response. Previous studies [17, 18] showed that the interaction between S-waves and P-waves, especially at resonant frequencies of propagating waves in the water, can mainly affect the vertical seafloor motion. Another contribution [19] considered a steel pipeline with outside diameter of OD = 350 mm, single span length of 16 meters and mechanical parameters (Table 1). By applying the commercial finite element analysis (FEA) package ABAQUS [20], in this section the same single span pipe (Figure 1) is considered and is placed on a soil domain characterized by two layers. The properties of the soil layers are shown in Table 2. The pipeline is modelled in ABAQUS using 2-node linear beam elements named PIPE31 [20]. The 16 m single span pipe is divided into 40 elements along its circumference and 100 elements in the longitudinal direction. The soil domain has surface dimensions of 48×48 m and a total depth of 40 meters. The adjacent spans are incorporated by simulating the boundary conditions with rotational springs (stiffness: 1.465×10^5 Nm/rad) and translational springs (stiffness: 1.1644×10^6 N/m) on either ends of the pipeline. The model presented in this paper was previously developed by [21] with the aim to apply a probability-based approach.

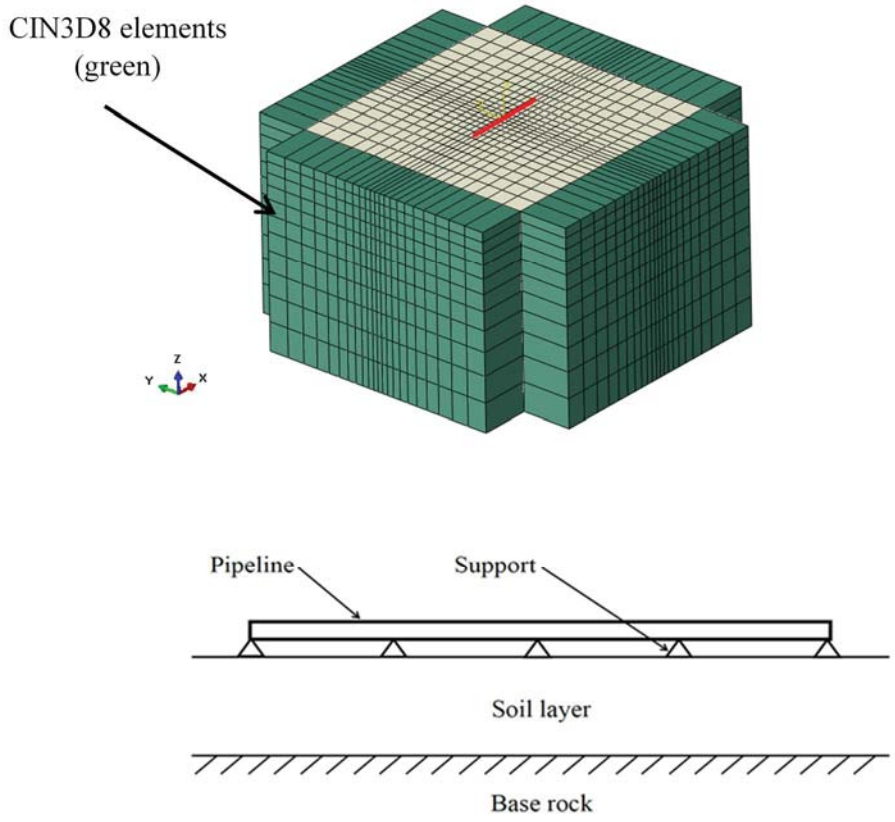

Figure 1: The FEA model, showing the pipeline and the soil and the numerical mesh used to validate the seismic analysis in comparison with the previous work [19].

Length, L (m)	16
Outer diameter, OD (mm)	350

Damping ratio, ξ (%)	1.2

Table 1: Single span steel pipeline properties used in the seismic validation model.

Parameter	Soil layer	Base rock
Layer thickness, h (m)	30	10
Mass density, ρ (kg/m^3)	2000	3000
Shear modulus, G (MPa)	200	1800
Poisson's ratio, v	0.4	0.33
Damping ratio, ξ (%)	5	5

Table 2: Soil domain properties used in the seismic validation model.

Both the soil layer and the bedrock are discretised using three-dimensional C3D8R 8-node solid elements that allowed to model realistic seismic wave propagation at a depth far enough from the pipeline, so that the scaling effects can be neglected [22, 23]. Soil mesh size are chosen based on the Rayleigh wavelength parameters [24-27]. A variable mesh dimension is chosen, with soil elements becoming denser towards the centre and the surface of the soil domain (elements side length: 4 m on the lateral borders and 1 m at the centre of the model). The base boundary are constrained in order to simulate bedrock conditions (at 40 m depth from ground surface). CIN3D8 elements (Figure 1) constrain each node on one side of the lateral boundary of the soil domain in order to move the same as the analogous node on the opposite side (in both horizontal and vertical directions). Such conditions are used to simulate real wave propagation in a presumably infinite (or at least very large) soil domain, avoiding wave reflection disturbance and allowing the seismic energy to be removed from the site itself [28-32]. The damping ratios (Table 1 and Table 2) are added to the materials properties in the form of Rayleigh damping coefficients [33, 34]:

$$[C] = \alpha_d [M] + \beta_d [K] \tag{1}$$

where $[C]$ is the damping matrix, $[M]$ is the mass matrix and $[K]$ is the stiffness matrix, α_d and β_d are the mass-proportional and stiffness-proportional damping coefficients, respectively (Table 3).

Material	ξ (%)	α_d	β_d
Steel (pipeline)	1.2	0.14053	0.001018
Soil layer	5	0.58555	0.004240
Base rock	5	0.58555	0.004240

Table 3: Rayleigh damping parameters.

Based on an eigenvalue analysis, the pipe fundamental vibration frequency is found to be in the transverse direction and equal to 3.8992 Hz, which is close to the vibration frequency of 3.8556 Hz obtained by Bi and Hao [19]. The pipe-soil system frequencies, ω_1 and ω_3 are found to be equal to 1.7213 Hz and 2.0322 Hz, respectively. The mass-proportional and stiffness-proportional damping coefficients are calculated and represented in Table 3.

A seismic input motion, San Fernando earthquake with a PGA of 0.026*g*, is selected from the Pacific Earthquake Engineering Research Centre (PEER) [34] database and applied at the base of the bedrock along the transverse direction (*y*-direction shown in Figure 1). Time histories of maximum displacements obtained from the current and from Bi and Hao [19] models are shown in Figure 2. It should be noted that in Bi and Hao's work [19] the pipeline is modelled with 3D 20-node solid elements, whereas in the current work 2-node beam elements are used. Therefore, the negligible discrepancies in the amplitude observed between the two time histories in Figure 2 may be related to the different pipe element types. The results are in good agreement and show that the adopted beam model can predict the seismic wave propagation properly.

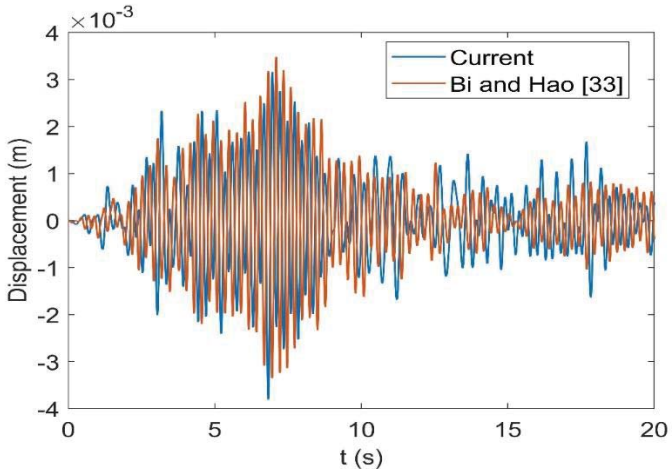

Figure 2: Seismic response of the pipeline in Figure 1, comparison between current results and Bi and Hao [19].

To study the interaction between thermal buckling and seismic disturbance, X65 steel pipeline with parameters represented in Table 4 is selected. The same pipeline is used in a thermal buckling study conducted by [36].

Length, L (m)	2000
Outer diameter, OD (mm)	254
Wall thickness, t (mm)	12.7
Thermal expansion coefficient, α (°C^{-1})	$1.01 \cdot 10^{-5}$
Young's modulus, E (MPa)	206000
Poisson's ratio, v	0.3
Lateral imperfection ratio, h_0/l_0	0.012

Seabed friction coefficient, μ_1	0.5
Sleeper friction coefficient, μ_2	0.3
Sleeper height, h (m)	0.5

Table 4: Pipeline and seabed properties.

3 RESULTS

3.1 Thermal buckling

The pipeline with length of 2000 meters is laid on a rigid seabed (Figure 3 and Table 4), by using PIPE31 beam elements. A sleeper with height h = 500 mm (h/OD = 1.97), laid under the pipeline at its mid-length is used in order to control the lateral buckling [35] and is modelled with R3D4 shell elements (semicircular cross section). The seabed was meshed using R3D4 rigid shell elements [20]. Pipe element size is gradually decreased towards the midpoint area, where the length is set as half the diameter [15]. Both ends of the pipeline are pin-connected to the seabed using multiple point constraint (MPC) elements. The ends are far enough from the sleeper, to allow sufficient feed-in length into the buckle region. The sleeper is fixed to the seabed with a tie constraint. Mohr-Coulomb constitutive contact behaviour is used to model the interaction between the pipeline and the seabed and between the pipeline and the sleeper, with friction coefficients of μ_1 and μ_2, respectively (see Table 4). A large penalty stiffness coefficient is used to simulate hard contact definition between the pipeline and sleeper and soil [11]. To control the lateral buckling response, a sinusoidal initial imperfection was imposed on the pipeline at the point of contact with the sleeper with an amplitude to half wave-length ratio, h_0/l_0 = 0.012 and a schematic shape (Figure 3).

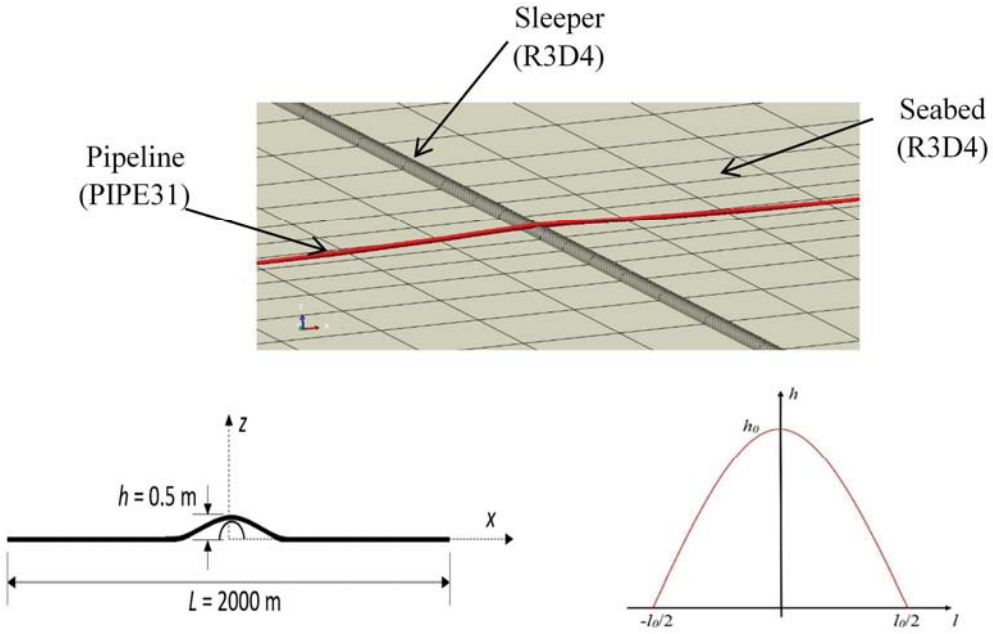

Figure 3: The pipeline and sleeper model used in the thermal buckling and seismic/thermal interaction models.

In order to obtain the thermal buckling response of the pipeline, the following load steps, in the mentioned sequence, are imposed to the pipeline, using a quasi-static dynamic analysis with geometric nonlinearity. (1) The self-weight is applied to the pipeline assuming a total buoyant weight of m = 153 kg/m (m included the submerged weight of the pipeline and its concrete coating). At the end of this load step, the pipeline deforms on the sleeper, with free-spans on either side of the sleeper and corresponding touchdown points [11, 36]. (2) An internal pressure of P_{int} = 12 MPa is applied to the pipeline, and (3) an increasing temperature change of ΔT is uniformly applied to the wall thickness. Due to the actions of the internal pressure and thermal

loading, the pipeline tends to expand. However, this expansion is balanced by the reaction of the soil, inducing axial forces in the wall thickness and causing a global lateral buckling in the pipeline [11, 15]. The maximum lateral buckle amplitude in the pipeline occurs at the contact point with the sleeper (Figure 4a). The temperature increased up to a critical value, after which the buckle amplitude monotonically upsurges with the corresponding increase in the temperature. The lateral buckle profiles at different temperatures are plotted in Figure 4b. The lateral buckle mode is shown to be similar to Hobb's mode 3 [37], as expected [11, 36]. In correspondence with the calculated (Figure 4a and 4b) critical temperature of the pipeline (T_{cr} = 26-30 °C), two scenarios are studied: scenario 1, post-buckle seismic input, and scenario 2 pre-buckle seismic input, by applying a total of 17 earthquake input motions from PEER database [35]. Input spectra of the selected 17 input motions are shown in Figures 5 and the characteristics of each input motion is outlined in Table 5.

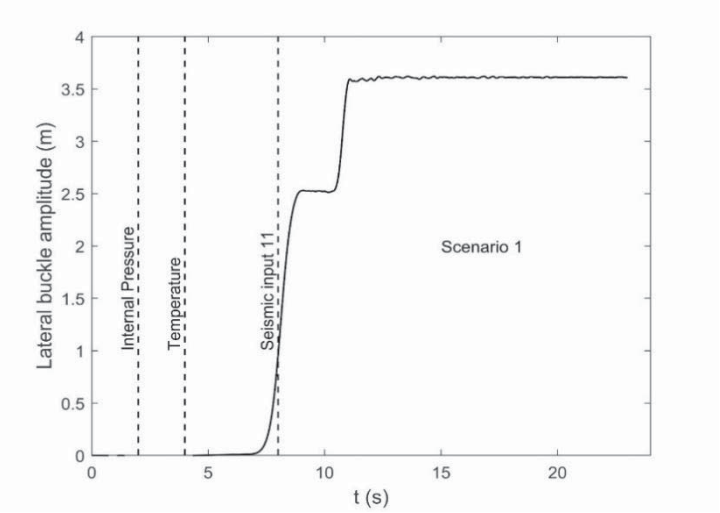
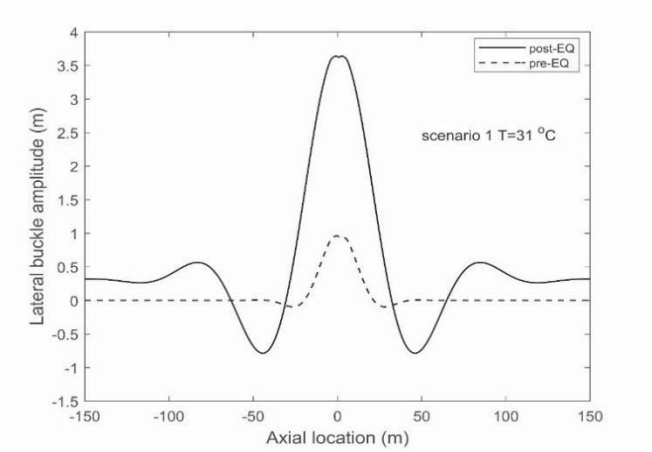
Table 5: Characteristics of the selected seismic input motions.

3.2 Scenario 1: post-buckle seismic input

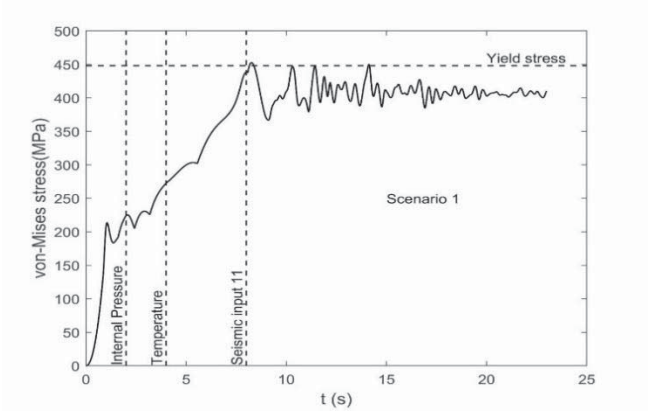
In addition to the self-weight (m = 153 kg/m) and internal pressure P_{int} = 12 MPa, the temperature in the pipeline is increased up to 31 °C (higher than the critical temperature). At this temperature, the pipeline has already buckled (see Figure 4b). Then, the seismic inputs are applied to the soil at a depth of 5 m below the seabed and in the y-direction (see Figure 3). The time histories of the lateral buckle amplitude at various stages of the loading are displayed in Figure 6. The lateral buckle profile and the crown stress distribution before and slightly after the application of the seismic input n.11 (Northridge) are shown in Figures 6b and 6c, respectively. It is worth noticing that the introduction of the seismic load significantly increases the buckle amplitude, and consequently the maximum stress at the crown of the buckled pipeline upsurges to a level slightly above the yield stress (448 MPa). The interaction buckle mode (solid line in Figure 6b) is similar to the thermal buckle mode (dashed line in Figure 6b).



(a)



(b)



(c)

Figure 6: Scenario 1, (a) displacement time history, (b) the buckle profile, and (c) the von Mises stress time history in the buckle crown.

3.3 Scenario 2: pre-buckle seismic input

Following the application of the self-weight and the internal pressure, the temperature variation is kept at $\Delta T = 25$ °C (slightly below the critical temperature), and then the seismic input is applied. Results for the seismic input n.11 are shown in Figure 7, where $t = 0$ s corresponds to the onset of application of the seismic load. Due to the seismic action, the pipeline buckles with a maximum crown displacement of 3 m (Figure 7b). Several findings are considered. (1) Maximum displacement value is smaller than that calculated in scenario 1 (Figure 6b); (2) the buckle shape is symmetric and similar to the buckle shape under thermal loading only; (3) the maximum stress in the crown increased from 380 MPa to almost 440 MPa (Figure 7c), due to the combination of thermal and seismic actions. However, the maximum stress is still lower than the assumed yield stress (448 MPa).

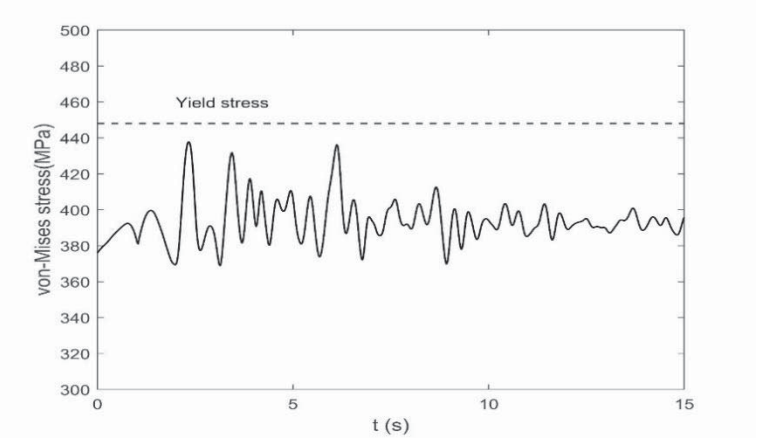
(b)



(c)

Figure 7: Scenario 2, (a) displacement time history, (b) the buckle profile, and (c) the von Mises stress time history in the buckle crown.

3.4 Bending response of the pipeline

It is worth noticing that even if the lateral buckling is not a failure mode by itself, yielding or rupture in the pipeline may occur when the bending stresses and local compressive strains exceed the ultimate values. In this regard, the bending response of the pipeline is assessed by modelling 1.27 m (5*D*) pipeline with 8-node linear brick elements (C3D8R) and by adopting isotropic bilinear material properties with yield stress of $\sigma_y = 448$ MPa and tangent modulus of $E_t = 0.01E$ (Table 4). Under symmetrical assumptions, half length of the pipe is modelled and a bending moment is applied at one end of the tube by applying a master/slave arrangement and by using MPC rigid elements (to restrain the ovalisation). The normalised moment-curvature response is shown in Figure 8, where moment is normalised to the plastic moment M_P, and curvature is normalised by the critical curvature k_c:

$$M_P = \sigma_y (D-t)^2 t \quad , \quad \kappa_c = \frac{t}{(D-t)^2} \tag{2}$$

At normalised moments $M/M_P > 0.9$, nonlinear material behaviour is observed, and is followed by a substantial increase in the curvature. The ultimate moment is reached at $1.08M_P$ (Figure 8a). Deformation and von Mises stress contours at selected stages of the curvature (I-IV) marked on the moment-curvature curve, are plotted in Figure 8b. At stage I, the von Mises stress in the pipe wall thickness reaches the yield stress. However, wrinkles in the compressive face (local buckle) start to appear at stage II. In stages III and IV, the compressive wrinkle progress substantially, and the cross section is significantly ovalised. The calculated critical strain in the pipe wall (ε_{cr}) at stage II (shown in Figure 8a) is $\varepsilon_{cr} = 1.576 \times 10^{-2}$ mm/mm, and it is about 1/4th of the well-known theoretical expression $\varepsilon_{cr} = 0.6\frac{2t}{D}$ as suggested in the previous experimental contribution [38] and recommendations of DNV [39].

4 CONCLUSIONS

A numerical model was proposed in order to study the interaction between earthquake and thermal buckling in a subsea pipeline. The thermal buckling response of the pipeline under action of buoyant self-weight, internal pressure and temperature variation from the inner fluid was analyzed. The interaction between seismic load and service loads (pressure and temperature) was studied using 17 earthquake inputs. The interaction study was conducted with two different scenarios: (1) the seismic input was imposed at a temperature of 31 °C (buckled pipeline) and (2) where the temperature was kept at 25 °C (unbuckled pipeline). Maximum stresses and compressive strains were compared. Future study will be conducted in order to assess analytical fragility curves.

Keywords: Gravity System, Special Steel Moment Frames, Energy Dissipation

Abstract.

The effect of the gravity framing system on the seismic performance of steel frame buildings is an essential, but currently challenging, aspect of predicting building performance and evaluating community resilience in earthquakes. Analytical studies and field observations have indicated that the gravity framing system, can have a profound effect on the lateral behavior of steel-framed buildings. The main factors that affect the influence of the gravity framing are the gravity columns and the beam-column connections. The gravity columns improve the performances of steel structures providing what is known as continuous stiffness. On the other hand, gravity connections provide strength and another source of energy dissipation. Even though different studies have concluded that the gravity system improves considerably the collapse performance of special steel frame structures, it is still neglected at the design and analysis stage. One of the main reasons why the gravity system is not considered is the difficulty of modeling the beam-column connections. The cyclic hysteretic behavior of commonly used gravity connections presents strength degradation and pinching behavior.

Previous investigations have shown the importance of modeling accurately the cyclic behavior of the lateral resisting system, especially to capture dynamic instability. However, there are no studies regarding the effects of accuracy when modeling gravity connections. This paper investigates the effects of modeling the gravity connections on the seismic performance of special steel structures different approaches that vary in difficulty. The effectiveness of the approaches is illustrated through the analysis of an 8-Story building. Nonlinear dynamic response history analyses are conducted and the effect of the approaches used is evaluated in terms of deformations, energy dissipation and the collapse performance. The results obtained in this investigation show that modeling in detail the gravity connection´s hysteretic behavior is not relevant when the dissipation of energy is compared to the main lateral resisting system.

1 INTRODUCTION

Nonlinear performance assessment of structures is becoming in the present a common procedure to analyze and design structures under seismic loads. According to the current code (ASCE7-16), if the nonlinear analysis is required, it is necessary to establish the probability of collapse at a seismic hazard with a 2% probability of exceedance in 50 years. This kind of analysis require a detailed mathematical model that represent all the main sources of energy dissipation within the structure. The dissipation of energy, when a structure is subjected to earthquake loads, is expected to occur only at the lateral resisting system. In the case of Special Steel Moment Frames (SMFs), the dissipation of energy is expected to undergo at the ends of beams and at the base of the columns of the lateral resistant system. As a result, it is common practice to neglect the gravity system strength and energy dissipation contribution.

It has been proven through experience in real events and numerical investigations that the gravity system contribution could be important when SMFs are subjected to seismic loads. During the Northridge earthquake in 1994, multiple beam-to-column connections in SMFs presented brittle failures and did not dissipate energy as expected. However, structures did not collapse and the most likely reason behind this, is because the gravity system helped to resist the seismic loads [1]. As a consequence of this event, different numerical and laboratory test investigations were developed in order to evaluate the real capacity of gravity connections and their influence on the seismic performance of SMFs.

Liu and Astaneh [2] performed cyclic tests to different commonly used gravity system connections. It was found that shear tab connections moment capacity was approximately 20% the beam plastic moment strength (Mp) if the slab contribution was neglected and 35% Mp if not. Moreover, it was found that shear tab connections have a large inelastic rotation capacity. Gupta and Krawinkler [3] addressed the seismic performance of SMFs at various hazard levels including the gravity system. The gravity connections were modeled using a bilinear moment rotation constitutive law with a strength capacity of 40%Mp for positive bending and 20%Mp for negative bending. One of the main conclusions from this investigation was that the gravity system improves the seismic response of the structure when it is subjected to large drifts. However, it is stated by the authors that the contribution of the gravity column continuity appeared to be the most important having the gravity connections a much less important role. Flores et al. (2014) [4] studied the effect of the gravity system on the collapse performance of SMFs. The study focused on the influence of the gravity columns and the strength of the gravity connections. In the investigation, a simple hysteretic behavior with a backbone curve that presented strength degradation was used to represent the gravity connections behavior. The conclusions were that gravity connections had more influence in low rise buildings but the continuity of gravity columns is what improves the most the performance, especially in high rise buildings. Another investigation was performed by Elkady and Lignos 2014 [5] were the influence of the gravity system on the collapse performance of SMFs was also computed. In this investigation, a very detailed hysteretic behavior was used to model the gravity connections. The main conclusion from this paper regarding the influence of the gravity connections was that they improve the collapse performance of SMFs.

Despite the fact to be known that the gravity system improves the seismic performance of SMFs when subjected to large deformations, its contribution is still neglected in analysis and design. One of the main reasons why the gravity system is not incorporated is the complex hysteretic behavior that gravity connections have when subjected to cyclic loads. It has been established by studies like the one presented by Ibarra and Krawinkler [6], that certain hysteretic behavior characteristics are fundamental to capture the structural dynamic instability. For instance, in order to evaluate the collapse performance of SMFs it is necessary to incorporate

cyclic and strength degradation into the hysteretic behavior of beams and columns. These modelling recommendations apply to the main lateral resisting system and it has been assumed that they have the same effect on the gravity system. However, there is no investigation, to the author's knowledge, where the main lateral resisting system fulfills all the modelling requirements to perform complex analyses and the hysteretic behavior of the gravity connections is studied to evaluate their effectiveness.

In this investigation, an 8-Story Special Steel Moment Frame is analyzed including the gravity system. The structure is analyzed under different hazard levels using Far Field ground motions from the FEMA P-695 methodology [7]. The lateral resisting system of the structure incorporates detailed hysteretic models making it able to capture dynamic stability. On the other hand, the gravity system is included to evaluate the effect that gravity connection's hysteretic behavior has on the performance. Three different hysteretic behaviors are considered: a simple bilinear model, a hysteretic model that follows a backbone curve with strength degradation but with an arbitrary cyclic behavior and a more realistic complex model. The effects of the gravity connection's hysteretic behavior are evaluated by comparing nonlinear static capacity curves (pushover curves), first floor interstory drifts and maximum drifts along the building height. Additionally, the energy dissipated by the gravity system is compared among the models.

2 BUILDING OVERVIEW

The structure to be analyzed in this investigation is one of the buildings that have been extensively investigated since they formed part of the ATC 76-1 project [8]. In the former study, multiple Special Steel Moment Frames (SMFs) were analyzed using the FEMA P-695 to evaluate their collapse performance. The purpose of the project was to establish if the seismic performance factors provided by current codes are adequate. As mandated by the FEMA P-695 methodology the gravity system was not considered as part of the lateral resisting system.

The analyzed system is an 8-Story SMF designed using Response Spectrum Analysis (RSA) following the requirements given in AISC 341-05 [6] and ASCE/SEI 7-05 [9] with the exception that the deflection amplifier Cd was taken equal to the response modification factor, R, as specified in FEMA P-695. The seismic design category used for the design was Dmax as defined by the FEMA P695 (Site Class D, S_s=1.5g, S_1=0.6g). The SMF was designed considering fixed at the base of the columns and using Reduced Beam Sections (RBS) connections.

Figure 1 displays the plan view of the structure. The building has been designed using two lateral resisting systems in each direction. The figure also shows the gravity system in half the structure that is going to be evaluated. The gravity connections are considered to have flexural strength when the beam frames into the column´s strong axis. The height of the first story is 15ft and the rest is 13ft. The design loads are 90 psf as dead load (D) and as live load (L) 50 psf on all floors, except on the roof were 20 psf was used. The load combination considered to perform nonlinear static and dynamic analysis is 1.0 D + 0.25L.

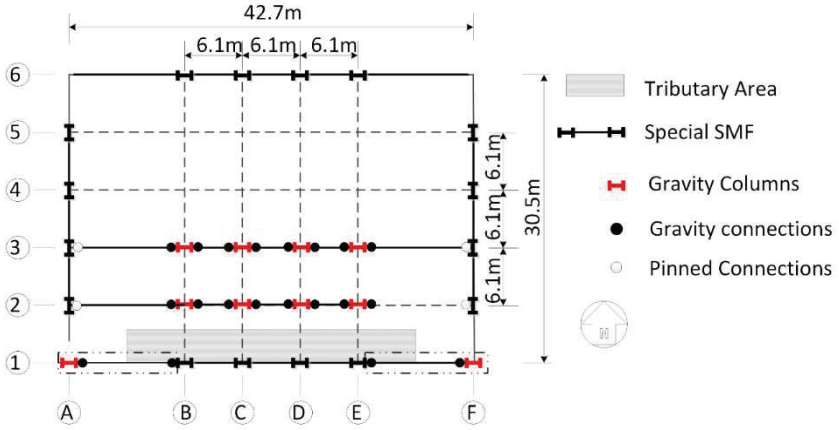

Figure 1 Plan View

The columns and beams of the gravity system were designed for the aforementioned loads using an A992 steel. The sections of the gravity system were designed following common practice, which is considering the gravity connections to have zero strength capacity. The column sections were considered the same along the height (W14x90), and the same beam sections were used on every floor (W24x55). It is important to point out that the gravity columns are considered continuous along their height in order to provide the benefits of continuous stiffness to the system Flores et al. [10]. This assumption implies that splices along the column's height provide full capacity.

3 SPECIAL STEEL MOMENT FRAME NONLINEAR MODEL

The purpose of this investigation is to evaluate the effect of modelling the gravity connections has on the performance of SMFs. However, the nonlinear mathematical model of the SMF, created in OpenSees [11], has to fulfill the minimum requirements to perform complex analyses such as evaluating the collapse performance. The material nonlinearities assumed in the 8-Story structure were represented using concentrated plasticity models at the panel zones and near the end of beams and columns. On the other hand, the geometric nonlinearities were incorporated using a leaning column when the gravity system was not explicitly modeled. The destabilizing load applied to this element corresponds to half of the building's gravity load minus the tributary load is taken by the SMF. Figure 2 displays a representation of the nonlinear mathematical model.

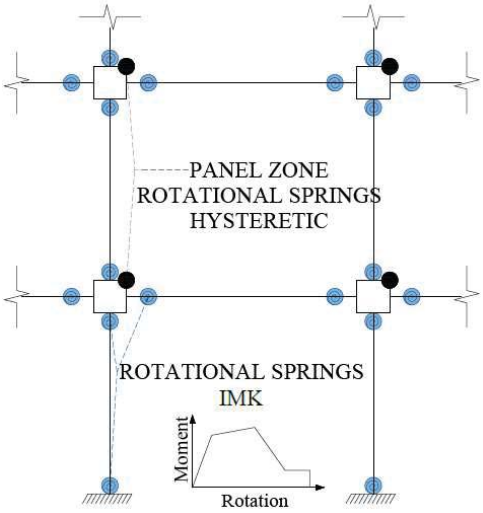

Figure 2 SMF Nonlinear Model

The hysteretic behavior assigned to beams and columns was proposed by Ibarra, Medina, and Krawinkler [12]. The backbone curve, as shown in Figure 3a, captures strength degradation. However, the cyclic behavior also incorporates strength and stiffness deterioration. All of these parameters are very important to capture residual deformations and dynamic instability [6]. The hysteretic behavior of beams and columns was calibrated using what is proposed by Lignos and Krawinkler [13]. One of the setbacks that column's hysteretic behavior currently have is that there is no phenomenological mathematical model that captures the Axial-Moment interaction. In order to overcome this, the flexural capacity of the column is reduced using a representative axial load which was taken equal to the gravity loads as proposed by Hartloper et al. [14]. Figure 3b and Figure 3c illustrates the hysteretic of one of the columns and one of the RBS connection respectively.

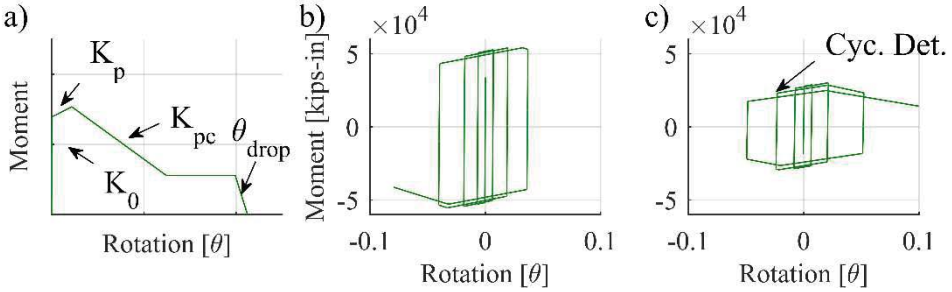

Figure 3 Beams and Columns Hysteretic Behavior a) Backbone curve b) Column c) RBS connection

The shear distortions that occur in the panel zone were modeled using a rectangular region composed of eight very stiff elastic beam-column elements and one nonlinear rotational spring (Figure 4a) proposed by Krawinkler [15]. The hysteretic backbone curve behavior is trilinear (Figure 4b) and represents shear yielding and column flange flexure yielding. The hysteretic behavior of these components is shown in Figure 4c.

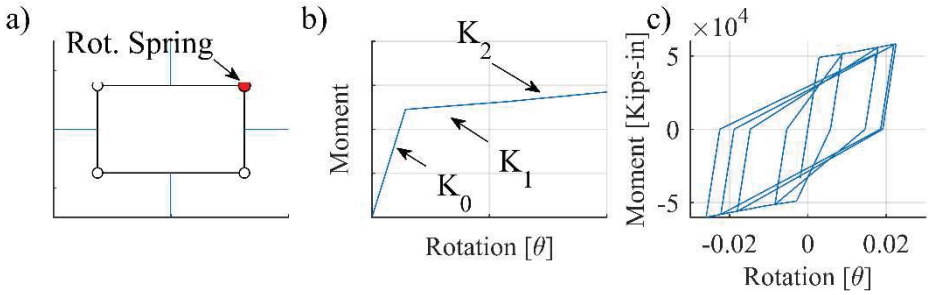

Figure 4 Panel Zone Model a) Geometry b) Backbone Curve c) Hysteretic behavior

4 GRAVITY SYSTEM NONLINEAR MODEL

In the case of the gravity system, columns, beams, and connections were explicitly modeled. The gravity columns were assumed to be continuous and pinned at the base in order to incorporate the continuous stiffness effect [10]. The gravity connections are the main point to be investigated in this study. The number of connections is generally much larger than the lateral resisting system connections, so the general trend is to assume that the influence is important. However, no investigation evaluates the importance of the detail required to model the gravity connections. Thus, in this investigation, three different hysteretic models are assigned to the connections, and the influence of the connection's flexural strength capacity is also evaluated. The flexural strength assigned to the connections was 0%, 15% and 35% the plastic capacity of the beams.

The importance of the gravity connection's hysteretic behavior is evaluated employing nonlinear static and dynamic analyses. In the first case, the back-bone curve will influence the structural force deformation response (pushover curve). In the second case, the gravity connection's cyclic behavior is going to influence the dynamic response. Each of the cyclic behavior assigned to the gravity connections is described in the following subsections.

4.1 Bilinear Model

This is the simplest of the nonlinear behaviors assigned to the gravity connections. In this case, an elastoplastic constitutive law is considered. The yielding rotation is equal to θ_y=0.008 and the maximum flexural capacity is a parameter to be investigated. Figure 5 illustrates the cyclic connection behavior.

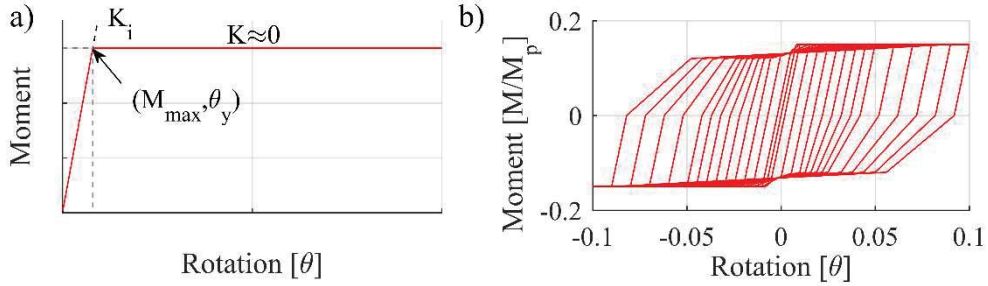

Figure 5 Gravity Connection Bilinear Hysteretic Behavior

4.2 ASCE41 Model

The hysteretic behavior assigned to the gravity connections in this model was based on what is recommended by ASCE41-17 [16] for Partially Restrained (PR) connections. Even though the former standard proposes the PR connections backbone curve model to be used in nonlinear static analyses, a cyclic behavior with pinching is considered in order to perform nonlinear

dynamic analysis. This model has strength degradation, but it does not include cyclic or stiffness deterioration. The yielding, and strength loss rotations are equal to θ_y=0.008 and θ_{drop}=0.08, respectively, as shown in Figure 6.

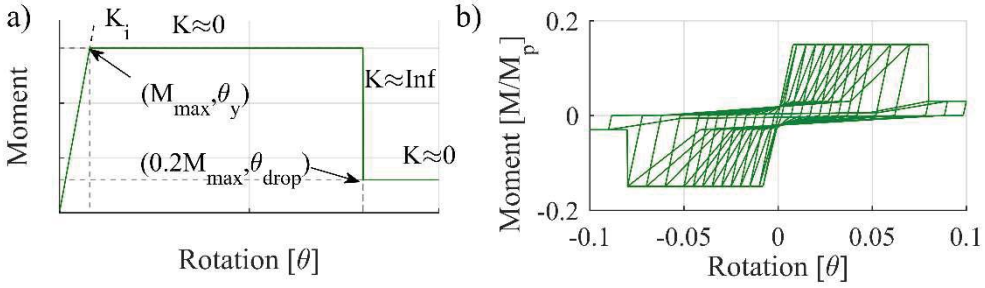

Figure 6 Gravity Connection Hysteretic Behavior

4.3 Deterioration Model

The final most detailed model has the purpose to investigate the importance of modeling accurately the gravity connections in the structural response. The cyclic behavior is based on real tests, and the mathematical model includes strength degradation, cyclic deterioration of strength and stiffness [5]. Unlike the two previously described cyclic simulations, this model presents a variation in stiffness, no reserved strength, and a more realistic pinching behavior. The backbone curve has a yielding (θ_y), maximum (θ_{max}) and dropping rotation (θ_{drop}) equal to 0.004, 0.03 and 0.08, respectively. Even though this model presents a maximum rotation different from the other two models, the initial stiffness is the same.

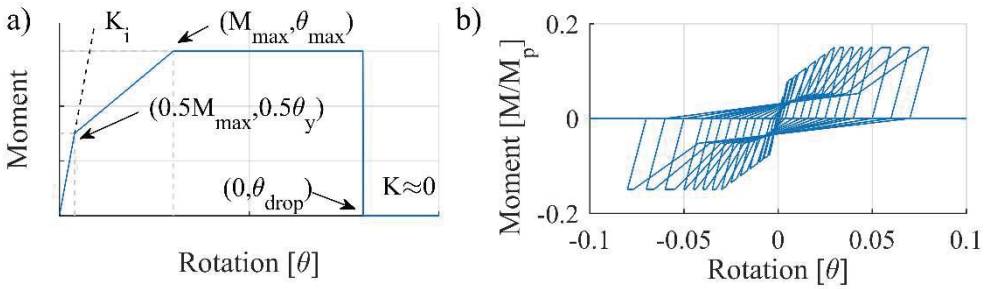

Figure 7 Gravity Connection Deterioration Hysteretic Behavior

5 NONLINEAR STATIC PUSHOVER CURVES

Static nonlinear pushover analyses are performed in order to evaluate the influence of the backbone curve on the capacity (overstrength) and the structure's ductility. The overstrength is the ratio between the maximum capacity and the design base shear. On the other hand, the ductility is computed following what is established by the FEMA P-695 methodology, the ratio between the displacement at which strength decreases 80% the maximum and the effective yielding displacement.

The models to be evaluated are the Special Steel Moment Frame (SMF) by itself, from now on called lateral system (LS), the SMF including the gravity columns (GC) and the three models incorporating the gravity connections (Bilinear, ASCE, and Deterioration). The flexural strength assigned to the gravity connections was 15% and 35% the beam plastic moment capacity.

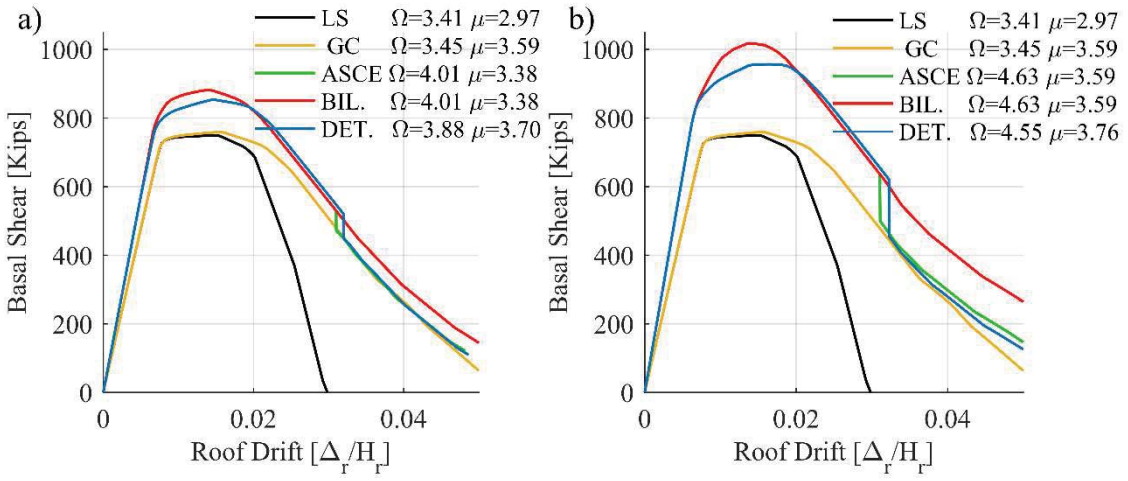

Figure 8 Pushover curves: a) Partial connections 15%Mp, b) Partial connections 35%Mp

Figure 8 a) and b) illustrate the force-roof drift capacity curves for the cases where the gravity connections have 15% and 35% flexural strength. Both figures include the capacity curve when the effect of the gravity column is considered, but the gravity connection's flexural strength is neglected (GC). The computed overstrength with the three different connection models are virtually the same with the exception of the Deterioration model that is around 4% smaller. These values are very similar, but the Deterioration model as expected, is more conservative. On the other hand, the ductility increases when compared to the LS model but among the models with different gravity connections, the ductility is very close. The difference between the bilinear and the other two models is seen on the post-yield stiffness where there is no strength loss. It has to be pointed out the maximum benefit from the gravity system on the post-yield stiffness is provided by the gravity columns. Therefore, in the static analysis the influence of the gravity system can be explained with an improvement of the overstrength due to partial connection capacity, and an improvement of the ductility and post-yield stiffness due to the gravity columns.

6 NONLINEAR DYNAMIC ANALYSES

Once the influence of the backbone curves was evaluated through nonlinear static analyses, nonlinear dynamic analyses are performed to measure the effects of the gravity connection's cyclic behavior. In this section, mathematical models are subjected to 44 ground Far-Field ground motions scaled to different intensity levels that represent different probability of recurrence. The seismic performance among all the models is compared using service, design, and maximum considered level earthquakes. In addition, the dissipated energy of the SMF and the gravity system is evaluated for all the mathematical models. Because the results obtained for the gravity connections with strength equal to 15% the beam plastic moment capacity were very similar to the 35%, only the latter are shown herein.

6.1 Service Level

The first comparison of the influence of the gravity connections is performed using the 44 Far Field ground motions scaled to represent a recurrence of 50% exceedance probability in 30 years (return period of 43 years). The comparison is done between the structure by itself (LS), the structure with gravity columns (GC) and the structure with the gravity system modeled with three different gravity connections. Figure 9 a) shows the first-floor inter-story drift for one of the ground motions that had somehow different results. Figure 9 b), on the other hand, displays

the maximum inter-story drift along the building's height. At this level of intensity, the difference in the results when different mathematical models on the gravity connections are used is negligible. As expected for small displacements, the gravity columns do not influence the structure's response.

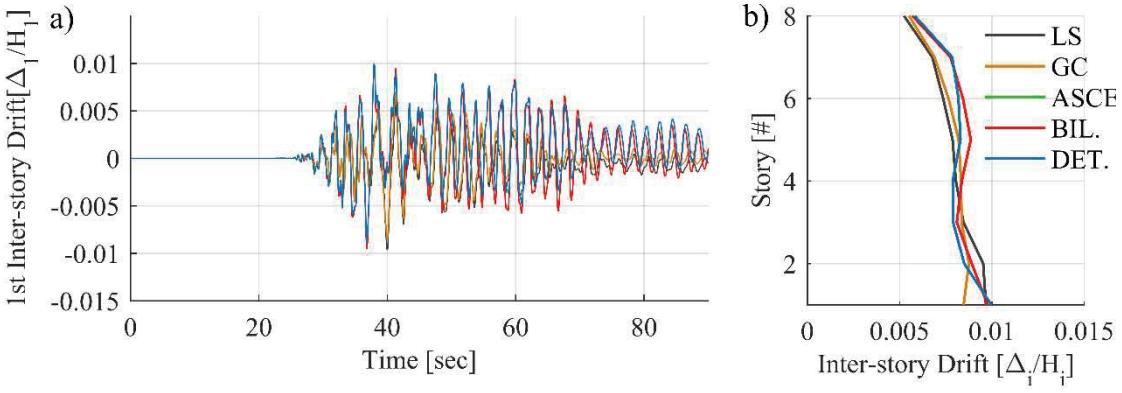

Figure 9 a) First Floor Inter-story Drift, b) Inter-story Drift Profile

Even though inter-story drift responses are widely used to evaluate structural seismic performance, energy balance is an alternative taken in this investigation in order to quantify the gravity system contribution. To the best of the author's knowledge, there are no investigations that evaluate the influence of the gravity connection's mathematical models by means of the dissipation of energy. Figure 10 a) displays the energy balance for all the models normalized by the input energy. The normalization is necessary in order to have comparable results because the input energy is larger for the structures that include the gravity system (stiffer). However, the purpose of this investigation is to quantify the amount of energy that the gravity system dissipates relatively to the main lateral resisting system.

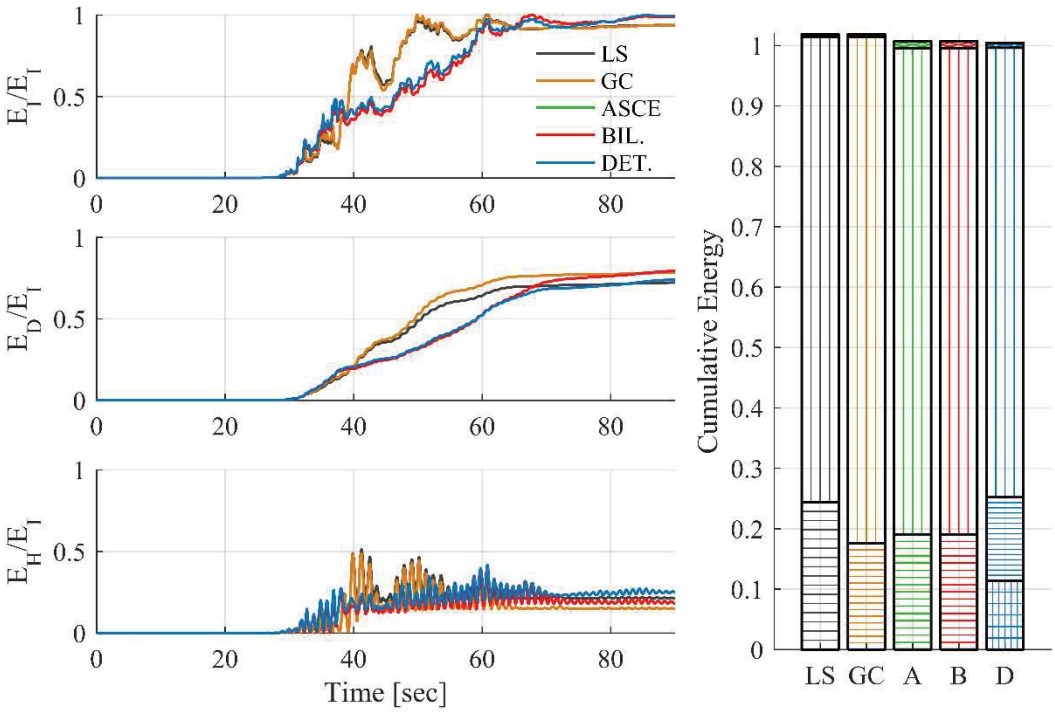

Figure 10 a) Normalized Input Energy b) Normalized Inherent Damping Energy c) Normalized Hysteretic Energy d) Energy Dissipation within the Structure

Figure 10 b) and c) illustrate the energy dissipated by the inherent and hysteretic damping for all models, respectively. It can be seen that, as expected at lower intensity levels, the inherent damping energy dissipation is larger than hysteretic energy because there is almost no damage. The ASCE and bilinear models give exactly the same results because these connections did not yield, while the deterioration model, for this specific earthquake, dissipated some energy. Figure 10 e) presents a bar graph with the percentages of the dissipated energy for each model. It can be seen that inherent damping energy is the one that dissipates the most for all models (around 75%). The Deterioration gravity connection model is the only one that presented energy dissipation within the gravity system. However, energy dissipated by the gravity system in comparison to the total energy (lateral plus inherent damping) is not considerable (around 10%).

6.2 Design Level

The second evaluation is performed using Design Level intensity earthquakes (return period of 475 years). At this intensity, it is expected that gravity and lateral system present damage. Thus, the mathematical models used to capture nonlinear behavior in the gravity connections could have an influence on the performance. Figure 11 displays results for one of the 44 analyzed ground motions. It is clear from Figure 11 a) and b), where the first-floor inter-story drift and maximum inter-story drift along the building are shown respectively, that the structure without the gravity system (LS) is subjected to very large displacements. As stated by different investigations [3, 4, 10], the gravity columns (GC) model improves the performance when SMFs are subjected to large deformations, and this is seen again in Figure 11. ASCE, Bilinear, and Deterioration models show slightly different results in terms of inter-story drifts and maximum drifts along the building's height. However, it is important to evaluate the importance of each mathematical model used for the gravity connections from an energy dissipation perspective.

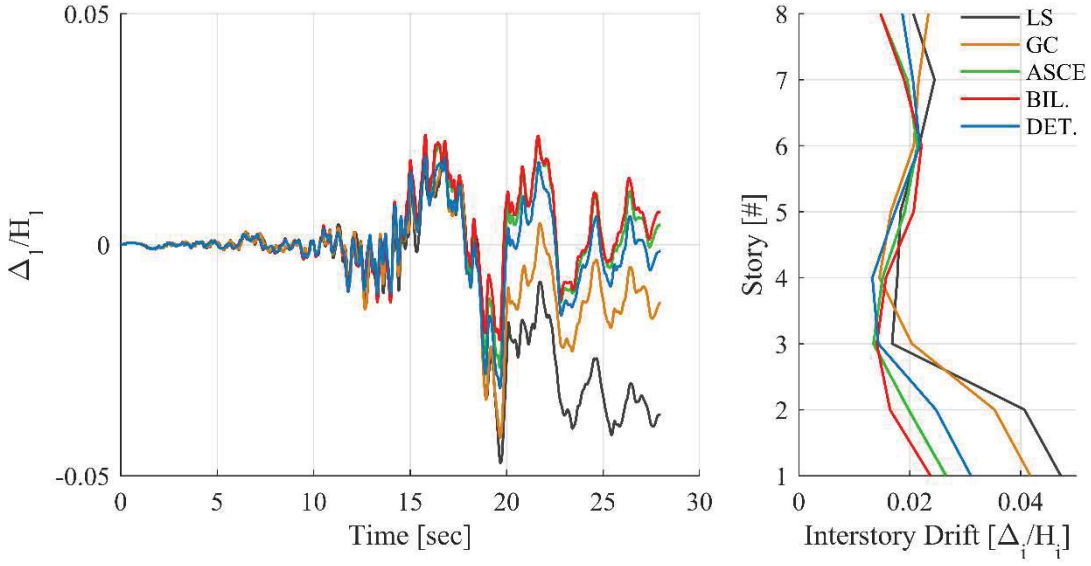

Figure 11 a) First Floor Interstory Drift b) Interstory Drift Profile

Figure 12 a) b) and c) display the normalized energy balance, the dissipated inherent damping energy, and the hysteretic damping energy, respectively. It can be seen from Figure 11b) and c) that the hysteretic energy is larger than inherent damping energy ,meaning that damage within the structures could be significant. The bar graph in Figure 12 d) illustrates the percentages of inherent damping, hysteretic lateral system, and hysteretic gravity system dissipated energy. At this level of intensity, it is clear that the lateral resisting system is the one that dissipates the vast majority of energy (around 70%). On the other hand, it is interesting to note that regardless of the mathematical model used for the gravity connections, the energy dissipated by the gravity system when compared to the main lateral resisting system is only a very small percentage. Even though the number of gravity connections is double the number of connections in the lateral resisting system, the amount of energy dissipated represents only 7% of the total dissipated energy. Therefore, modeling gravity connections in detail might not represent an important factor to consider when the seismic performance of SMFs is required.

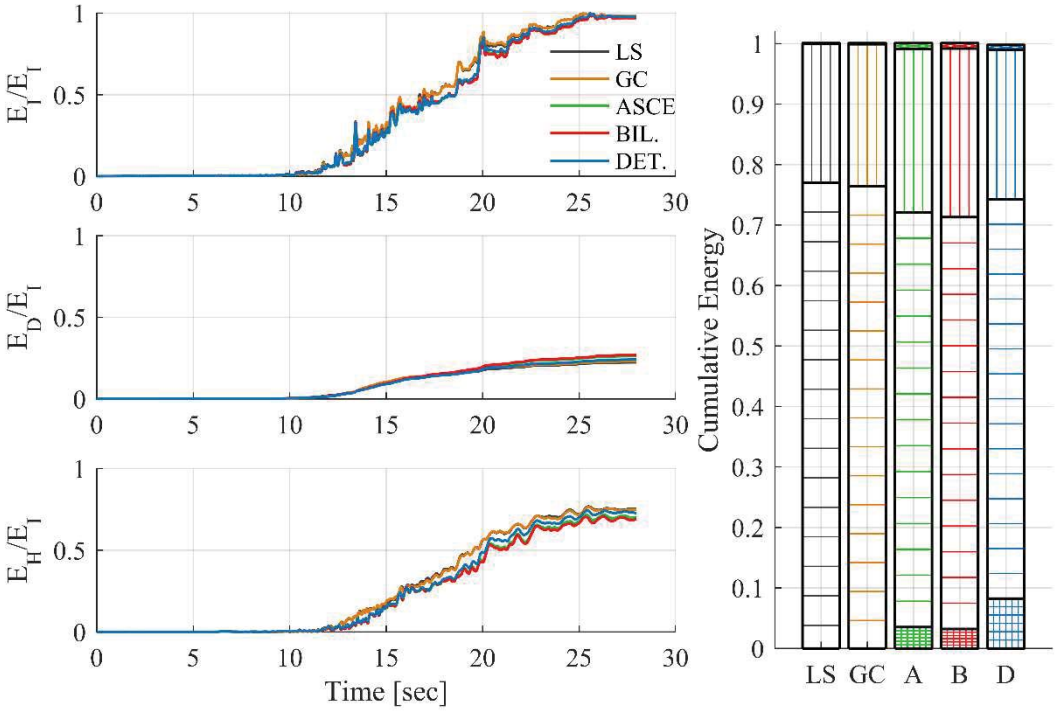

Figure 12 a) Normalized Input Energy b) Normalized Inherent Damping Energy c) Normalized Hysteretic Energy d) Energy Dissipation within the Structure

6.3 MCE Level

Analyses performed using ground motions scaled to the Maximum Considered Earthquake (MCE), which represent a 2% probability of exceedance in 50 years (return period of 2476 years) are in the present required in certain cases by codes like the ASCE7-16 [17]. In this section of the investigation, the influence of modeling the gravity connections is quantified performing nonlinear time history analyses using the 44 Far Field ground motions taken from the FEMA P-695 procedure. Figure 13 a) and b) illustrates the first inter-story drift and the maximum drift profile of one of the ground motions that caused large deformations within the structures. Figure 13 a) shows how the GC model improves drastically the performance of the LS model. On the other hand, the Bilinear ASCE and Deterioration models yielded similar results, but the bilinear model presented slightly larger deformations. Even though the results vary, the overall structural performance is quantified well by any of the mathematical models used to represent the gravity connections.

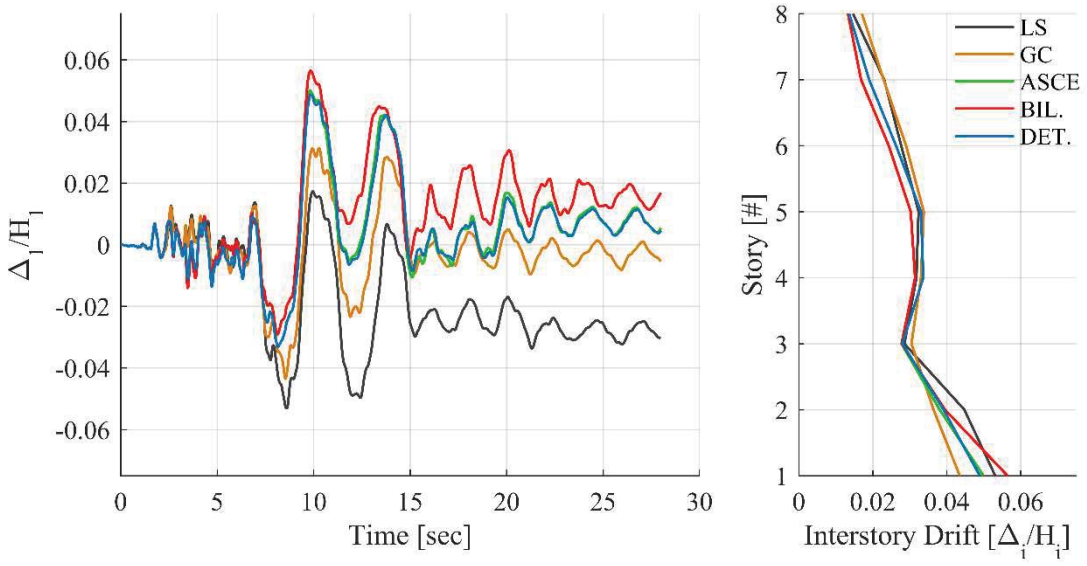

Figure 13 a) First Floor Interstory Drift b) Interstory Drift Profile

Figure 14 shows once again the influence of the gravity connections from a perspective of the dissipation of energy. Figure 14 a) b) and c) display the normalized energy balance, the dissipated inherent damping energy, and the hysteretic damping energy respectively. From Figure 14 b) it can be seen that the role of the inherent damping energy dissipation is almost negligible when compared to the hysteretic energy dissipated by the lateral and gravity system (Figure 14 c)). The bar graph in Figure 14 d) displays the amount of energy dissipated by inherent and hysteretic damping divided into the lateral and gravity system. Even though it is known that the gravity system has a positive effect on the performance of SMFs, it is interesting to see how much the influence is from an energy standpoint. According to Figure 14 d), the gravity system dissipates around 8% of the total energy regardless of the mathematical model used. The energy dissipated by the gravity system is even lower than dissipated energy by inherent damping. This is an important finding that could allow in the future and, with more research, incorporate the gravity connection´s nonlinear behavior in the analysis in a simple manner.

7 CONCLUSIONS

This investigation focused on the influence of modeling gravity connections on the performance of Special Steel Moment Frames (SMFs). An 8-Story SMF from the ATC76-1 investigation was taken as the structure to be evaluated under different conditions. Five different models were created within OpenSees in order to perform nonlinear static and dynamic analyses. The first model was the SMF by itself (LS), the second model includes the gravity columns only (GC), and the last three models include the whole gravity system modeling the gravity connections using different approaches. The gravity connections were modeled using a detailed approach (Deterioration model), an approach that includes strength degradation taken from the ASCE41-16 code (ASCE model) and a simple bilinear approach (Bilinear). Moreover, two gravity connection´s strengths were considered, 15% and 35% the plastic moment of the beams. After performing all the nonlinear static and dynamic analyses, the following conclusions were found:

- Gravity connection's strength improves the building overstrength regardless of the approach used for the mathematical model. However, the results in terms of energy dissipation the gravity system dissipated around 8% regardless of the mathematical model or connection strength.
- The difference between the Bilinear and the other two approaches that incorporate strength degradation is clearly seen in the pushover curve, where there is no sudden strength lost.
- At service level, the gravity connections have more influence than higher-level intensities. The Detailed mathematical model of the gravity connections was the only one that yielded and dissipated energy under service level ground motions.
- Even though the Deterioration model dissipated energy under different ground motions scaled at the service level, the amount was no considerable in comparison to

the energy dissipated by inherent damping and laterals system hysteretic energy together.

- The gravity columns did not have any influence at the service level.
- At the design level, the gravity system improves the building's seismic performance, especially the gravity columns. The time history responses have a slight variation depending on the approach used to model the gravity connections. However, the difference is not significant.
- The gravity connections dissipation of energy is virtually the same regardless of the approach used for the mathematical models. Moreover, the gravity system dissipation of energy is only 8% for the deterioration model and around 4% for the ASCE and Bilinear Model.
- At the MCE level, the gravity columns have a significant influence on the performance. The gravity connections did not influence the behavior drastically, and the energy dissipated was around 8 % for all models.

Keywords: FE model, Large-size WF brace, Cyclic behaviour, Frame action.

Abstract. *Large size wide-flanged (WF) steel members are being used increasingly in steel braced frames to resist lateral cyclic actions. A finite element model is presented to simulate the cyclic behaviour of a large size WF bracing member in a single-bay diagonally braced frame. Shell elements are used to represent the components of the WF frame (beam columns, shear tabs, stiffener plates) and the brace components (WF specimen, gusset, net-section reinforcing and web plates). Multi-point constraints are used to connect the components. The effect of frame action on the hysteresis behaviour is investigated. Results indicate that the columns have a significant effect on the cyclic lateral hysteresis behaviour of WF braced frames. Recommendations for future cyclic WF simulations are presented.*

1 INTRODUCTION

Understanding the behaviour of concentrically braced frames (CBFs) subjected to cyclic lateral movements is necessary for the design of skeletal structures. In CBFs, the braces are expected to absorb the seismic energy through cyclic yielding and buckling, while the framing elements (beams and columns) remain elastic. Wide flange (WF) sections are being used as bracing members in building structures located in moderate and high seismic areas. WF members have the advantages of greater tensile resistance and longer fracture life when compared to tubular section braces (Popov and Black [1], Gugerli and Goel [2], Fell et al. [3], Tremblay et al. [4], Richard [5], Powell [6], Clark [7], Hsiao [8], Lai [9]).

Finite element models (FEMs) of braced frames need more attention than just modelling individual braces (Haddad et al. [10-18], Uriz et al. [19,20], Fell et al. [21], Myers et al. [22], Huang and Mahin [23,24], Lai [9]). FE modelling represents a complementary technique to develop understanding of the behaviour of braced frames under cyclic lateral movements in addition to experimental testing The FEMs presented in the current study were validated with the results of Haddad [16]. It is therefore reasonable to use these FEMs to simulate the response in CBFs. The shear tab-plate connection is adopted here as this connection detail is believed to be ductile and suitable for connecting the WF beams to the WF columns.

The objective of the current study is to build FEMs to capture the hysteresis response and assess the performance of single diagonal CBFs. The models are used to investigate the effects of brace inclination and frame action on the performance of the WF braced frames. The effect of restraining the vertical displacement of the centreline of the upper-flange of the beam on the hysteresis behaviour was investigated. The brace is connected to the frame, while the tab-plates are connected to the web of the beam by means of multi-point constraints (MPCs) representing the bolts for the latter.

2 BRACED FRAME AND DISPLACEMENT HISTORY

Brace W6 (10 × 77) of the tests reported by Tremblay et al. [4] was designed by the first author of the current study according to the AISC-05b [25] and AISC-05 (seismic) [26] provisions. This large-size WF-section brace and the framing elements (beam and columns) were manufactured from ASTM A992, Grade 50 steel [27] while the gusset, connection, doubler, and stiffener plates were made of ASTM A572 Grade 50 steel [28]. The end connections of the specimen represented the connections of a brace inside a frame in practice, with the minimum possible thickness for the gusset plates. The work-point was located at the intersection of the bottom-flange of the beam and the inner flange of the adjacent column to minimize the gusset plate dimensions (Sabelli [29]). The gusset was welded to the beam and column and detailed to accommodate inelastic rotation associated with out-of-plane buckling of the brace. Following the suggestion of Astaneh-Asl et al. [30], the free length of each gusset plate was thus defined to be twice the plate thickness. The free length of the gusset plates allows plastic hinges to develop in the end gussets which in turn reduces the demand on the mid-span plastic hinge. At connections, the net-sections were reinforced with cover plates, while the gusset plate and web were connected through a doubler plate. The design approach was weak-brace strong-gusset with all possible failure modes being considered. The effective length factor was taken as 0.9, as this accounts reasonably for the small capacity of the gusset plates to rotate out-of-plane compared to the WF member and is typically recommended for pin-pin compressive members.

Brace W6 met the stringent AISC-05 [26], AISC-10 [31], and the AISC-16 [32] seismic code limits with an effective slenderness ratio of 60 and a width-to-thickness ratio of 5.86. W6 was tested inside a 12 MN capacity frame in both compression and tension with 1.5 MN.m

capacity in bending. In practice, large-size section braces, similar to W6, are frequently selected and used in braced steel frame structures in locations of high seismic activity.

The lateral frame cyclic displacements in moderate and high seismic regions are implemented in the quasi-static cycles of the FEMs through the far-field symmetrical loading protocols of Izvernari et al. [33] and Fell et al. [3], respectively with an additional two cycles of a smaller amplitude between the previous loading protocols. These lateral frame cyclic displacements were developed in terms of frame drift ratio (Δ/hs). The lateral frame displacement (Δ) is equal to the corresponding frame drift ratio multiplied by the frame height (hs) as shown in Figure 1(a). For the individual brace models, these lateral frame cyclic displacements are transformed into axial brace cyclic displacements (δ) through the equation of Tremblay et al. [4].

$$\frac{\delta}{L_H} = 1.3\frac{\Delta}{h_s}\cos(\theta)\sin(\theta) \tag{1}$$

where θ is the angle of inclination of the brace with respect to the horizontal axis of the frame as shown in Figure 1(a). The 1.3 is the ratio of the length (L_H) between the far end hinges of the brace and the length (L_{cc}) between corresponding work-points along the axis of the brace that is typically used in the design of frames.

The cyclic axial displacements applied to the brace are divided by the distance between the plastic hinges at the ends of the brace to produce the normalized axial deformation shown in Figure 1(b). The angle of inclination of the brace with respect to the horizontal axis of the frame was 35 degrees.

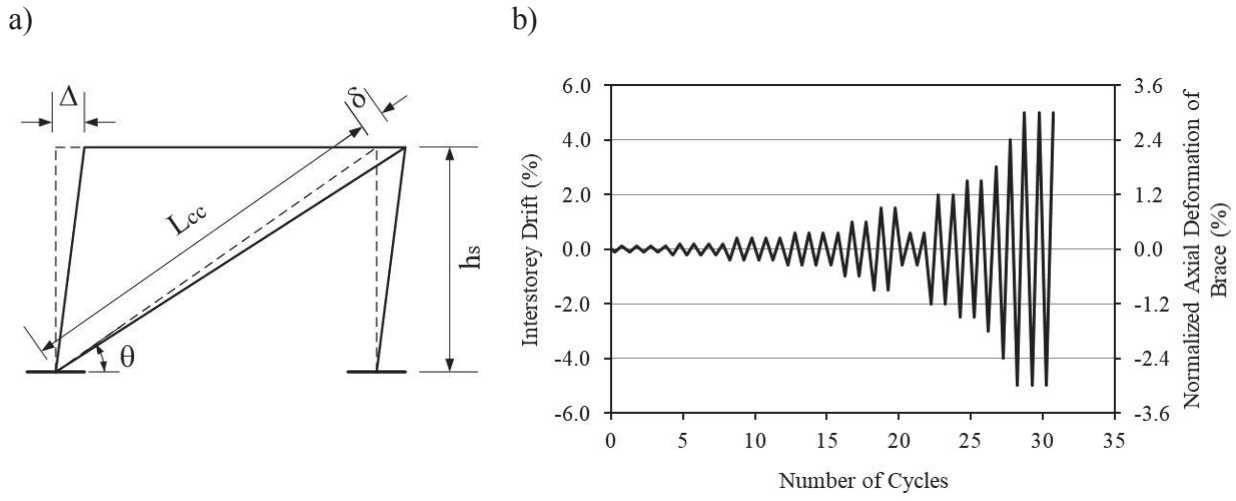

Figure 1(a): Concentrically braced frame and (b) Loading protocol.

3 DESCRIPTION OF THE FE MODEL

The nonlinear FE analyses were solved using Abaqus [34]. Four-node quadrilateral shell elements with nine integration points through the thickness of each element were used in meshing all components of the braced frames. Simpson's integration rule was used. The lateral cyclic displacements were applied at the centreline of the upper-flange of the beam. At this location, the out-of-plane translational degrees of freedom were restrained. In practice, this represents the connection of the centreline of the upper-flange of the beam to a concrete slab by means of double headed studs. The web of the beam at the beam mid-span was restrained against out-of-plane displacement to represent the presence or action of sub-beams. The columns were also

restrained against out-of-plane movement at the level of the upper-flange of the beam, simulating the presence of a concrete slab there. In addition, the vertical centreline of the web of the column is restrained against out-of-plane translation for a length equal to (d - 2k). This represents the presence of the beam intersecting the column in the out-of-plane direction of the frame. d is the depth of the intersecting beam and k is the k-distance as described in the WF steel sections of the AISC manual.

Stiffener plates are added to both sides of the beam in the vertical direction perpendicular to its web at the inner connection of the brace upper gusset plate to the beam bottom-flange. In the FE analysis, these beam stiffeners were perfectly connected to both the flanges and web of the beam. This in turn will guarantee that the axial cyclic force of the brace is transmitted to both flanges of the beam to prevent the possibility of the out-of-plane deformation of the web, especially when the braced frame is subjected to high lateral drift. In braced frames, stiffener plates are needed at these locations in practice for stability purposes that may result from the three-dimensional effect of the frames.

Fixed boundary conditions were applied at the base of each column and at the base of the left gusset of the brace. This represents the bottom braced frame connection to the base plates by means of welds. The far ends of the brace were connected to the frame by means of MPCs. Similarly, the doubler and connection plates were connected to the web and flanges of the WF specimen, respectively by means of MPCs. A tab-plate was used to connect the web of the beam at its far ends to the adjacent flange of each column by means of MPCs representing the bolts for the former (web of beam) and the weld for the latter (flange of column). Two types of MPC were used: the beam type for all except the MPC connecting the tab-plates to the web of the beam where the rotation about the Z-axis (axis of the bolts) is released.

In the FEM, the centrelines of the beam and column must align. Therefore, the shear tab-plates were offset a distance of one-half of the beam web thickness on one side or the other of the centreline of the column in the out-of-plane direction of the frame. The positive Z-direction was selected in the FEMs in the present modelling. In practice, the tab-plates are welded to the inner flanges of the columns with fillet welds on each side of the tab-plates. The weld was not modelled here: a beam type MPC was used instead to connect the tab-plates to the adjacent flanges of the columns. In addition, the beam has a 12.5 mm (½ in.) setback, or clearance, between the end of the beam and the face of the adjacent flange of the column in the plane of the frame in the current FEMs. Given the modelling approach adopted, residual stresses from welding were not included in the analyses.

The material in all elements was specified with the same initial Elastic modulus of 200 GPa and Poisson's ratio of 0.3, and a combined isotropic-kinematic hardening material model. This hardening model simulates the expansion, contraction and shift of the yield surface in stress space during compression-tension cyclic loading of the material.

The FE analyses of the WF braced frames were performed in two stages. First, the first modal shape of buckling was obtained from static linear analysis through the perturbation technique with ramp amplitude while multiplying the mid-span out-of-plane deformation of the brace by the geometric initial imperfection value of 0.2% of the total length of the brace according to Zeiman [35]. Second, the analysis of the WF braced frame model with the cyclic steps of applied lateral displacements was accomplished. Throughout the analysis, 1000 increments were used in each step with the full Newton-Raphson method being used to satisfy equilibrium at each increment.

The analytical average true stress-strain curve suggested by Haddad ad Shrive [36] was used here for the various components (brace, beam, and columns) of the WF braced frames. This analytical average true stress-strain curve was developed through trial and error utilizing a sim-

ple power-hardening law to obtain a hysteresis response that is a reasonable match to the experimental response for a single diagonal WF brace made from ASTM A992 grade 50 steel [27]. The yield surface is defined by:

$$F(\sigma_{ij}, k) = \sqrt{\frac{3}{2}(S_{ij} - \alpha_{ij}^{d})(S_{ij} - \alpha_{ij}^{d})} - \bar{\sigma}_y = 0 \tag{2}$$

In this equation, σ_{ij} is the stress tensor, α_{ij}^{d} is the deviatoric component of the backstress tensor S_{ij}, $\bar{\sigma}_y$ is a stress quantity related to the size of the yield surface and k is a hardening parameter that defines the size of the yield surface. With an initial yield stress of σ_{yo}, $\bar{\sigma}_y$ is defined as

$$\bar{\sigma}_y = \sigma_{yo} + k \tag{3}$$

Further, in Equation (2), the translation of the yield surface α_{ij}^{d} is subtracted from the corresponding stresses S_{ij}. The increment of the deviatoric part of the backstress tensor is defined according to Ziegler's [37] kinematic hardening rule as:

$$d\alpha_{ij}^{d} = \frac{H}{\bar{\sigma}_y}(S_{ij} - \alpha_{ij}^{d})\, d\epsilon_{eq}^{p} \tag{4}$$

where

$$H = \frac{d\sigma}{d\varepsilon^{p}} \tag{5}$$

4 SINGLE INCLINED BRACE

The axial displacement history (δ) is applied to the W6 brace producing a normalized axial hysteresis response that matches the hysteresis response of the experiment as shown in Figures 2(a) and (b), respectively. Further, the lateral displacements (Δ) are applied to the same W6 brace when inclined at 35 degrees to the horizontal axis. The normalized axial hysteresis loops for both the axial and inclined single brace W6 are shown in Figure 2(a). δ/L_H is the normalized axial displacement and $P_a/A_g F_y$ is the normalized axial response force. δ is the applied axial displacement; L_H is the distance between the plastic hinges at the ends of the brace and; P_a, A_g, and F_y are the load resistance, cross-sectional area, and yield strength of the WF brace member, respectively. The behaviour of the axial and inclined braces is identical. The normalized axial and lateral hysteresis responses of the inclined brace are shown in Figure 3.

Brace W6 first buckled in the compressive section of the ninth compressive-tensile loading cycle, both experimentally and in the FE analysis. Plastic hinges formed in the free lengths of the gusset plates at each end of the brace. In the tension portion of that cycle, the brace straightened and yielded. In the following cycles, the compressive capacity of the brace decreased markedly both experimentally and in the analysis as a result of the residual elongation. The bow shape of the buckled brace was enlarged in cycle ten, with the gusset plastic hinges becoming complete over the free-length cross-section. In the FEM, complete section plasticity was seen to occur in all subsequent cycles. The brace strength and stiffness reduced noticeably during the two smaller amplitude cycles of the loading sequence (cycles 21 and 22), followed by local

buckling during the compressive portion of cycle twenty-five. Fracture occurred during the tensile portion of cycle thirty-one.

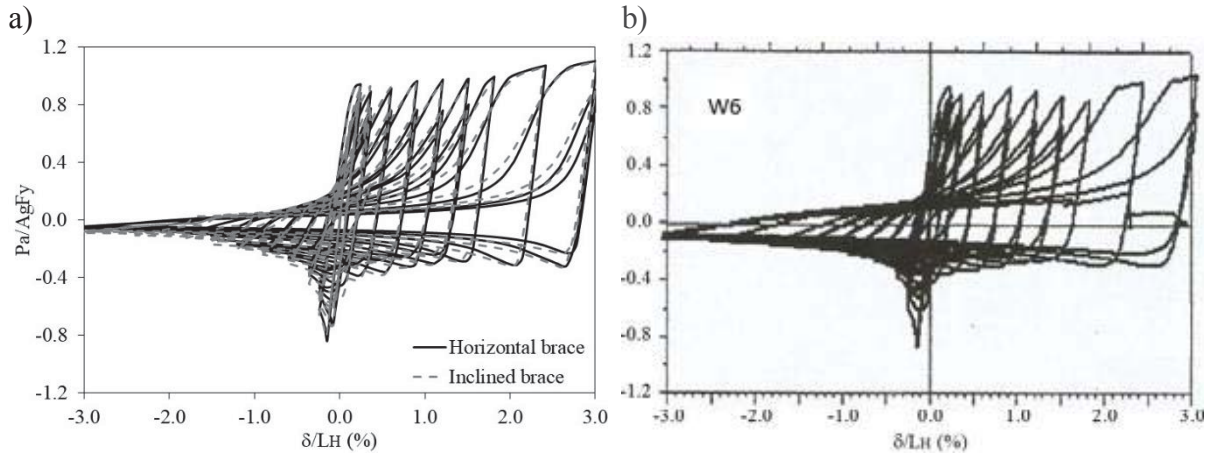

Figure 2: Normalized axial hysteresis response (a) Numerical and (b) Experimental.

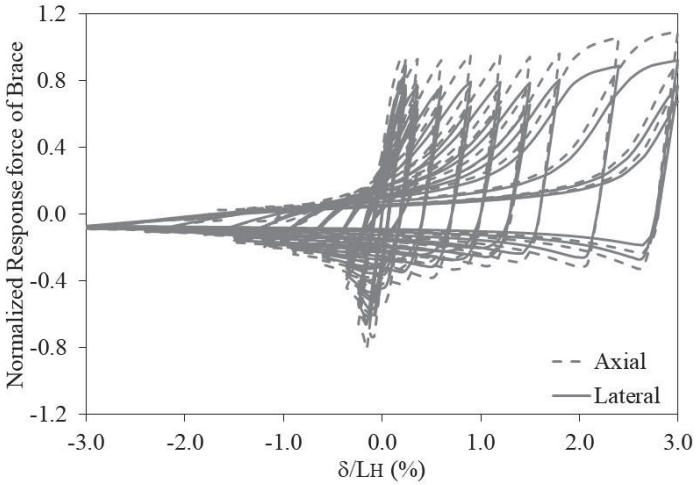

Figure 3: Normalized hysteresis response of the inclined brace.

5 FRAME ACTION

The W6 brace was modelled as a diagonal member inside a single frame with W10 × 77 or W14 × 370 columns and a W27 × 235 beam. The dimensions of the frame are height (hs) = 3.46 m (11.35 ft), width = 4.88 m (16.01 ft) centre-to-centre. All the sections selected met the stringent limits of compactness for seismic design according to the AISC 341-10 [29]. For the W10 × 77 columns and the W27 × 235 beam, local buckling occurred in the flange and web of the braced column, whereas the unbraced column has substantially less local buckling. The desired behaviour of the braced frame is seen when selecting a W27 × 235 beam with W14 × 370 columns: for instance, the local buckling failure mode did not occur in the columns. Active yielding at the base of the columns and at the tab-plates connection area in addition to the expected plastic hinges at the mid-span of the brace and the gussets are all shown in Figure 4.

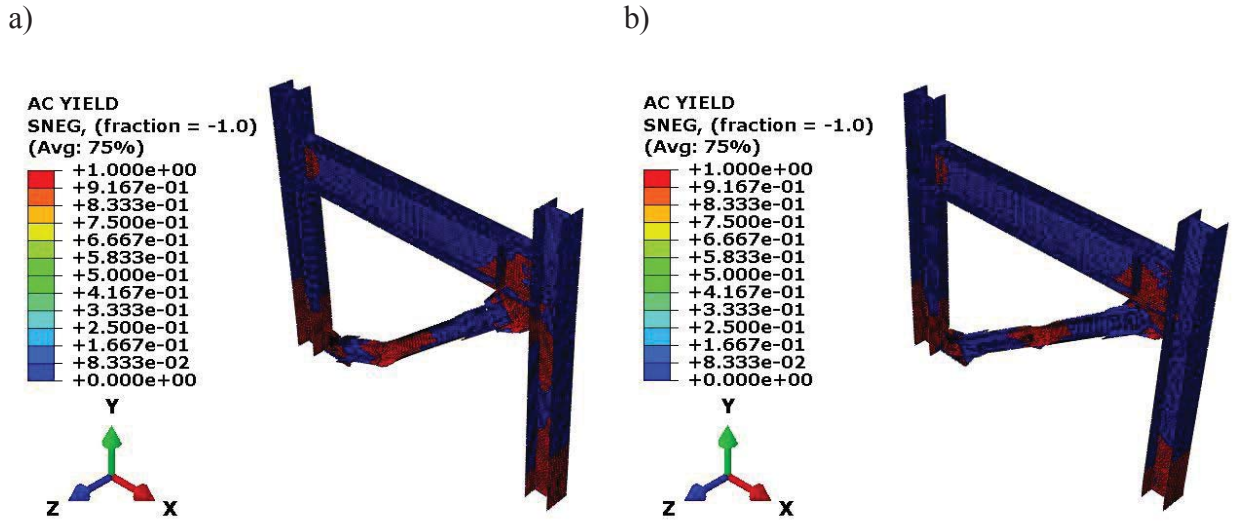

Figure 4: Active yield of the braced frame with the W27 × 235 beam and the W14 × 370 columns under lateral (a) compression and (b) tension deformation.

The applied lateral displacement of the frame (Δ) is transformed back to the axial displacements (δ) of the brace according to Equation (1) and normalized with respect the distance between the two end hinges of the brace (L_H). Having the same axial displacement for both the single brace and the braced frame facilitates comparison of the response. The lateral resistance (response) force (Pl) of the braced frame is normalized with respect to the axial yield force of the brace ($P_y = A_g F_y$). As such, the normalized lateral hysteresis behaviour of the braced frames with the W10 × 77 and W14 × 370 column sizes are shown in Figures 5(a) and (b), respectively.

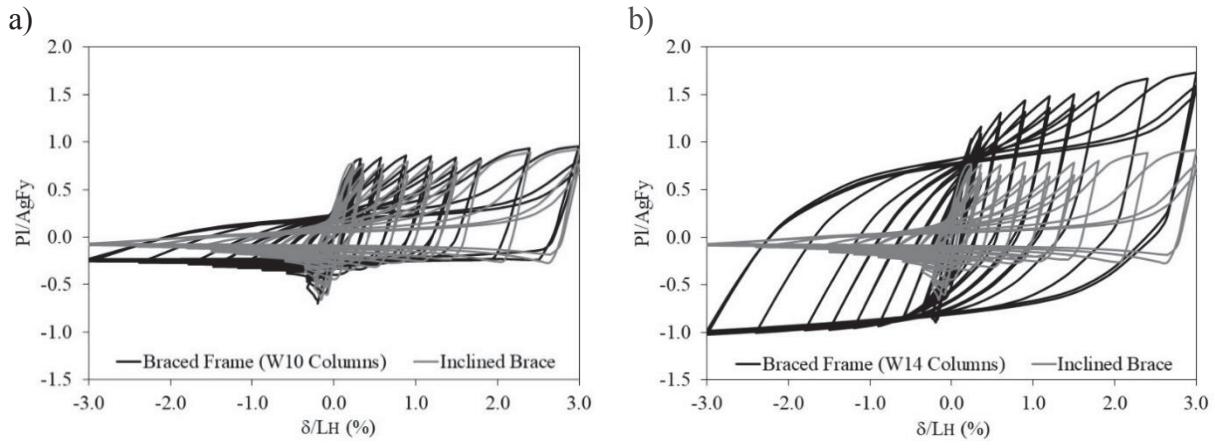

Figure 5: Normalized lateral hysteresis response of the (a) braced frame with the W10 columns and (b) braced frame with the W14 columns.

The maximum tensile and compressive normalized lateral response forces of the braced frame with the W10 × 77 columns are similar to those of the single inclined brace as seen in Figure 5(a), suggesting that the response of the braced frame is governed by the brace. On the other hand, the normalized lateral response forces of the braced frame with the W14 × 370 columns are greater than those for the single inclined brace as shown in Figure 5(b). Therefore, the columns contribute significantly to the seismic response of the concentrically braced frame.

Light roofs (metal decking with insulation or a sandwich panel) or heavy floors (composite metal decking or cast-in-place or precast concrete) are possible roof/floor system scenarios that can be used in residential or office buildings. The effect of releasing or restraining the vertical movement at the centreline of the upper flange of the beam simulates these scenarios, respectively. However, the deflection of the W27 × 235 beam was negligible for these scenarios, so the effect of restraining the vertical movement of the beam did not affect the hysteresis response of the braced frame.

6 CONCLUSIONS AND RECOMMENDATIONS

- The response of the individual brace and the same brace contained in a frame is different under the same loading protocol. This is mainly attributed to frame action.
- The columns contribute significantly to the seismic response of the concentrically braced frames.
- Yielding occurred in the columns regardless of the sizes examined here. Local buckling failure modes occurred in the W10 × 77 column when the frame was subjected to the high seismic load loading protocol. However, those modes did not occur when column size was increased to W14 × 370 or in the W27 × 235 beam.
- It is recommended to consider modelling the base plates with the anchorage rods. In addition, it recommended to model the bolts with holes and to consider the contact in between. It is also recommended to model the welds.

ACKNOWLEDGEMENT

The study was funded the Research Grants of the UAE University (SEED – G00001044 and UPAR – G00001916). In addition, thanks to the UAE University for providing the computational simulation facilities to conduct the current research.

Abstract. *One of the most important methods to improve the seismic performance of structures is the using of multi-layer elastomeric bearings (EB). The main purpose of applying this elastomeric device in the base level of structures is Separating of ground vibrations from body of structures. Recent researches have indicated although EB is capable to decrease damages of buildings, especially in irregular buildings despite of torsion cause of increasing roof displacement total collapse of buildings is likely so multi-layer elastomeric bearings braced with steel cable (EBBSC)to control displacement has been introduced. In this study, three different models of EBs have been studied. The first model is Simple multi-layer elastomeric bearings (SEB), the second model is multi-layer elastomeric bearing with vertical steel cable (EBBVSC), and the third model is multi-layer elastomeric bearing with diagonal steel cable (EBBDSC). By applying the cyclic lateral displacement to top level of specimens, their hysteresis load- displacement behavior was achieved under finite element analysis. The results have indicated increasing strength and stiffness for multi-layer elastomeric bearing braced with steel cable. In other hand, the strength and stiffness value in the EBDSC model in compare with the EBVSC model has been increased 28% and 32%, respectively.*

1. INTRODUCTION:

Reinforced elastomeric bearings have been used in the United States in non-seismic applications, such as bridge bearings and anti-vibration mounts, for over 30 years [Long, 1974; Stanton and Roeder, 1982]. The materials and fabrication techniques used in manufacturing seismic and non-seismic bearings are essentially the same. Seismic bearings decouple the motion of a structure from the motion of its foundation, increasing the fundamental period of the structure to a value beyond the range containing the principal earthquake energies. This can reduce the magnitude of the earthquake-induced forces by as much as a factor of 5 to 10 [Mayes, et al. 1988, Kelly, et al. 1989] and consequently reduce damage to the structure and its contents, and reduce danger to its occupants. [1], [2]. To decouple ground vibration from main body of structures, many devices such as types of dissipating steel fuses in buildings with rocking motion or the different models of Elastomeric Bearings have been suggested. [3], [4], [5]. In recent years many different approaches about EB have been performed. By J. S. Hwang et al. an analytical model for high damping elastomeric isolation bearings is presented. Both material tests and shaking table tests were performed to validate the proposed model, then Ten parameters have been identified from cyclic loading tests are included in the model. [6] To investigate the tension bulking behavior in multilayer elastomeric bearings it was presented the buckling solution to an ideal double-symmetric prismatic column clamped at both ends and free to sway and subjected to vertical loads at the ends only by James M. Kelly. [7], [8]. Furthermore, by G. P. Warn and et al. an experimental study to investigate the influence of lateral displacement on the vertical stiffness of elastomeric and lead–rubber seismic isolation bearings has been summarized. Two identically constructed low-damping rubber and lead–rubber seismic isolation bearings were subjected to a series of tests with varying levels of combined lateral displacement and axial compressive loading to study this relationship. The results of these tests showed the vertical stiffness decreases with increasing lateral displacement for each bearing tested. [9], [10], [11]. multilayer elastomeric isolator has enough stiffness to carry vertical load but it is soft in horizontal direction. It has been described the horizontal behavior of EB in spite of buckling in vertical load in large deformation by Forcellini, et al. with driving a simple two-spring model. [12], [13], [14]. In other case a series of experiments were conducted at University at Buffalo to characterize the behavior of elastomeric bearings in tension by Manish Kumar et al. Sixteen low damping rubber bearings from two manufacturers, with similar geometric properties but different shear moduli, were tested under various loading conditions to determine factors that affect cavitation in an elastomeric bearing. The effect of cavitation on the shear and axial properties of elastomeric bearings was investigated by performing post-cavitation tests. The test data were used to validate a phenomenological model of an elastomeric bearing in tension, which is implemented in OpenSees, ABAQUS and LS-DYNA. [15]. the other researches has performed analytical study to evaluated EB under axial and lateral loadings such as Vladimirs Gonca et al. [16] In 2017, by Forcellini et al. the response of the elastomeric bearings with 3D numerical simulation has been verified to experimental results. This paper aims to identify the accuracy of this theory using experimental results and de-tailed numerical simulations carried out on ABAQUS. The finite element (FE) model has been reproduced with a layered system able to represent the alternating steel and rubber layers and the bolted connections. The presented FE model can be used as a powerful tool for predicting the non-linear behaviors registered during the lab tests [17], [18], [19], [20]. Furthermore, in 2017, by Konstantinos N. Kalfas, a numerical study on the response of steel-laminated elastomeric bearings under cyclic shear and variable axial loads has been conducted to understand their behavior with emphasis placed on the tensile stresses within the elastomer, their stiffness and dissipation capacity. Extensive numerical re-

search was con-ducted with ABAQUS and the Ogden hyperplastic model was used for modelling the elastomeric material. The analyses showed that steel-laminated elastomeric bearings exhibit local tensile stresses, which alter significantly their stiffness and damping ratio. Most importantly, significant tensile stresses within the elastomer were observed locally, even when the bearings were subjected to a combination of shearing and compression. [21], [22], [23]. The cyclic loading experimental tests are an important part in the process of completing the design of the isolators, yet they are very expensive and time consuming. Using the accurate analytical modeling of hysteresis tests and knowing the limitations and the amount of error of the finite elements model and its effect on designing the isolated structure make it possible to reduce the financial and time expenses involved in designing seismic isolators along with experimental tests.[24] By Saedniya and et al., the cyclic loading of two different isolating systems, namely, the high damping rubber bearing (HDRB) and lead rubber bearing (LRB) have been modeled and analyzed in ABAQUS and the outcomes were compared with the experimental results attained by other researchers. After comparing the effective stiffness of the experimental sample with the analytical model of HDRB, the results have been shown that Yeoh function had the best performance in determining the effective stiffness of the isolating system with an error of less than 7%. [25]. Finally, in 2016, by Saman Rastgoo Moghadam, Dimitrios Konstantinidis, the effect of rotation on the horizontal behavior of elastomeric bearings using 3D Finite Element Analysis (FEA) has been investigated. It was observed that constitutive modeling assumptions can have a notable influence on the results, especially at low vertical pressure where the critical shear strain is large. Support rotation did not affect the critical displacement appreciably, but it significantly affects the critical shear force. It is observed that support rotation becomes important for bearings with low second shape factor, even if their first shape factor is large. [26]. In this study, three different models of multilayer elastomeric bearings have been evaluated by using of finite element analysis under cyclic lateral load and torsional displacement. To verify the results, as the first step, the laminated base isolation introduced by Rastgoo and et al. was analyzed in ABAQUS software. The results of this verification indicated appropriate coincidence for relative displacement- average stress curve in this study with results of Rastgoo and et al. research.

2. MODELING OF SPECIMENS:

Previous researches indicated although EBs can be prevented damaging of structural members cause of separating ground vibration from main body of structures during the earthquake, applying them in base level of structures have many significant points. One of the most important problem in this challenge is that using elastomeric layer as soft material can be caused buckling of EB under vertical load and it can be effected on stability of the EB in seismic loading. The second is that in the buildings equipped with EB cause of increasing period and roof displacement, in the strong ground motion, collapse prevention requirements seriously must be satisfied. Finally, in the irregular buildings in spite of torsion, initial torsion can be influenced on the behavior of EB under lateral load. so it seen that designing EBs with considering elements which they can be effective in stability would be useful. For this purpose, in this study, as it is shown in Fig. 1., three different models of EBs by performing finite element analysis in ABAQUS software by regarding two steps of loading have been evaluated.

Figure 1. The different specimens of EBs: a. SEB, b. EBVSC, c. EBDSC

The main parts of these base isolation are including of anchor plate in top and bottom, rubber layers, and steel sheets. The geometrical dimensions for all of these parts have been gathered in Table 1. All of the interactions was considered as Tie. Furthermore, the mesh size for all of the parts was equal to 15mm. For the two specimens, EBVSC and EBDSC, the diameter of steel cable was regarded equal to 5mm. the material properties for steel in Table 2. and for rubber in Table 3. have been presented.

Table 1. Geometrical dimensions of studied EBs

Parts	Diameter(mm)	Thickness(mm)
Anchor Plate	250	21
Rubber Layer	140	10
Steel Sheet	140	2

Table 2. Material of properties for steel

Parts	Poisson Ratio	Ultimate Stress (N/mm^2)	Ultimate Strain	Yielding Stress (N/mm^2)	Elasticity Modulus ($N/mm^{2)}$)	Gravity (Kg/mm^3)

0.048	0.085
0.046	0.083
0.045	0.08
0.044	0.079

Two loading steps were introduced. in the first step a torsional displacement equal to 0.02 Rad as static/general, and in second step, a lateral cyclic displacement as static/general have been applied. The bottom anchor plate was fixed in through of the analysis. The specified boundary condition for specimens, and the cyclic displacement protocol has been shown in Fig. 2 and Fig. 3. respectively. To gain the results, it was made two set including of nodes in bottom anchor plate and nodes of top anchor plate as named “reaction force” and “displacement”. For reaction force set, RF1 and for displacement set, U1 as the history output was requested.

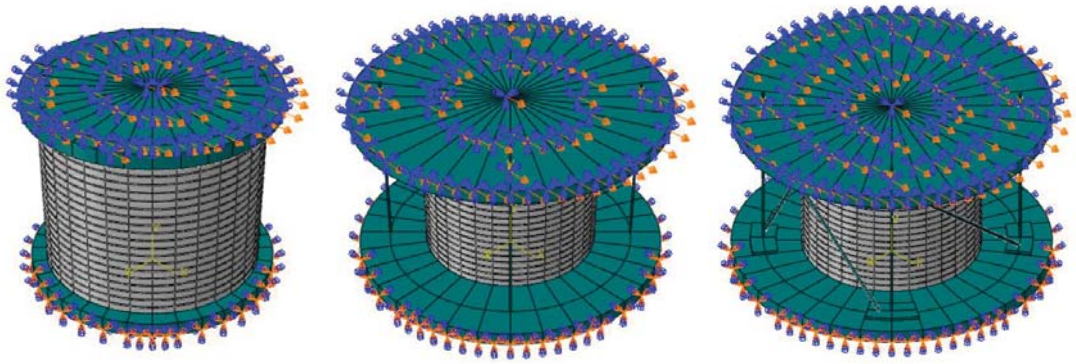

Figure 2. The boundary conditions and loadings in the specimens

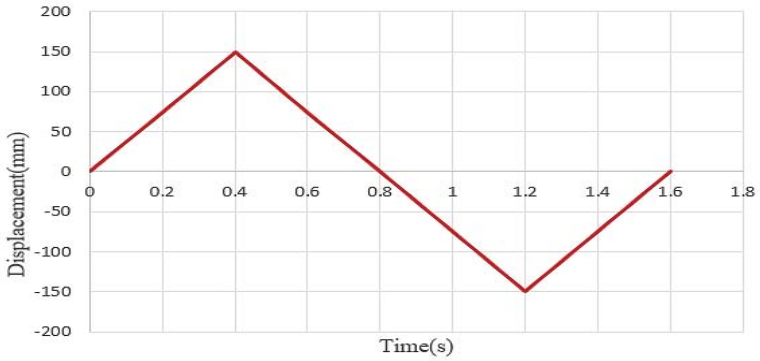

Figure 3. The cyclic displacement protocol

3. RESULTS OF FINITE ELEMENT ANALYSIS:

After analyzing all of the models, with getting summation of RF1 for all nodes belong to “reaction force” set and average of U1 for all nodes belong to “displacement” set, the hysteresis curve by combining U1 and RF1 have been plotted. As it has been shown in Fig. 4. Using of diagonal steel cable can be caused of increasing strength and stiffness in EB. Furthermore, increasing dissipation energy to this model comparing with EBVSC is visible.

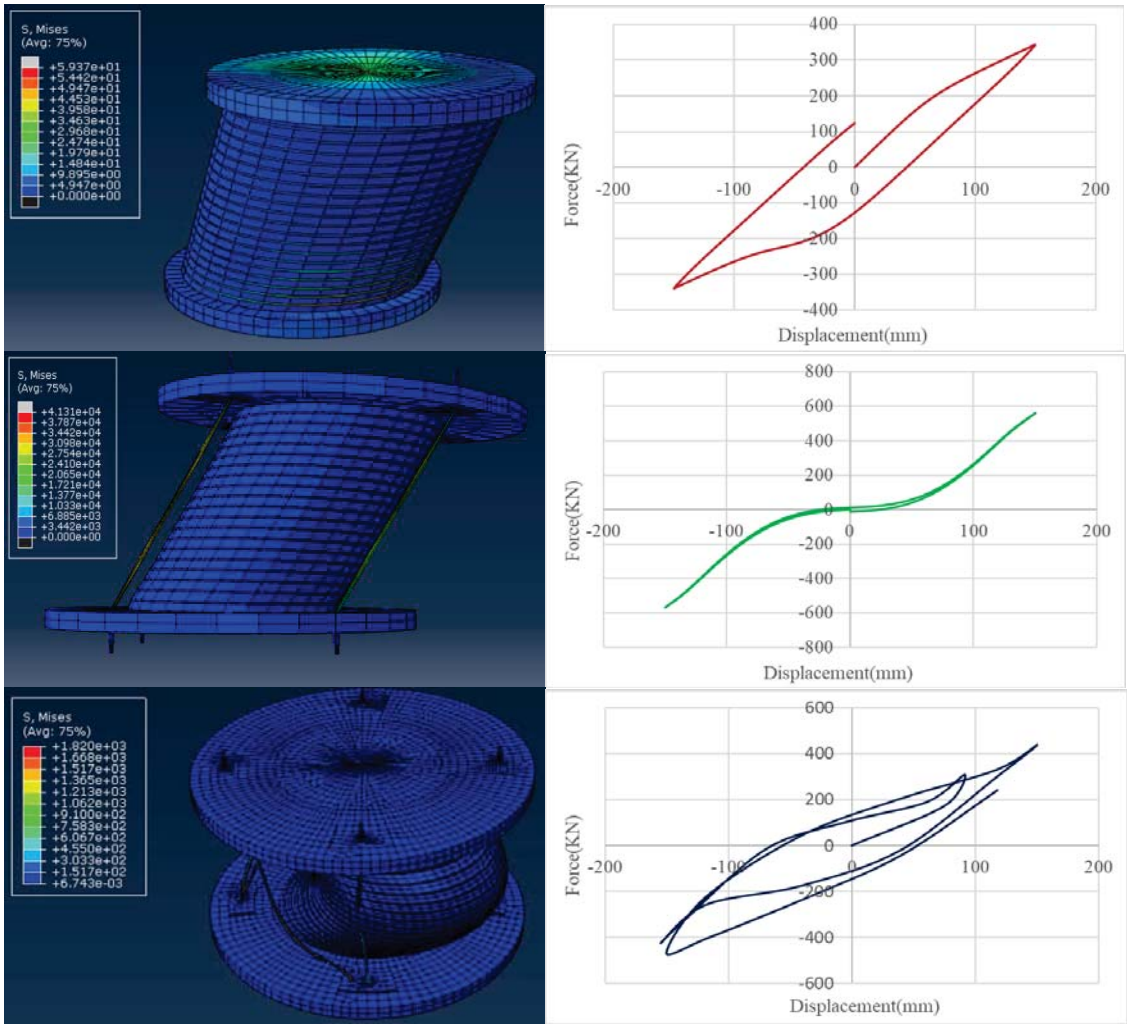

Figure 4. The cyclic displacement protocol

4. VERIFICATION:

In this study three different models of EB under finite element analysis by ABAQUS software was evaluated to verify the results due to finite element analysis, at first a kind of elastomeric bearing that has been studied by Saman Rastgoo Moghadam, and Dimitrios Konstantinidis, to investigate the effect of support rotation on the horizontal behavior of elastomeric bearings have been analyzed. For this purpose, according to Fig. 6. A multilayer elastomeric bearing with 20 rubber layers and 19 steel sheets between two anchor plates was investigated. The diameter of anchor plate which is located on upper and lower level, and its thickness were 320mm, and 21mm. Furthermore, the diameter of intermediate layered body, the thickness of steel sheets, and rubber layer were considered 280mm, 2mm, and 10mm, respectively. For whole models in this study all of the parts were considered as 3D, deformable, solid with 8-node elements.

a b

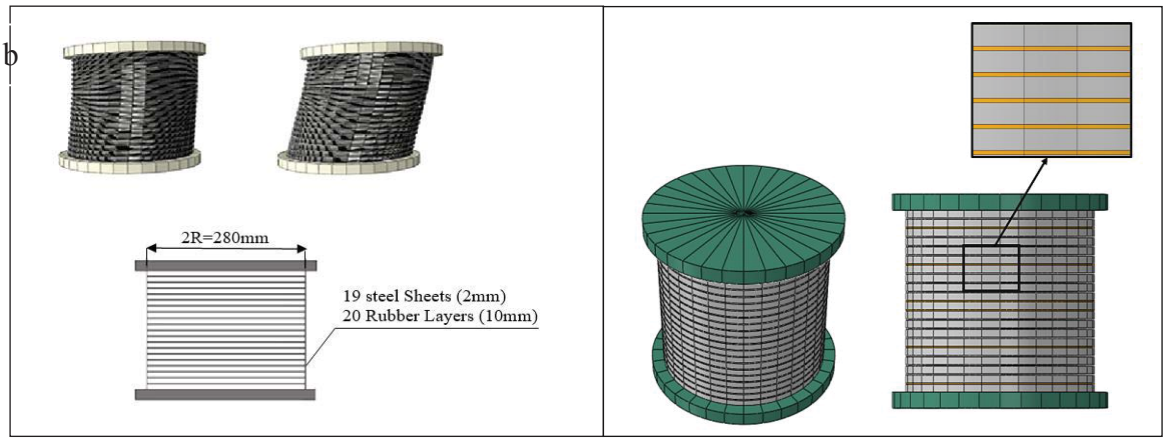

Figure5. a. the view of studied EB by Saman Rastgoo Moghadam and et al. b. EB Model in ABAQUS

in this study, the studied base isolation by Saman Rastgoo Moghadam and et al. other time analyzed to verify the future results. To make this model all of the geometrical dimensions and mechanical properties of material is completely similar to reference. For introducing of rubber's material properties has been used from Neo-Hookean model as it is presented to Table.4. All of the interactions to model this base isolation as surface to surface have been tied.

Table4. Neo-Hookean Model properties for the Rubber

Material Model	C10 (MPa)	D10 (MPa^{-1})
Neo-Hookean	0.45	0.001

Boundary conditions and loading for this model are illustrated in Fig. 7. Two loading steps were considered to apply load. In first step, a vertical load equal to 200KN (CFY=200E3 N), and a rotational displacement equal to 0.02Rad (UR3=0.02 Rad), and in the second step, a lateral load equal to 5 KN (CFX=5000 N), and propagating vertical load from previous step, have been introduced. The bottom anchor plate was fixes in all of during analysis. (UX=UY=UZ=URX=URY=URZ=0)

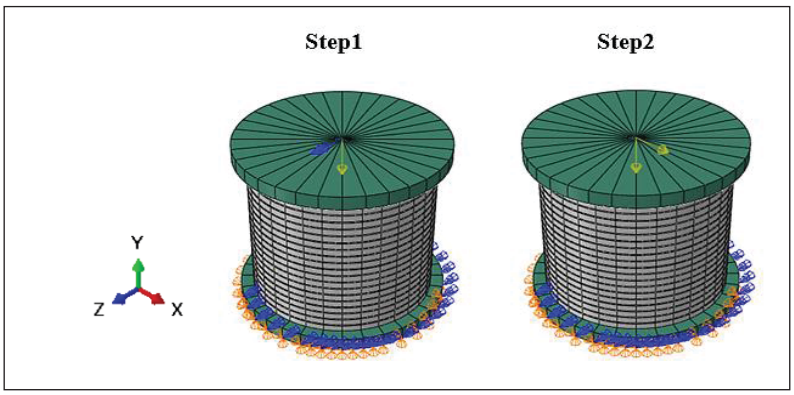

Figure6. Boundary Conditions and Loading.

After analyzing the history outputs including of reaction forces (RFX, RFY) for the bottom anchor plate, and displacements (U1, U2) for the top anchor plate were achieved. Furthermore, by introducing a set from all elements of the middle section of EB, average stress (P0) was reported, and then the relative displacement- stress behavior curve has been plotted. In this presented curve shown in Fig. 8., Uh, and Ur are lateral displacement, and the thickness of rubber, respectively.

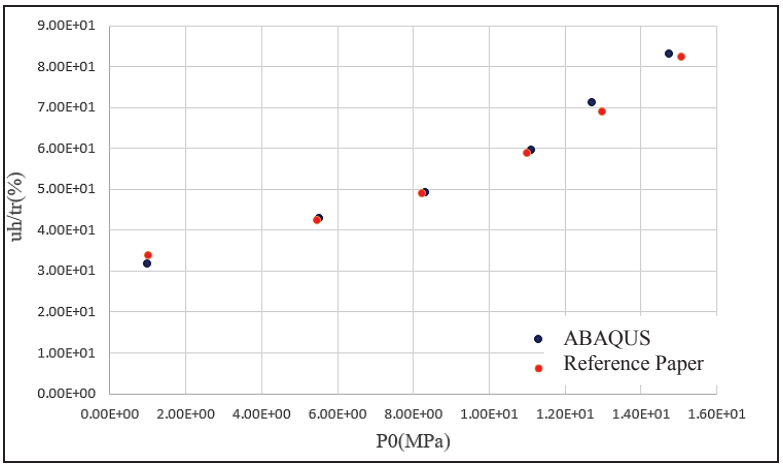

Figure 7. relative displacement-stress curve for studied EB by Saman Rastgoo Moghadam and et al.

5. CONCLUSIONS:

In this study, to control displacements in EBs, elastomeric bearings braced with steel cable has been investigated. By performing a finite element analysis for three different models of EBs under torsional displacement and cyclic lateral displacement, load-displacement hysteresis curves for all of them were achieved. Comparing the hysteresis behavior of specimens, increasing in strength and stiffness for the EBDSC was indicated. the strength and stiffness value in the EBDSC model in compare with the EBVSC model has been increased 28% and 32%, respectively.

Keywords: FE model, WF brace, Cyclic response, Fracture.

Abstract. *Concentrically braced frames (CBFs) are increasingly used in the construction of steel buildings located in moderate and high seismic regions. Wide flange (WF) sections represent a possible alternative to hollow structural steel sections as bracing members. The effects of plate thickness (tab or stiffener or gusset) and the number of bolts on the hysteresis response and fracture a single-bay WF steel braced frame subjected to reverse axial displacements has been assessed through a parametric study using finite element modelling. It is found that reducing the number of bolts while increasing their diameter and the thickness of tab-plates to satisfy the AISC standards for tab-plate connection design had negligible effect on the hysteresis response of the single-bay braced frame.*

1 INTRODUCTION

Optimizing the hysteresis response of CBFs is needed to increase their capacity in resisting lateral loads that result from ground motions. Under these motions, braces are expected to yield in tension and buckle in compression, reducing the impact of ground motions, and thereby preventing the catastrophic failure of buildings that could lead to human and economic losses. These braces are connected to the framing elements (beams and columns) by gusset plates. Beams are typically connected to columns by tab-plates. Vertical stiffener plates may also be needed in beams. The effects of these frame components on the hysteresis response of braced frames need to be analyzed and understood.

The finite element model (FEM) presented by Haddad and Shrive [1] was developed by extending previous models (Haddad et al. [2-7], Uriz et al. [8,9], Fell et al. [10], Myers et al. [11], Huang and Mahin [12,13], Lai [14]) and was used here to study the effects of various components of a single-bay frame on the hysteresis response and fracture life of the brace.

The longer fracture life of WF braces compared to hollow structural steel (HSS) section braces is advantageous (Popov and Black [15], Gugerli and Goel [16], Fell et al. [17], Tremblay et al. [18], Richard [19], Powell [20], Clark [21], Hsiao [22], Lai [14]). As there are a limited number of cyclic test data for individual WF braces, the possibility of presenting a reliable WF brace empirical fracture model based on the accumulated deformation, equivalent total ductility or tension-ductility is not feasible in the near future. Thus, both the significant cumulative plastic strain which is believed to be a reasonable damage index and a refined fracture model are used to assess the performance and predict the fracture life of the large-size WF braced frames simulated here. The FEMs presented here were validated by the results of Haddad [23]. It is therefore reasonable to use these FEMs to simulate the response and predict fracture in multi-storey braced frames and possibly even the whole structure.

Thus, the objective of the current study was to use the previously validated FE and fracture models to capture the hysteresis response and assess the behaviour of single-bay CBFs. The models were used to investigate the effects of the thickness of the tab-plates in relation to the number of bolts used to connect the tab-plates to the web of the beam on the behaviour and fracture of the WF braced frames. In addition, the effects of increasing thickness of gusset and stiffener plate were investigated.

2 FE AND FRACTURE MODELLING

Brace W6 (10 × 77) of the tests reported by Tremblay et al. [18] was modelled inside the single-bay braced frame of W14 × 370 columns and W27 × 235 beam sizes by Haddad and Shrive [1] using the FE analysis software (Abaqus [24]) as shown in Figure 1(a). Multi-point constraints (MPCs) were used to connect the frame components at corresponding nodes. The dimensions of the frame are height = 3.46 m (11.35 ft), width = 4.88 m (16.01 ft) centre-to-centre. The upper nodes at centreline of the beam upper flange were subjected to the loading protocol described in [1]. Lateral behaviour and out-of-plane deformation of the single-bay braced frame are shown in Figures 1(b) and (c), respectively with the corresponding von Mises stress distribution. The FE model was shown to be valid given the results. In addition to modelling of the braced frame presented in [1], the frame was modeled without the brace and beam-to-column connection with and without the brace in the current study.

The difference in response between the braced beam-column and the braced frame shown in Figure 2 basically results from the column and is not from the shear-tab beam-to-column connection or the beam. Therefore, the columns contribute significantly to the seismic response of the CBF. δ/L_H is the normalized axial displacement and P_a/A_gF_y is the normalized axial response force. δ is the applied axial displacement; L_H is the distance between the plastic hinges

at the ends of the brace and; P_a, A_g, and F_y are the load resistance, cross-sectional area, and yield strength of the WF brace member, respectively.

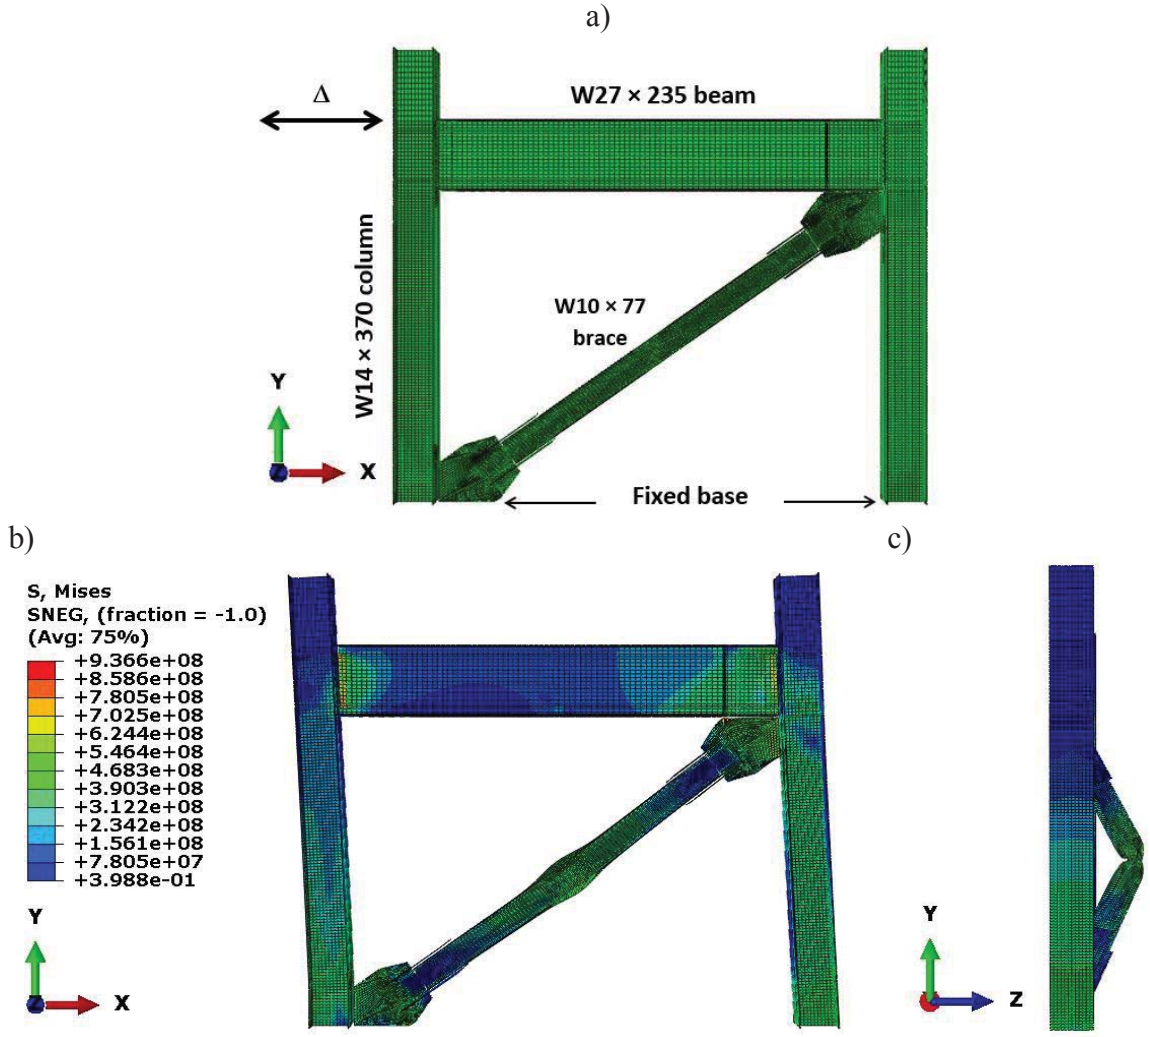

Figure 1(a): Single-bay concentrically braced frame, (b) lateral behaviour, and (c) out-of-plane deformation.

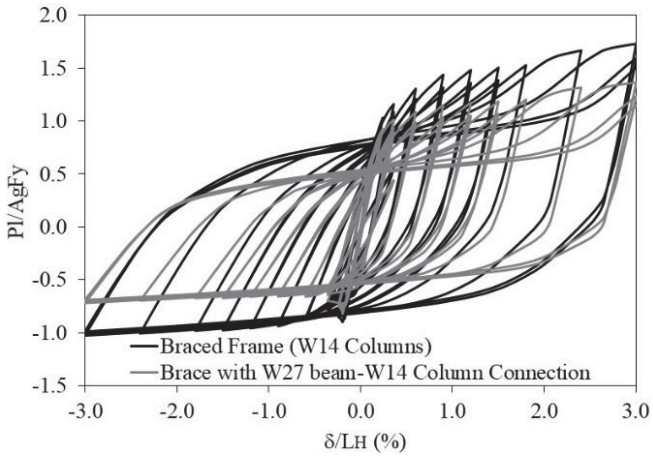

Figure 2: Normalized lateral hysteresis response of the braced frame with the W14 columns and the brace with the beam-to-column connection.

The effect of modelling the frame without the brace and the beam-column without the brace on the hysteresis behaviour is shown in Figure 3. The columns significantly affect the hysteresis response.

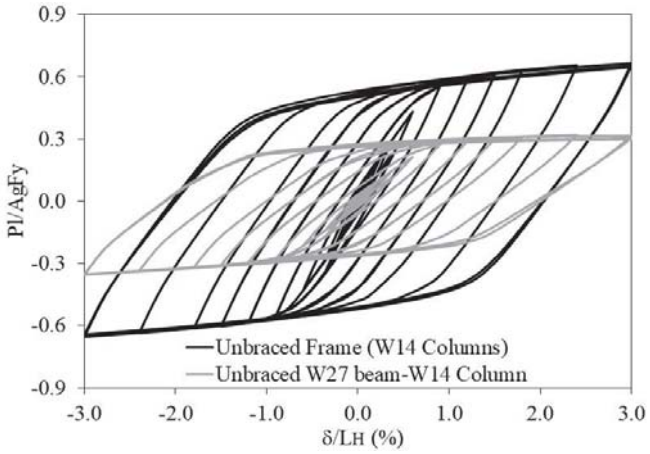

Figure 3: Normalized lateral hysteresis response of the unbraced frame and the unbraced beam-column.

A refined fracture model was implemented here to predict the fracture life of the brace. A strain-based approach to fracture prediction was defined, based on the accumulation of plastic strain. The increment in significant plastic strain in each portion of each cycle was summed as:

$$\varepsilon_{p\ significant} = \sum_{tensile} \int_{\varepsilon_1}^{\epsilon_2} exp^{|1.5T|}\, d\varepsilon_t - \sum_{compressive} \int_{\varepsilon_1}^{\epsilon_2} exp^{|1.5T|}\, d\varepsilon_c \quad (1)$$

In Equation (1), T is the triaxiality ratio (defined as the mean stress divided by the effective or von Mises stress) and the compressive strain is deducted from the tensile strain in each cycle. That is, the significant plastic strain is the sum of the magnitudes of the tensile and compressive strains (compressive strain being negative). When triaxiality is negative, strains are taken as compressive. In the fracture model, the monotonic tensile capacity is degraded during cyclic loading by the coefficient λ_{CVGM}. This coefficient is obtained from Equation 2:

$$\eta_{cyclic} = exp^{(\lambda_{CVGM}\varepsilon_p)} \left(\int_0^{\varepsilon_p} exp^{1.5T} d\varepsilon_p\right)_{monotonic} \quad (2)$$

where ε_p is the accumulated plastic strain and the values of the monotonic capacity (and thus λ_{CVGM}) were calibrated from the experimental results presented by Kanvinde and Deierlein [25] on monotonic and cyclic tests on notched bars manufactured from several types of steel.

3 THICKNESS OF PLATES (TAB OR STIFFENER OR GUSSET) AND NUMBER OF BOLTS

Shear tab-plate connections are economical to fabricate and simple to erect. This popular type of connection is the quickest connection to erect. It consists of a length of plate welded in the workshop to the column flange, onto which the supported beam web is bolted on site. The tab-plate welds are typically sized to the full length. These tab-plates are welded to the column flange at an offset distance of ½ the beam web thickness. A small clearance equal to 12.5 mm (½ in) the column width is typically left between the end of the supported beam and the supporting column flange. In the FE analysis, increasing the thickness of shear-tab plate connection

from 12.5 to 25 mm (½ to 1 in) has negligible effect on the hysteresis response of both the braced frame and braced beam-to-column connection as shown in Figures 4(a) and (b) for the braced frame and the braced beam-to-column connection, respectively. The effect of increasing the thickness of the tab-plates on the hysteresis response of the frame without the brace and the beam-to-column without the brace is minor as shown in Figures 5(a) and (b), respectively.

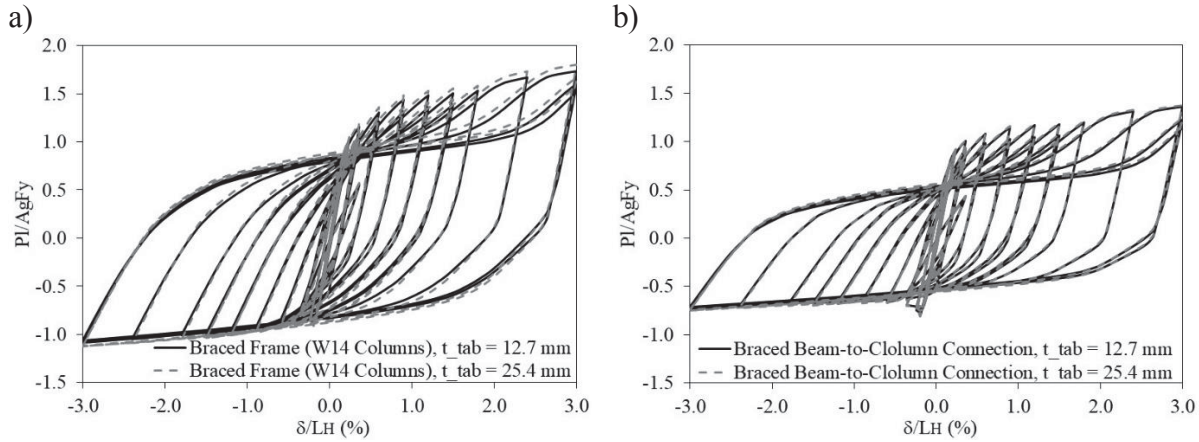

Figure 4: Effect of thickness of tab-plate on the lateral hysteresis response of the (a) braced frame and (b) braced beam-to-column connection.

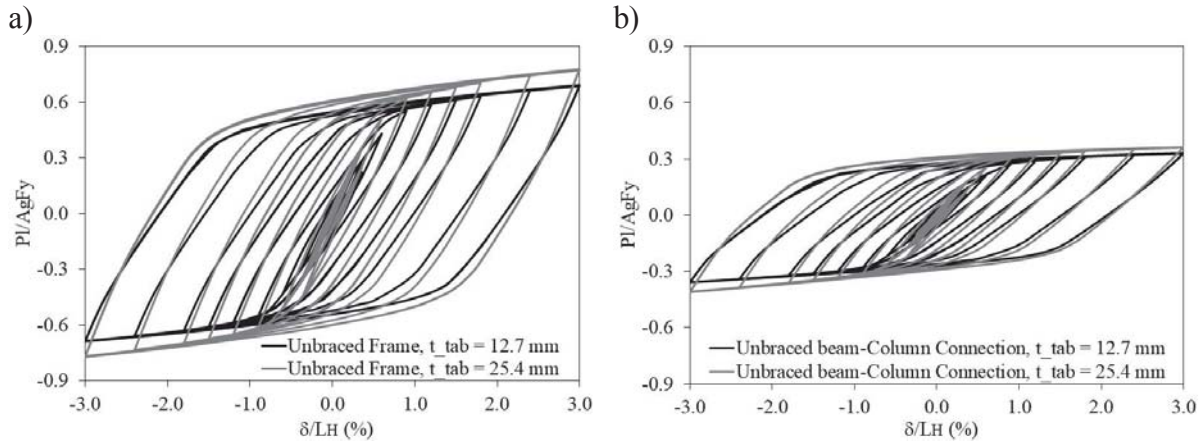

Figure 5: Effect of thickness of tab-plate on the cyclic hysteresis response of the (a) unbraced frame and (b) unbraced beam-to-column connection.

In the FEM, beam type MPCs were used to connect the tab-plate to the column flange at the same location used in practice. The rotation about the axis of the bolts was released in the MPCs connecting the tab-plate to the web of the beam. In addition, seven, five or three MPCs were used to represent the bolts connecting the tab-plates to the web of the WF beam. Reducing the number of the pin type MPCs representing the bolts results in a reduction of the yield demand on the shear-tab plate connection as shown in Figure 6(a) when the thickness of the tab-plate is 12.5 mm (½ in).

In practice, the holes through the plate are horizontal short-slotted rather than round holes. When calling for this type of connections, designers and fabricators commonly use horizontal slotted holes through either the beam or the tab-plate to give the field erection crews more leeway in making the connection on site. To study this effect a simple or pinned type MPC was used to connect the tab-plates to the far ends of the beam. The response is shown in Figure 6(b) when the thickness of tab-plates was 12.5 mm (½ in). Increasing the thickness of tab-plates to

25.4 mm (1 in) when using 3-bolts to comply with the increase in bolt diameter according to the AISC code results in an acceptable hysteresis response as shown in Figure 6(c).

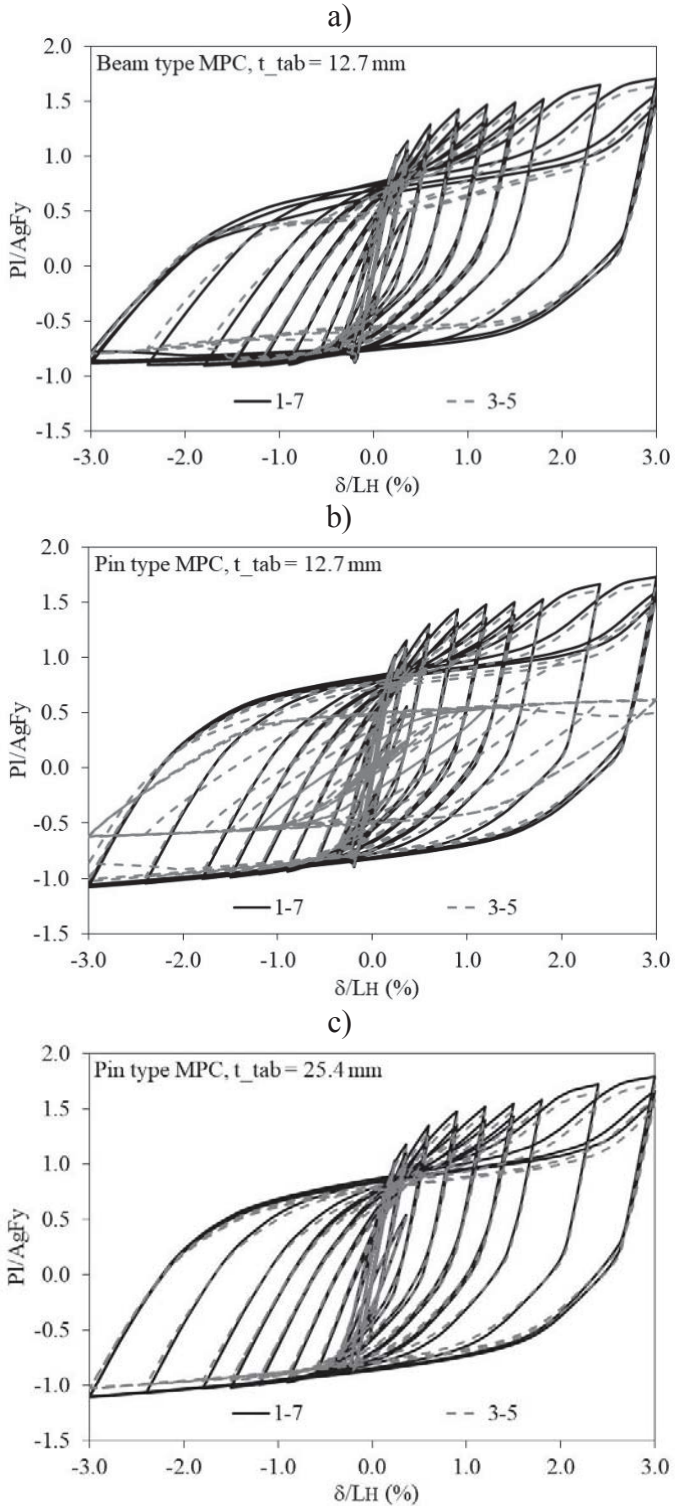

Figure 6: Effect of number of bolts and thickness of tab-plate on the cyclic hysteresis response for (a) beam type MPC with tab-plate thickness of 12.7 mm, (b) pin type MPC with tab-plate thickness of 12.7 mm, and (c) pin type MPC with tab-plate thickness of 25.4 mm. 1-7 means 7 MPCs, 3-5 means 3 MPCs.

The in-plane rotational capacity of the tab-plate connections comes from the distortion of the bolt holes in bearing, from the bolt deformation in shear and from the out-of-plane bending of the tab-plate. Tab-plates with long projections have the tendency of lateral torsional buckling (W27 compared to W18 or W21, for instance). For beams over 610 mm (24 in) nominal depth, the span to depth ratio of the beam should not exceed 20 and the vertical distance between extreme bolts should not exceed 530.86 mm (20.9 in) according to the standard fin-plates connection details of the British standards. The current W27 × 235 beam complies with the British standards. However, the effect of restraining the end beam away from the gusset connection on the hysteresis response is negligible. Therefore, increasing the thickness of tab-plates and reducing the number of bolts while increasing their sizes will reduce the possibility of lateral torsional buckling of the tab-plates.

The effect of increasing the thickness of the stiffener plates on the hysteresis response is negligible for the braced frame modelled in the current study.

Gusset plates must resist the full tensile and compressive capacities of the WF brace during significant cyclic loading [26-29] and permit large inelastic out-of-plane deformation when the brace buckles [30]. Increasing the thickness of gusset plates from 34.925 mm (1 3/8 in.) to 47.625 mm (1 7/8 in.) has a negligible effect on the hysteresis response as shown in Figure 7.

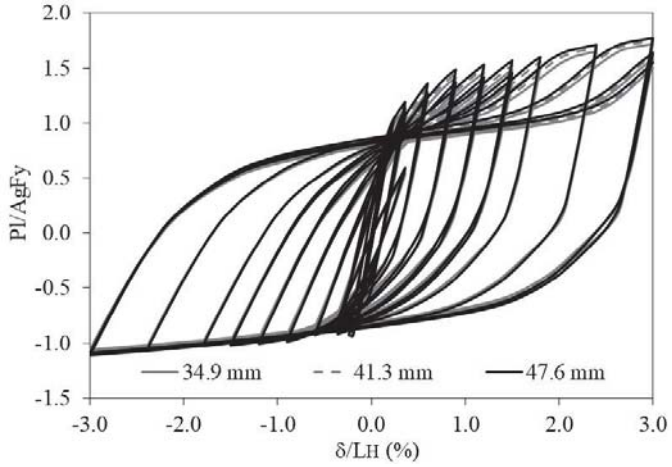

Figure 7: Effect of gusset thickness on the cyclic hysteresis response.

4 FRACTURE LIFE OF BRACE AND PERFORMANCE OF THE FRAME

The fracture life of the brace was not affected by the presence of the frame when using the calibrated cyclic void growth model (CVGM) for ultra-low cycle fatigue based on the significant cumulative plastic strains. A typical fracture life for the horizontal brace is shown in Figure 8. An average value of 2.90 was determined for the monotonic tensile capacity, which is similar to the value obtained by Kanvinde and Deierlein [25] for AW50 (ASTM A572 Grade 50) steel [31]. To predict the initiation of fracture of the WF brace the capacity was decreased with a degradation coefficient of 0.11, obtained by trial and error. The effect of reducing the number of bolts did not affect the fracture life of the brace.

The significant cumulative plastic strains were greater at both the corners of the gusset plate and at the tab-plates especially at the upper and lower locations of the MPCs connecting the tab-plates to the web of the beam compared to those at the mid-span plastic hinge of the WF brace member. This suggests that weld fracture may occur at these locations before the initiation of brace fracture at the mid-span plastic hinge.

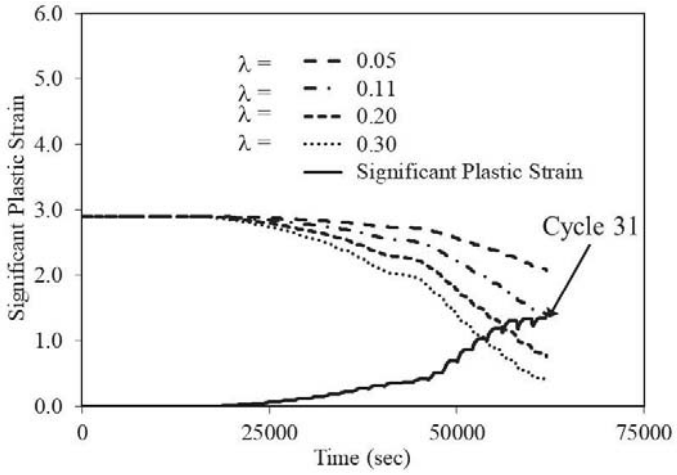

Figure 8: Fracture life of W6 brace.

5 CONCLUSIONS

- Increasing the thickness of the tab-plate will reduce the possibility of fracture of the weld connecting the tab-plate to the flange of the column. In addition, increasing the thickness of the tab-plate will force yielding in the web of the beam and prevent fracture of the tab-plates.
- Reducing the number of bolts while increasing both their diameter and the thickness of tab-plates to satisfy the AISC standards for tab-plate connection design had negligible effect on the hysteresis response of braced frames. Companies are producing bolts with larger diameters than what is available in the AISC tables.
- Reducing the number of bolts reduces the yielding demand on the connection and increases the rotational flexibility of the connection.

ACKNOWLEDGEMENT

The study was funded the Research Grants of the UAE University (SEED – G00001044 and UPAR – G00001916). In addition, thanks to the UAE University for providing the computational simulation facilities to conduct the current research.

Abstract. *This paper deals with the effectiveness of various configurations of a geofoam-filled barrier including single, double and triangle wall trenches in isolating the ground vibrations induced by a harmonic load. A $3D$ finite element program (Plaxis) is used and the model is verified by the result of the analytical solution for the active scheme. Furthermore, a comprehensive parametric study is performed to evaluate the effect of geometrical factors including the depth, width and the length for all systems. The main assumption during the parametric study is treating each parameter as an independent variable and keeping other parameters constant. A genetic algorithm is a proper tool for optimizing all key parameters that can have mutual effects on the vibration attenuation since the vibration isolation is a non-linear problem. A genetic algorithm code is implemented with the help of Python Software and Finite Element Program (Plaxis) for all three systems and the optimized parameters for reaching 75% efficiency of the barrier are calculated. The result of the parametric study showed that the single wall system needs the lowest value of normalized depth for reaching the highest value of the efficiency. Also, the mutual study of all parameters proved that the results are very different from a single parametric study. The comparison of all systems demonstrated that a double wall barrier is the best system for different frequencies.*

1 INTRODUCTION

The number of people who are interested in living in the big towns are increasing. This growth in population results in constructing more buildings and transport networks in and around the city [1]. Therefore, residence will have more vibration problems from the vibration sources like the passing train, machine foundation, traffic and other constructional activities. The body and Rayleigh waves produced from these sources results in ground-born vibration. The vibration is transmitted through the ground surface to the foundation of the building and create distress to the buildings and their inhabitants [2]. Mitigation measures are used to solve this problem, which include control of the vibration at the source, along the propagation path and at the place of immission. This paper deals with mitigation measure in the transmission path through installing a geofoam-filled barrier for attenuating the incoming waves.

Different approaches including experimental and numerical methods have been carried out to solve the problem of vibration isolation by trench. Since the experimental test is too expensive and the parameters to be assessed are fixed, a numerical model is an effective alternative method for assessing governing parameters in vibration isolation.

Woods conducted a series of field tests for evaluating the efficiency of the open trench and suggested that 75% reduction in incoming waves is enough to have a successful system [3]. Multiple rows of geofoam-filled trenches were applied for screening train-induced ground vibration and the results showed that increasing the depth of the barrier up to $1\lambda_{\mathrm{r}}$ is enough to reach the highest value of efficiency and further increase in depth does not have an effect on isolation capability [4]. A full experimental study was investigated to assess the efficiency of open and geofoam-filled barrier and the normalized depth of 0.6 was selected as an optimum depth for both open and geofoam-filled trench [5]. Mahdavisefat et al. [6] performed a full-scale field experiment to study the effect of open and sand-rubber mixture-filled trench and the normalized depth of 1.5 is recommended by the authors for reaching $60-70\%$ of attenuation of the incoming waves.

Tulika et al. investigated the efficiency of open and in-filled barrier by developing a numerical model and concluded that low-density material performs better than high-density [7]. Beskos et al. developed a BEM to study the efficiency of open and concrete filled in homogeneous and layered soils [8]. A FEM was used to evaluate the governing parameters of water and geofoam-filled barrier by [9] and they concluded that depth of the trench is a key parameter for assessing the efficiency of the trench. Ahmad and Al-hussain compared the screening efficiency of the stiff and soft trenches and developed a simple model for predicting the efficiency of the trench in the active and passive schemes [10]. Naghizadehrokni et al. [11] did a full experimental and parametric study and they suggested that the depth and width of approximately $1\lambda_{\mathrm{r}}$ and $0.2\lambda_{\mathrm{r}}$, respectively are enough to reach the acceptable amount of efficiency for the active isolation.

Most studies have mainly focused on one system like rectangular single wall and few researchers compared the efficiency of different configurations of the trench and only a few parametric studies investigated the optimization of different parameters together. Therefore, a full parametric study for assessing the effect of various configurations of geofoam-filled trench is missing. For this purpose, three different systems including the single, double and triangle wall systems are analysed and the efficiency of the systems are compared. There is also a need for mutual optimization of governing factors in evaluating of trench efficiency. It is not possible to treat each parameter as an independent variable in vibration isolation problem.

2 NUMERICAL MODEL

A wave barrier creates a finite material discontinuity for the incoming waves by intercepting, scattering, diffraction and refraction of wave propagation in soil, which can decrease the vibration amplitude beyond the obstacle. A time domain numerical model using the finite element package, Plaxis (2019) is developed to assess the effectiveness of different isolation systems as the wave barriers for the active isolation due to harmonic load in vertical direction. A $3D$ view of the vibration isolation problem and the soil and geofoam properties are illustrated in Fig. 1. Here, the depth D, width W and the length L of the trench are dimensionless values, which are in relation to the Rayleigh wavelength. The geofoam-filled trench is installed at the normalized distance of 1.25 for all three systems. A normalized distance of 7 beyond the trench is selected for calculating the average amplitude reduction ratio.

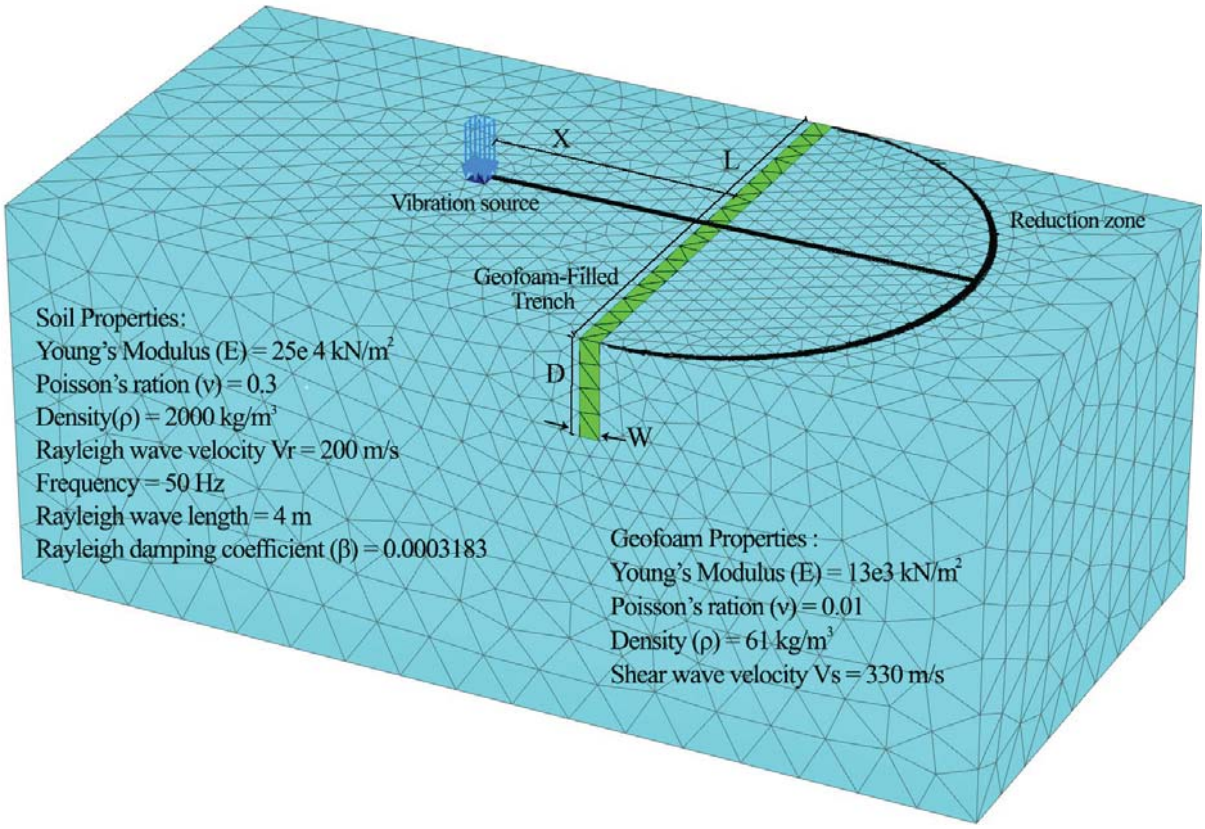

Figure 1: $3D$ model fir finite element analysis

3 ANALYTICAL VALIDATION OF FINITE ELEMENT METHOD

The developed model in Plaxis is verified by comparing the result of wave theory in terms of time of arriving to a specific point. There are two types of elastic waves in the elastic half-space theory including body and surface waves. Body waves are measured through equations 1 and 2.

$$V_p = \sqrt{\frac{E(1-\nu)}{\rho(1+\nu)(1-2\nu)}} \tag{1}$$

$$V_s = \sqrt{\frac{E}{2\rho(1+\nu)}} \tag{2}$$

The Rayleigh wave propagates along the surface of the half-space with a phase velocity, Vr, which is related to the shear wave velocity Vs and the poison's ratio. The Rayleigh wave velocity is calculated by:

$$K^6 - 8K^4 + (24 - 16\alpha^2)K^2 + 16(\alpha^2 - 1) = 1 \tag{3}$$

Where $K = Vr/Vs$ and $\alpha = Vs/Vp$.

Those equation are used just in an isotropic, homogeneous and elastic medium. For verifying the developed model for an open trench, a point at the location of $24\ m$ from the vibration source on the ground surface has been selected. The trench is located at the distance of $12\ m$ from the vibration source with the depth, width of and the length of 3, 0.25 and $10\ m$, respectively. Based on the equations of 1-3 the wave velocities are calculated as:

$$Vp = 406.6,\ Vs = 217.2,\ Vr = 200$$

Hence, the first time of arriving the waves to the selected point are measured as:

$$T_p = (24/406.3) = 0.059sec,\ T_s = (24/217.2) = 0.11sec,\ T_r = (24/200) = 0.12sec$$

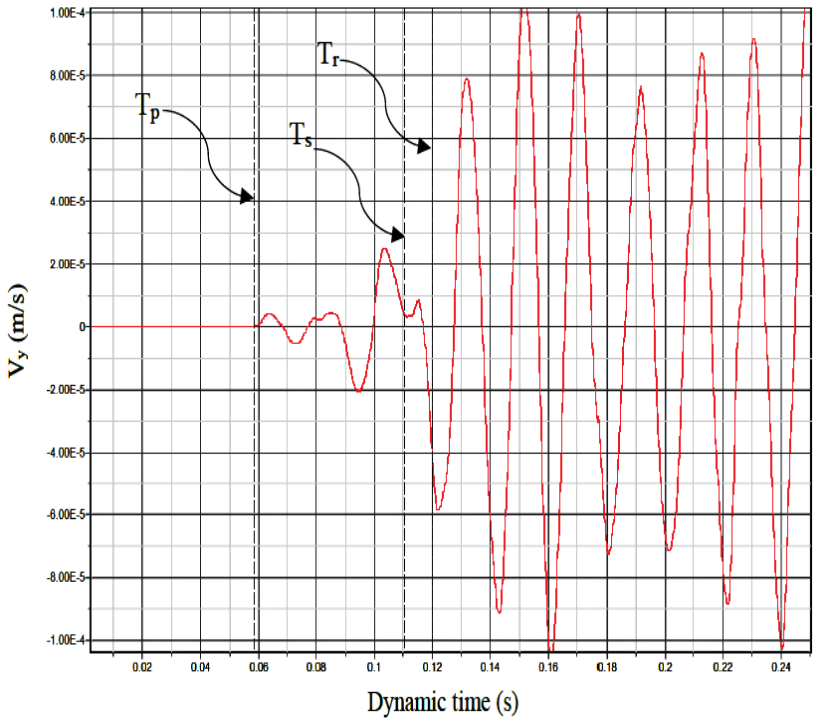

Figure 2: The motion of the selected point in homogeneous, isotropic and elastic soil media without damping

As it can be seen from Fig. 2 that the time of arriving of the body waves (P and S) to the selected point completely matches the analytical solution. The most important vibration will occur after arriving of the Rayleigh wave; that is 0.12 s and it is indicated as the third vertical dashed line. This confirms that the Rayleigh wave is the most important wave that should be considered in vibration isolation problem. Comparing the result of the developed numerical model and the analytical solution of the wave theory confirm the accuracy of Plaxis model.

4 SINGLE WALL SYSTEM

Fig. 3 shows the efficiency of an EPS Geofoam-filled obstacle as a function of normalized length. The average amplitude reduction ratio decreases dramatically with increasing the normalized length from 0.625 to approximately 2.5. It is apparent from the figure that the normalized length beyond around 2.5 does not create any further changes and $\overline{A}_r$ may be conservatively assumed to remind unchanged thereafter. Therefore, the normalized length of 2.5 is selected for the rest of the parametric study.

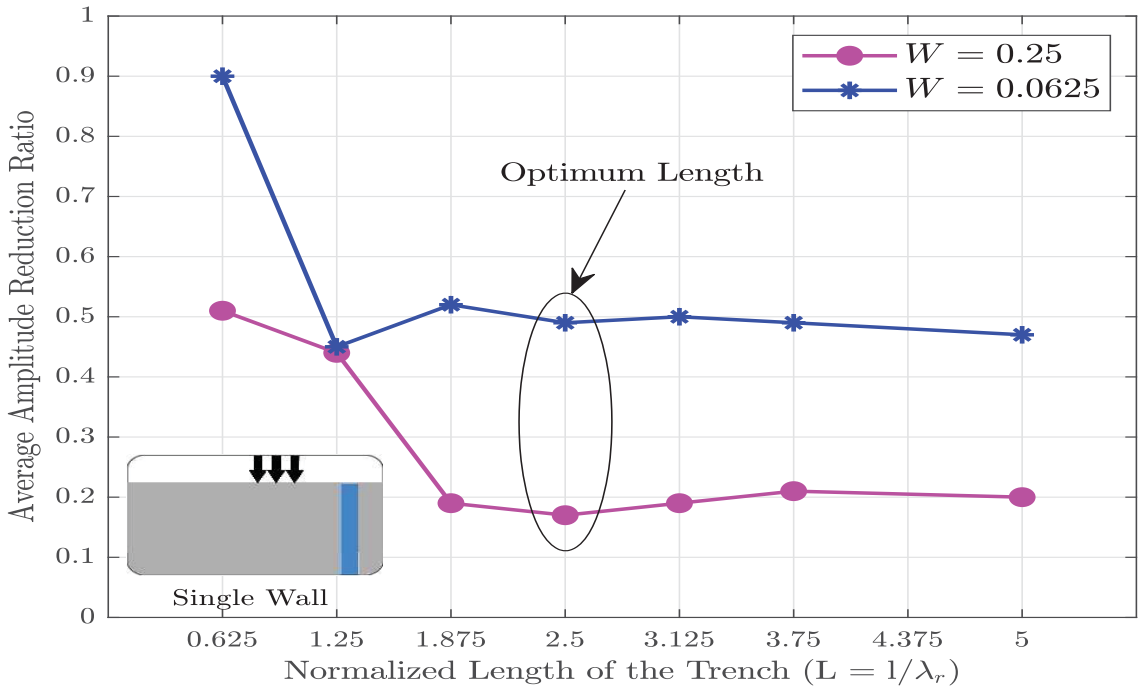

Figure 3: Influence of normalized length of the trench (normalized distance 1.25 from the vibration source, normalized depth of 1.25)

Fig. 4 illustrates the variation of $\overline{A}_r$ along the surface of soil domain for different trench depths. The effect of normalized trench depth is affected in a complex pattern with the effect of normalized trench widths. The efficiency of the trench reaches it's maximum value at D value around 1.25 for almost all widths. The optimum D has a close relationship with the width of the barrier and the efficiency of the trench increases gradually with increasing the normalized width for the same depth (optimum depth). Another important point in this figure is unexpected peaks and valleys in $\overline{A}_r$ value for various widths, which is caused by constructive and destructive interference of the barrier.

The importance of the normalized width on $\overline{A}_r$ is presented in Fig. 5. The width appears to play a significant role in screening efficiency of the trench. A reduction of approximately 50% is visible by increasing W from 0.0625 to 0.25 for almost all trench depths and it seems that $W = 0.25$ is an optimum width for achieving a reasonable amount of wave scattering. Increasing the normalized width means increasing the distance between two corners. The barrier bottom corners act as an additional geometric discontinuity and this issue results in mode conversation of incoming waves for converting part of the R-waves energy into the body waves

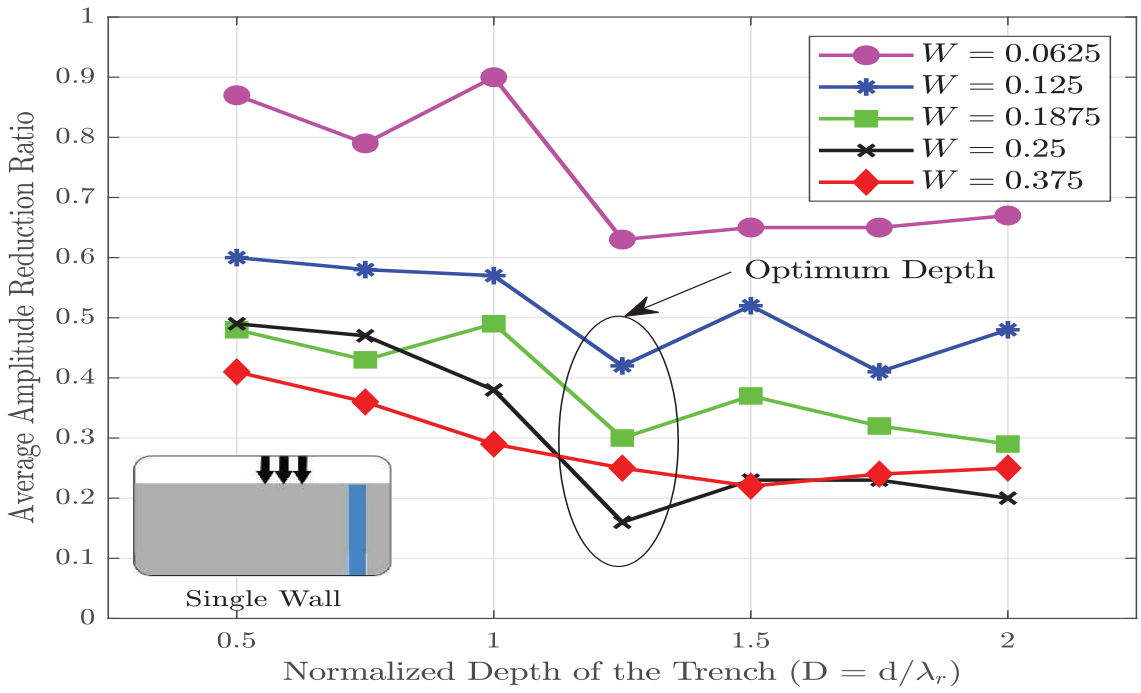

Figure 4: Influence of normalized depth of the trench

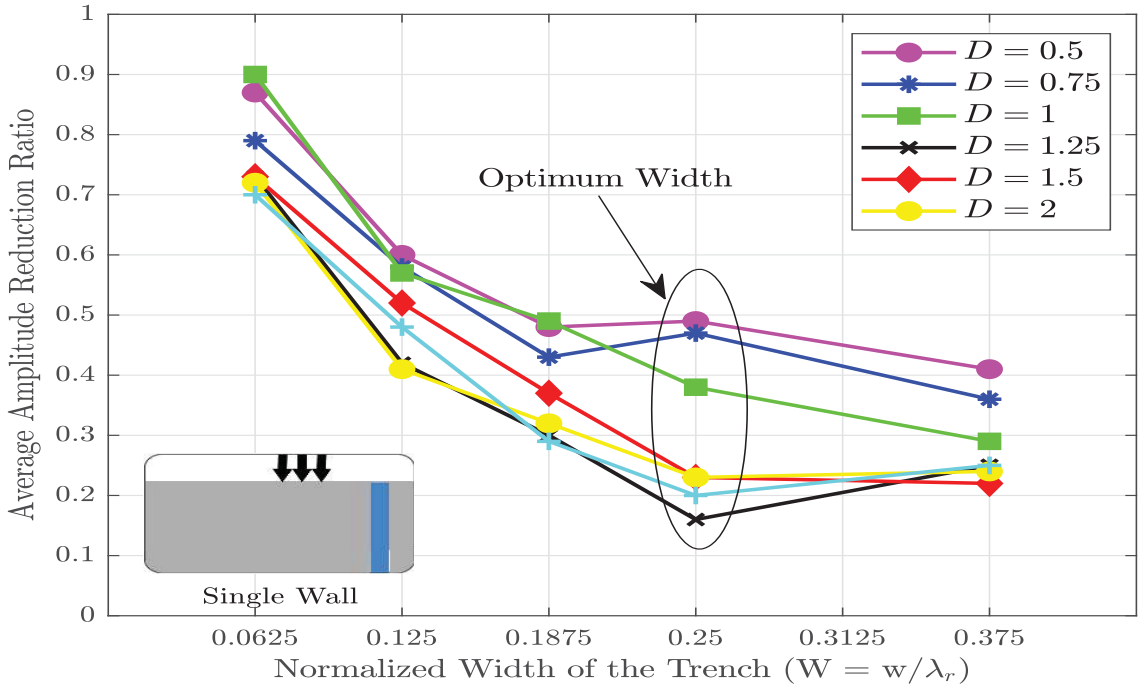

Figure 5: Influence of normalized width of the trench

5 DOUBLE WALL SYSTEM

The efficiency of the double wall system is compared with the single wall system with a thickness of $2W$, having the same width, depth and the length like the single wall obstacle. Hence, for this system the width of both barriers is considered as one width, which is W. This normalized width is the width for both trenches.

At the first step, a parametric study should be done for finding the optimum spacing between the barriers to achieve the best wave attenuation. The influence of spacing between trench walls is plotted in Fig. 6 with the constant normalized depth, width and length of 1, 0.25 and 2.5, respectively.

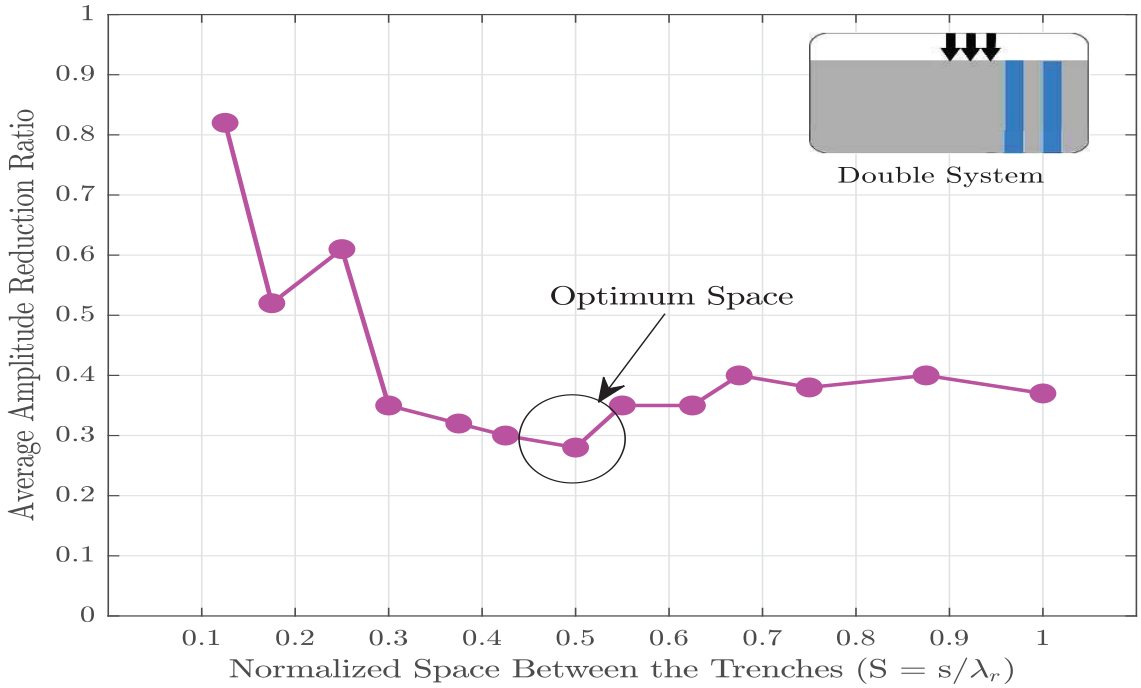

Figure 6: Influence of normalized space between the trenches

The normalized spacing (S) between the walls appears to govern the screening effectiveness of the trench. The efficiency of the double wall system is maximized at S value around 0.5. Therefore, the normalized optimum spacing between the wave barriers is considered as 0.5, which is compatible with the result of [5] for optimum spacing between trenches, for further parametric studies.

An investigation is done for finding the influence of the normalized length on wave attenuation like single wall system. The result of the parametric study doesn't show any specific change in comparison with the result of the single wall study. Therefore, to avoid the presentation of unchanged results, the normalized length of 2.5 is selected as the optimum length for this system.

Based on the information of Fig. 7, which is the calculated value of $\overline{A}_r$ as a function of the normalized depth, D for narrow trench ($W = 0.0625$) seems to govern the wave attenuation for the normalized depth between 0.5 and 1.5. For wider trenches, increasing the normalized depth of the barrier leads to blocking of more incident propagated waves until around $D = 1.25$, which is selected for the optimum depth of the trench for achieving approximately 80% of the barrier's efficiency for the wider trenches.

The effect of the width on $\overline{A}_r$ for an EPS Geofoam-filled barrier is presented in Fig. 8. It is obvious from the results that the value of average amplitude reduction ratio decreases dramatically with increasing the normalized width of the trench from 0.0625 to around 0.2 and thereafter, it remains at the constant value with increasing W to 0.375. An optimum width of almost 0.2 is enough for achieving the highest value of screening performance.

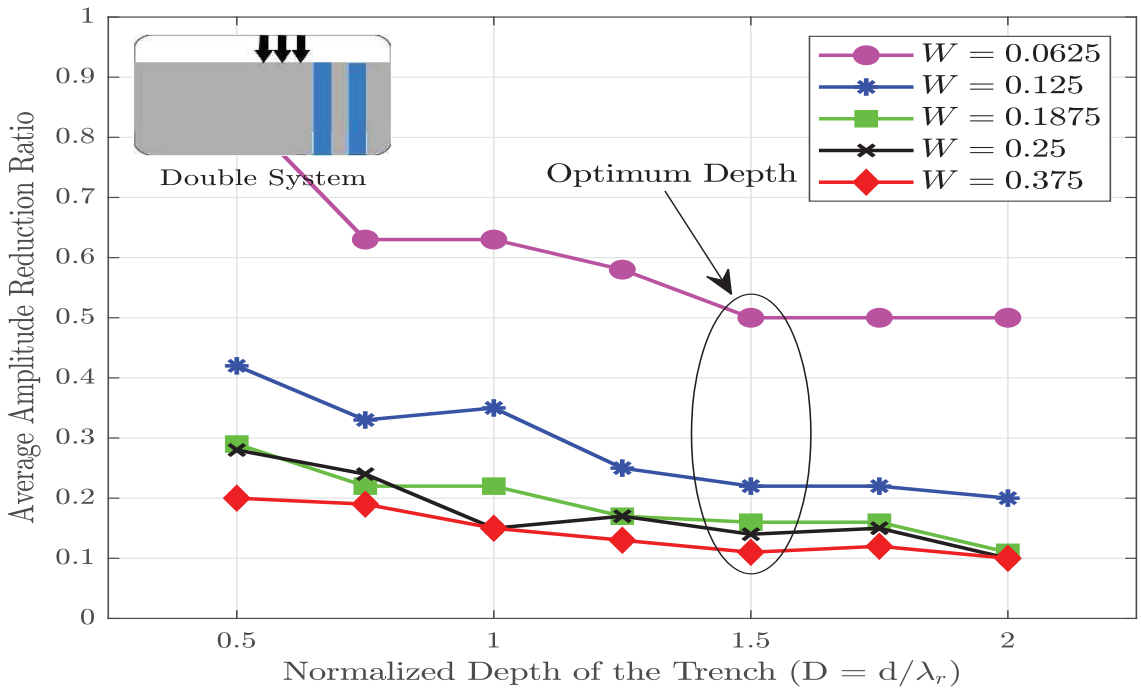

Figure 7: Influence of normalized depth of the trench

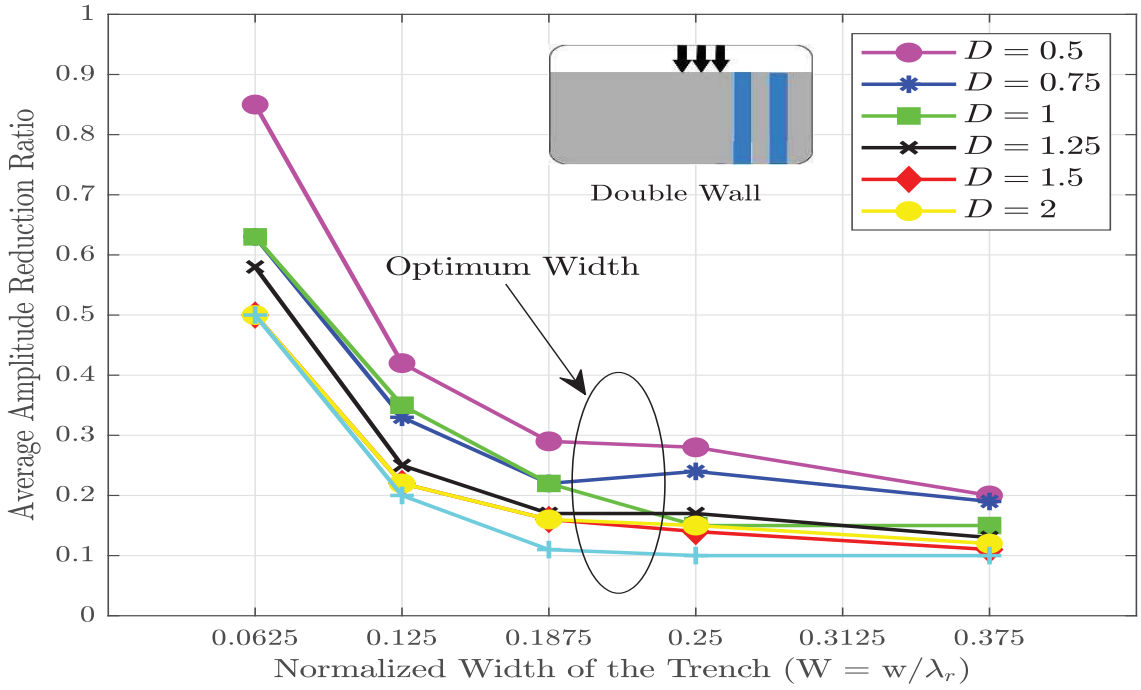

Figure 8: Influence of normalized width of the trench

6 TRIANGLE WALL SYSTEM AS WAVE BARRIER

For making a proper comparison with the single and double wall systems, triangle wall is considered with the same depth and the same area like single and double wall. However the width of the trench is different from those systems. Since increasing the width and the depth of the triangle trench leads to changing in the slope side wall of the trench, inclination

angle is proposed as an alternative parameter for measuring the efficiency of the barrier. As a consequence, the value of inclination angle is calculated with keeping the width of the trench at ground surface constant and calculating the inclination angle through increasing the depth.

A parametric study is done for finding the effect of the length on the efficiency of the trench and to see how far the results match with the results of the single and double wall systems. The results show that an optimum length of 2.5 is enough for the triangle wall system like for previous systems.

The effect of the normalized depth on the wave attenuation performance is presented in Fig. 9. The results reflect that in general a normalized depth of almost 1.5 appears to be the maximum depth for achieving at least 70% of system's effectiveness except for the narrow trench ($W = 0.125$). An approximately 50% reduction for almost all barrier with different normalized widths is seen by increasing D from 0.5 to 1.5

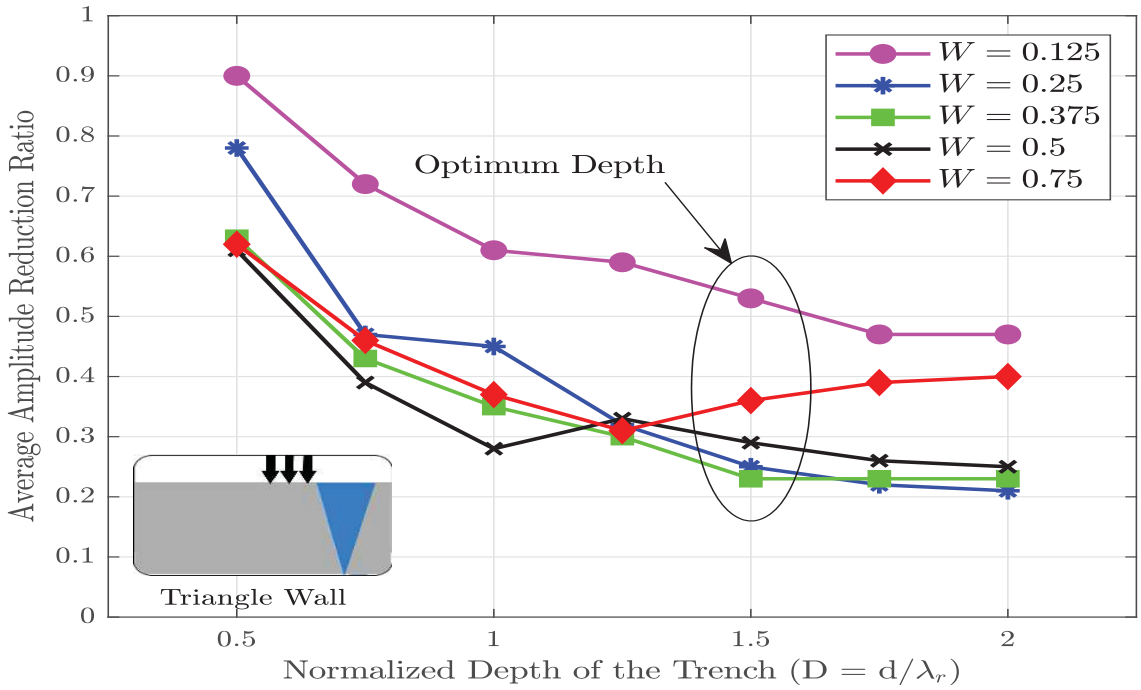

Figure 9: Influence of normalized barrier depth

The effect of varying the normalized width is studied by varying W from 0.125 to 0.75 which is the normalized width of the triangle wall system at the ground surface, while the normalized depth of the trench is varied from 0.5 to 4.

According to Fig. 10, vibration screening performance reaches the highest value when the normalized trench width is approximately 0.4 for shallow trenches ($D = 0.5$ to 1), which is considered as optimum W for shallow barriers. However, increasing the normalized depth ($D > 1$) leads to the highest value of wave attenuation when W is around 0.3. Therefore, a wider trench is needed (for $D < 1$) for reaching the highest value of screening performance, while by increasing the normalized depth of the trench ($D > 1$), a slender barrier is sufficient for reaching highest value of vibration isolation.

The performance of the trench inclination angle is investigated for $W = 0.125$ and three different normalized locations including 0.5, 1.25 and 2, respectively. Fig. 11 represent the effect of inclination on different situations.

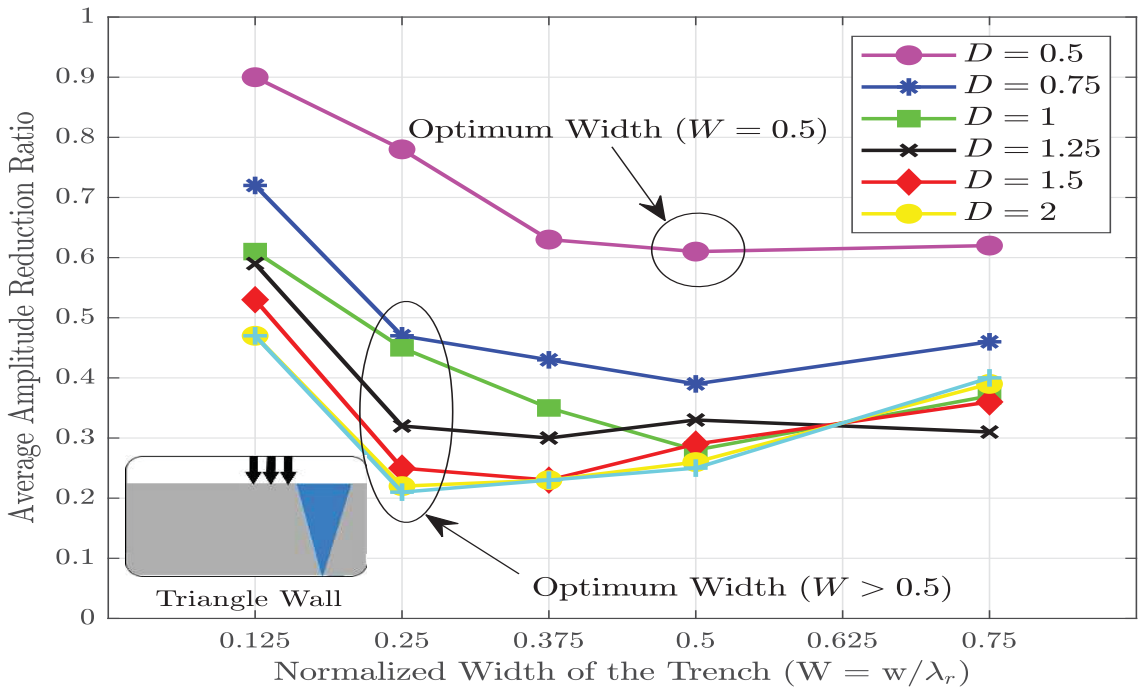

Figure 10: Influence of normalized width on the trench

It is observed that the average amplitude reduction ratio decreases dramatically with increasing the inclination angle from 35 to 60 degree. This angle is considered as the optimum angle for all locations.

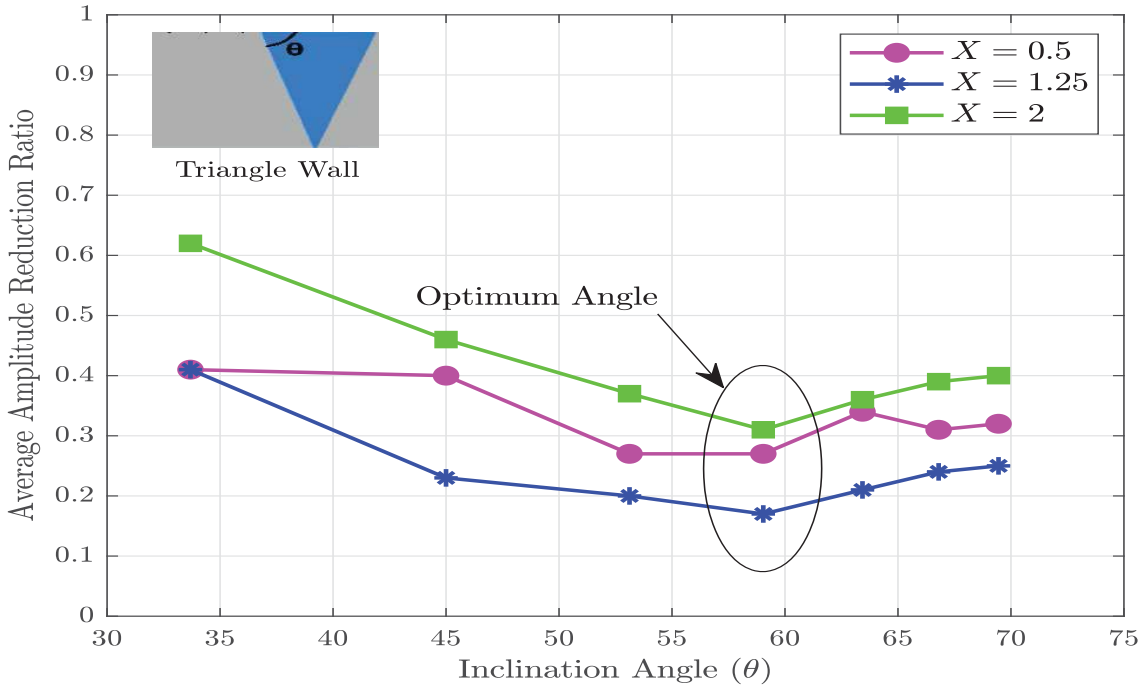

Figure 11: Influence of inclination angle of the trench with ground surface (normalized width 0.125)

7 COMPARISON OF DIFFERENT SYSTEMS

A comparison is performed between all proposed systems through calculating the screening performance as a function of D. The results are depicted in Fig. 12. The results show that the efficiency of the trench increases by increasing D for both widths ($W = 0.0625$ and 1). There is a considerable gap between the value of $\overline{A}_r$ for narrow and wide trenches that shows the significance of W.

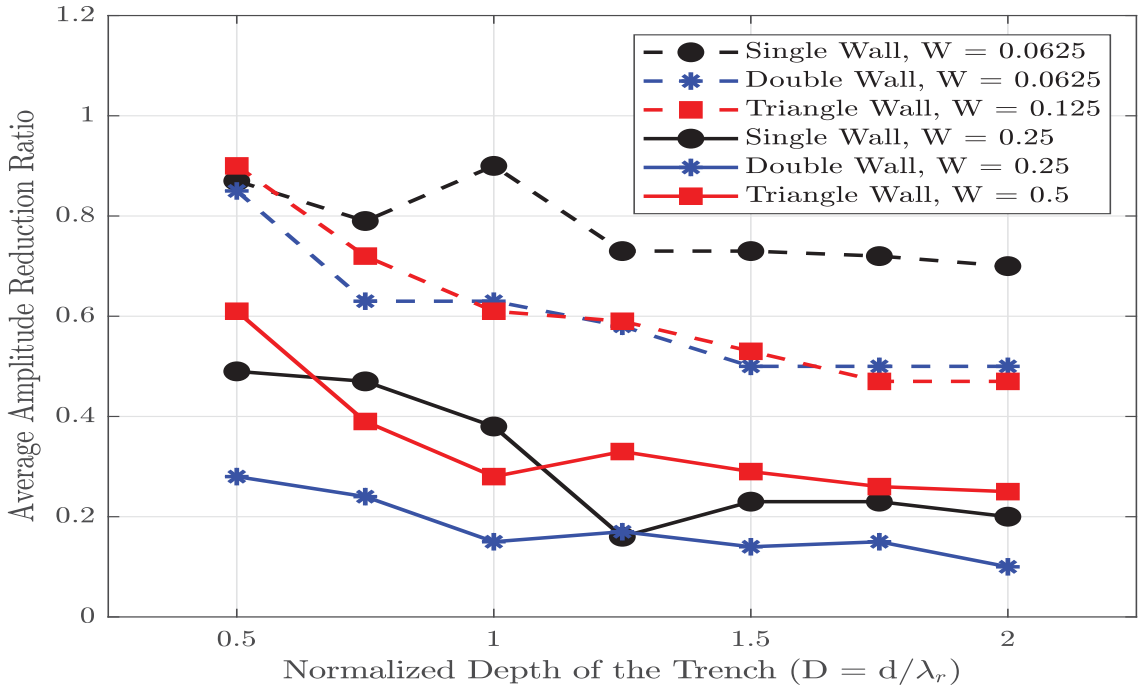

Figure 12: Comparison between different systems (normalized distance 2 from the vibration source)

Regarding the narrow trench, double wall systems has the highest value of screening efficiency for the normalized depth until 1. After this depth, double and triangle wall barriers have almost the same efficiency for all depths. However, the single wall system has the lowest value of efficiency in comparison with other systems.

As the width of the systems increases, the efficiency of all systems increases, too. However, the double wall system still performs better than the other systems in attenuating the incoming waves. There is a remarkable decrease in the amount of $\overline{A}_r$ for the single wall barrier which is the result of increasing the depth from 1 to 1.25. For making a comparison for the single and triangle wall system, it is divided into two different categories for shallower trenches ($D < 1$), in which triangle wall has better efficiency and deeper trenches ($D > 1$), in which single wall has more capability in blocking the incoming waves.

8 OPTIMIZATION PROCESS WITH GENETIC ALGORITHM

Until now, the problem of the vibration isolation has been solved for a specific parameter like depth, width, length or locations and keeping other factors constant. However, it is not reasonable to compute the wave barrier performance by allowing just one parameter to change since the parametric study proved that the dimensional and geometrical factors of a barrier are not independent and sometimes they may have an effect on each other. Therefore, it is imperative to study the mutual effect of all parameters including the dimensional and geometrical factors to

implement a successful wave barrier through optimal combination of parameters. This aim has been achieved through a genetic algorithm optimization technique for three different configurations of obstacles including the single, double and the triangle wall systems, respectively. It was tried to adjust the parameters to reach the same value of cross-sectional area for each system. The first step in the implementation of a genetic algorithm is to randomly create an initial population. Through reviewing empirical studies carried out and doing some trial and error for the initial population, population size equal 30 is found to be optimal for the problems in vibration isolation. Since the vibration isolation problem is an inherent complex and non-linear problem, the finite element program (Plaxis) and Python programming language are utilized as a fitness function to calculate the quality of a chromosome as a solution. A remote scripting interface is an option for building a model automatically in Plaxis and this ability creates a possibility to use Plaxis as a fitness function in genetic algorithm. The code is developed for vibration isolation study and all analyses steps are automatized. Another important feature of this code is the changeability of the soil and geofoam material, the geometrical dimensions and the shape of the barrier.

Woods suggested that a successful wave barrier should reach at least 75% mitigation in scattering of incoming waves. On the other hand, reaching to a deep trench like 5 or $6\ m$ is relatively tough and sometimes impossible in reality. All of these issues lead to create a restriction amount for $\overline{A}_r$ which is 0.75. In addition, we know that depth of the trench is one of the most important factors in achieving an acceptable efficiency for the wave mitigation. Therefore, defining a cost function for optimizing $\overline{A}_r$ value and simultaneously considering the depth of the barrier is a proper solution for increasing the importance of D in the optimization process. This is done by assigning two different constant coefficients including Alpha and Beta for $\overline{A}_r$ and the depth in a cost function, which are 0.995 and 0.005, respectively.

The next step is applying crossover, which is the genetic operator and uses to combine two chromosomes, or parents, to generate a crossover child for the next generation. Crossover is applied to the random selected parents with a crossover probability Pc of equal 0.8. The mutation operator is applied with a mutation probability Pm equal to 0.2. After completing the process of selection, recombination and mutation, the next population can be generated. This process of evaluation, selection, recombination and mutation is repeated until finishing the iteration number. A summary of implementation of the genetic algorithm for vibration isolation problem is presented in Fig. 13.

9 OPTIMIZATION OF DIFFERENT SYSTEMS

A genetic algorithm code with the above-mentioned properties is implemented in Python through writing a script for optimizing various parameters of the trench. It is mandatory to write a script that is readable by Plaxis for creating the model automatically including soil contour, borehole, soil model, structure, mesh, calculation phases, and calculating the efficiency of the trench.

A quantitative range for different parameters is defined for finding the optimal solutions of the problem. In order to make a proper comparison for all three configurations, the same depth and cross-sectional area is assumed for all three systems. For each system, different boundaries are defined as the maximum and minimum value for various variables, which are presented in Table 1.

A genetic algorithm is used for optimizing the important parameters of the barrier for the vibration isolation problem for reaching the efficiency of almost 75%. The variation of the parameters is assumed as the same value for having the equal cross-sectional area, while one of

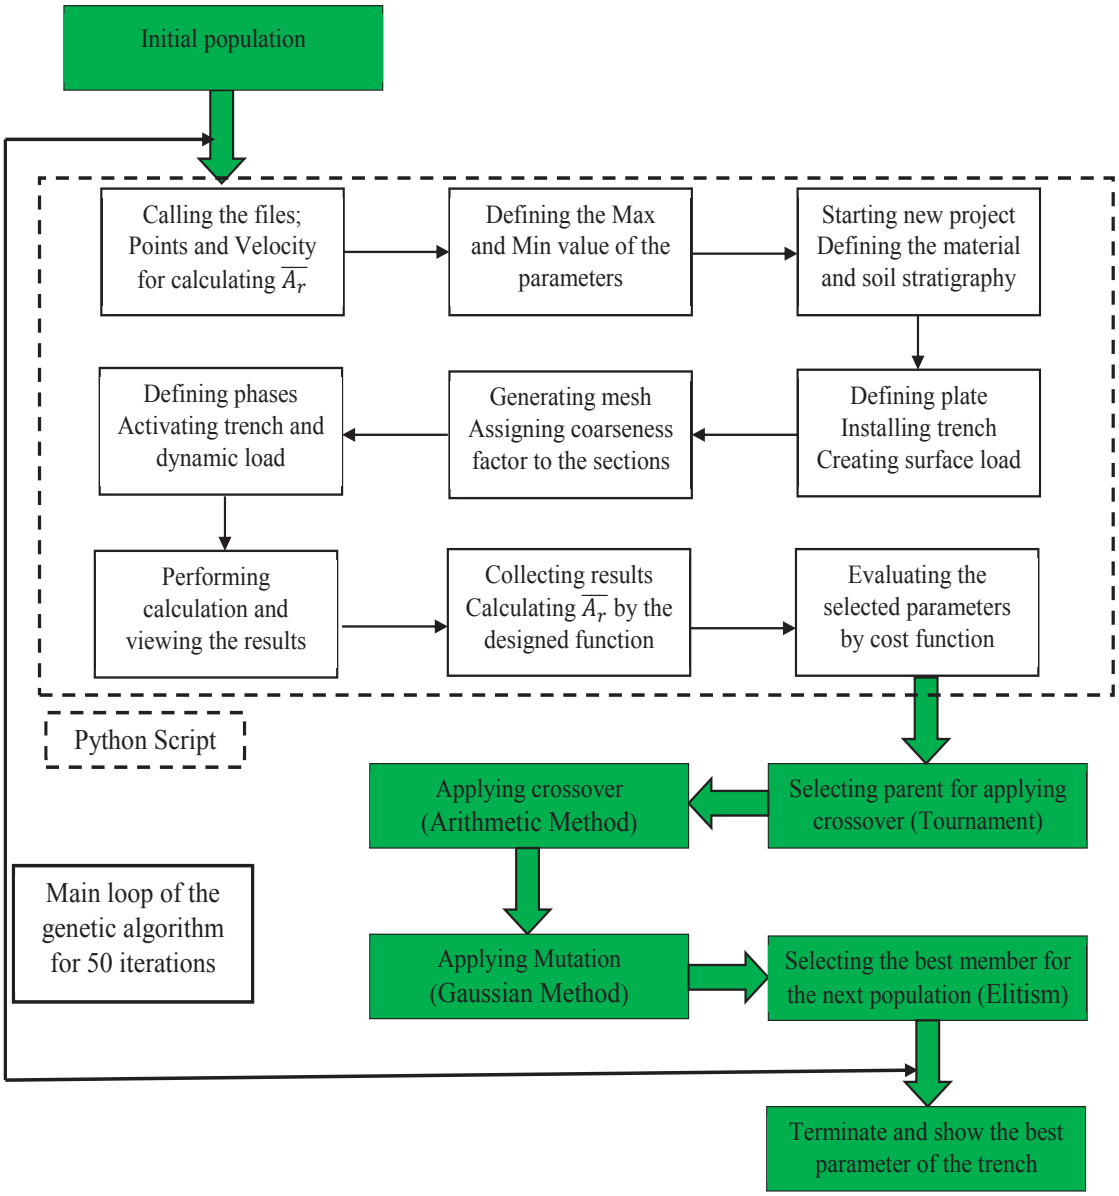

Figure 13: Implementation of the genetic algorithm for the vibration isolation problem

Type of system	Location (m)	Depth (m)	Width (m)	Length (m)	Distance (m)
Single	2-20	2-6	0.25-1	5-15	-
Double	2-20	2-6	0.25-1	5-15	2-4
Triangle	2-20	2-6	0.5-2	5-15	-

Table 1: Defined boundaries for different parameters in the genetic algorithm

the purposes of this study is evaluating the effect of the shape of the trench on mitigating of the incoming waves. The optimal parameters of geofoam-filled barrier for different systems in the case of active isolation and for the frequency of $50\ Hz$ is presented in Table 2.

The trench length for the single wall system is calculated with the same value of parametric study, so it is concluded that the length of $10\ m$ for the single wall system is suitable for reaching the desired efficiency. In addition, the space between the barriers for double wall system is in a

System	Location (m)	Depth (m)	Width (m)	Length (m)	Distance between trenches (m)	Efficiency (%)
Single Wall	5.38	2.96	0.95	10	-	78
Double Wall	4.06	2.6	1.2	6.05	2	78
Triangle Wall	2.18	2.98	1.92	8.15	-	74

Table 2: Optimized dimensions of the trench for different systems ($50Hz$)

good agreement with the result of parametric study.

An initial observation of the optimized parameters shows that the triangle wall system should be installed more near to the vibration source in comparison with other systems. In addition, the results show that the depth of the barrier is almost independent on the shape of the trench for the single and triangle wall systems, since the depth of the trench reminds almost has the same value for these systems. A pair of double wall barriers needs more width and lower depth in comparison with other configurations. Moreover, the length of the trench decreases in comparison with the other systems. Generally speaking, if reaching a depth of around $3m$ is difficult for a trench, double wall system is a good solution by having lower depth.

10 COMPARISON BETWEEN DIFFERENT SYSTEMS

Since the frequency of the applied load plays an important role in vibration isolation, a comparison has been done for different configurations with optimized parameters. By changing the frequency of the applied load, the average amplitude reduction ratio is calculated for the vertical response for the area beyond the trench and the results are illustrated in Fig. 14.

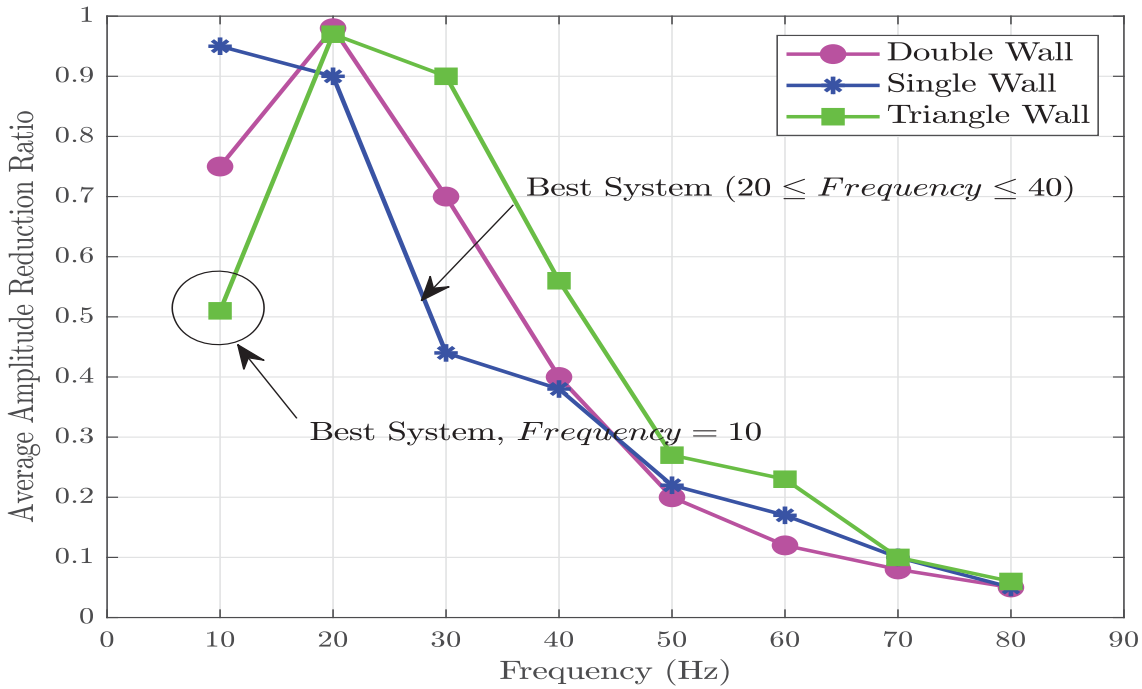

Figure 14: Influence of frequency of the applied load (Optimized parameters for all systems)

The results state that frequency of applied load plays a significant role in attenuating of incoming waves for various systems including the triangle, double and the single wall in orders.

Increasing the frequency of the load leads to a dramatic decrease in $\overline{A}_r$ value. For instance, increasing the frequency of the applied load from 20 to $70HZ$ results in reducing the average amplitude reduction ratios, which are approximately 85% for almost all systems.

11 Conclusion

The developed numerical model is verified by an analytical method. Then, a full parametric study is done for evaluating the effect of the governing factors including the depth, width and the length of the barrier in the active isolation and the results are compared. Three different systems including the single, double and the triangle wall are selected for assessing the effect of the shape of the trench on vibration isolation. Based on the results of parametric investigations:

- The normalized length of 2.5 is recommended for all three systems for having the highest amount of efficiency.
- The single wall system needs the lowest value of normalized depth for attenuating the incoming waves at an optimum depth, which is equal to 1.25. However, the optimum depth for double and triangle wall system is calculated to 1.5.
- The double wall system needs an optimum width of 0.2, which is the lowest width in comparison with other systems, whereas the optimum width of single wall system is calculated to 0.25. For triangle wall system, shallow trenches need more width ($W = 0.4$) to reach the highest value of efficiency in comparison with a deep trench, which is 0.3.
- The double wall is the best system for attenuating the highest amount of incoming waves in comparison with other systems.

Finally, the most significant finding of the research is the developed genetic algorithm code that can be used as a reference for geotechnical engineers for designing the barrier for achieving at least 75% mitigation in vibration amplitudes. In addition, the mutual study of all parameters demonstrated that the results are different to those of a single parametric study. The result of the comparison of all systems in the frequency domain revealed that the single and the double wall barriers are the best systems for the frequency in the range of $20-40\ Hz$ for the active isolation and the triangle wall system is highly recommended for the frequency of $10\ Hz$. However,

Keywords: 2D phononic crystal, Stopbands, Rainbow, Experimental, Additive manufacturing

Abstract. *Phononic crystals (PnCs) and metamaterials are nowadays widely investigated for vibration suppression owing to their stopbands that prohibit wave propagation. The application of PnCs and metamaterials is however limited by their narrow bandgaps especially for low frequencies. The recently introduced rainbow metamaterials composed of spatially varied oscillating unit cells are found to generate broader bandgaps than the periodic structures. 2D rainbow PnCs consisting of cubic blocks with internal voids connected by curved beam are proposed in the present paper. Masses of the cubic blocks differ due to different dimensions of internal voids. To prove the effects of rainbow design, two 2D block-beam lattice structures, with periodic and nonperiodic units respectively, were manufactured by additive manufacturing method. Frequency response functions of the manufactured PnCs were measured with a testing system containing a mechanical shaker, an impedance head and a laser Doppler vibrometer. Receptance functions of the PnCs in two directions were measured separately. The obtained experimental results show that the PnC with rainbow mass has extended bandgaps compared with the periodic one.*

1 INTRODUCTION

In recent years, a great deal of engineering materials and structures have been proposed for vibration and noise control [1-13]. Among all the promising structures, phononic crystals (PnCs) received much attention due to its outstanding wave control abilities. PnCs can be considered as engineered materials with designed macroscopic periodic structures that manifest outstanding properties such as bandgaps, i.e., frequency ranges within which acoustic/elastic waves cannot propagate and hence effectively attenuated. The existence of bandgaps enables a wide application of PnCs, such as wave filter, waveguide and wave trapping, vibration isolation, etc [7-13].

The bandgaps of PnCs are mainly generated by two phenomena, Bragg scattering and local resonances. The bandgaps by Bragg scattering occur when the wavelength of the propagating wave is comparable to the lattice dimension of the PnC [14-16]. This means it is hard to achieve Bragg scattering bandgaps in the low frequency ranges due to the limitation of lattice constant in application. In contrast, locally resonant bandgaps rely on the resonance of scattering units. The frequency of locally resonant bandgaps is much lower than that of Bragg scattering bandgaps [17-21].

Even though locally resonant PnCs can attenuation vibration greatly in the bandgaps at low frequencies, the bandwidth is still narrow for real-world applications. Broadening low frequency bandgaps remains a challenge for the design of PnCs. This consideration led to the design of nonperiodic structures. Zhu *et al*. [22] proposed rainbow wave trapping composed of grooves of different depth, Meng *et al*. [23-25] recently developed and manufactured beams with spatially varying resonators. These structures with rainbow profiles were found to possess enlarged locally resonant bandgaps compared with periodic structures. The concept of nonperiodicity opening new and innovative possibilities for design of PnCs and metamaterials.

Inspired by these results, we proposed a 2D rainbow PnCs consisting of spatially distributed cubic blocks connected by curved beams. The masses of blocks are adjusted by opening different internal voids. Two rainbow and periodic PnCs are manufactured with the employment of the additive manufacturing (AM) method, and tested with the frequency response functions (FRFs) measurement system. It is shown by the experimental results, broadband stopbands can be achieved in x and y directions as a result of the rainbow-based PnC design.

2 DESIGN OF 2D RAINBOW PHONONIC CRYSTALS

With the purpose of delivering the rainbow 2D PnCs, structures consisting of spatially distributed blocks connected by two curved struts are created as shown in Fig. 1. Each block contains a perforated hole in the middle. Masses of blocks differ due to the different diameters of internal voids. This maximum mass reduction is set as 70% in order to preserve the structural integrity of the blocks and to maintain the assumption that blocks act as rigid bodies. The masses of blocks are set as sinusoidally varied over the two directions of the rainbow structure with the aim of inducing a smooth near-periodicity and excluding rapid changes for consecutive masses. The two curved beams between blocks are inverted, which can both enhance stability and reduce transmission rigidity compared to straight ones. The cross-section and curvature of connection beams and consequently stiffness is fixed. The equivalent periodic structure is derived by setting the diameter of internal holes equal to the average hole diameter of the rainbow PnCs.

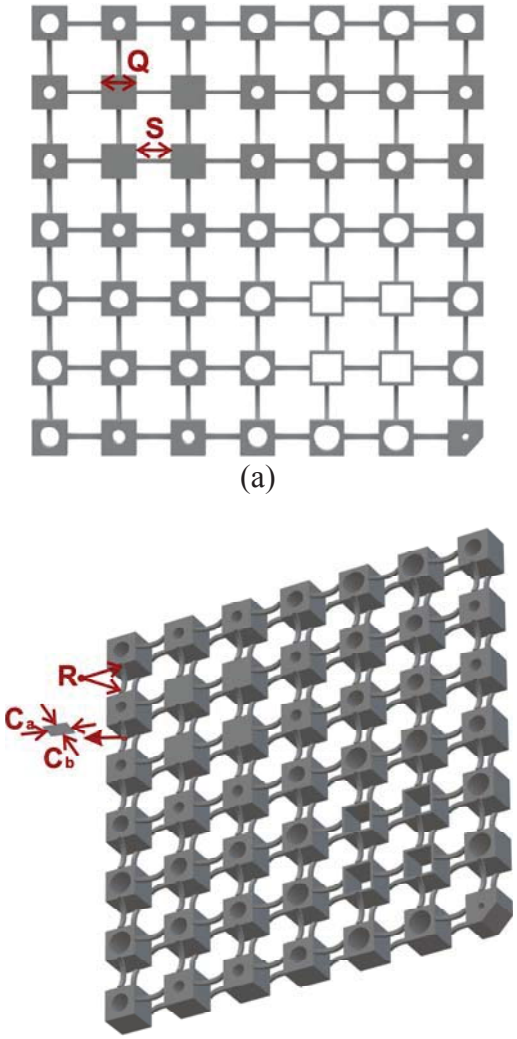

Figure 1: Schema of the 2D rainbow PnC, (a) top view, (b) global view. the labels show the geometric parameters block side length (Q), blocks distance (S), curvature radius of the curved beam (R), cross-section dimensions of the curved beams (C_a, C_b).

3 EXPERIMENTAL MEASUREMENT OF THE FRFS OF 2D PHONONIC CRYSTALS

3.1 Manufacturing of the PnCs

Influences of non-periodicity on the FRFs of the structure were explored experimentally with two rainbow and periodic PnCs. The two samples were manufactured by AM method. AM has become the most popular manufacturing method for PnCs and metamaterials owing to its distinct advantages over traditional subtractive manufacturing processes. AM technologies create structures by deposing materials layer-by-layer. A great number of AM technologies have emerged, including laser sintering, binder jetting and stereolithography, etc [26,27]. Given the geometrical dimension and structural physical parameter requirements as well as price factors, a Selective Laser Sintered (SLS) was selected for the fabrication of the 2D PnCs. A schematic illustration of the SLS process can be seen in Fig. 2.

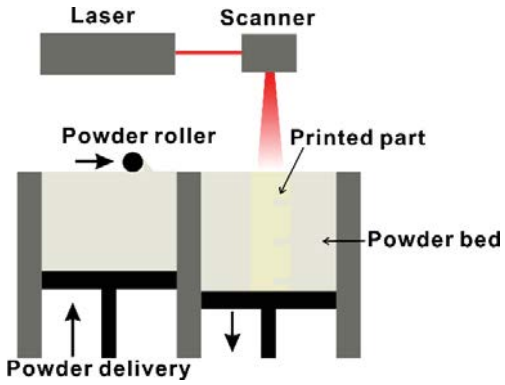

Figure 2: Schematic illustration of the SLS process [23].

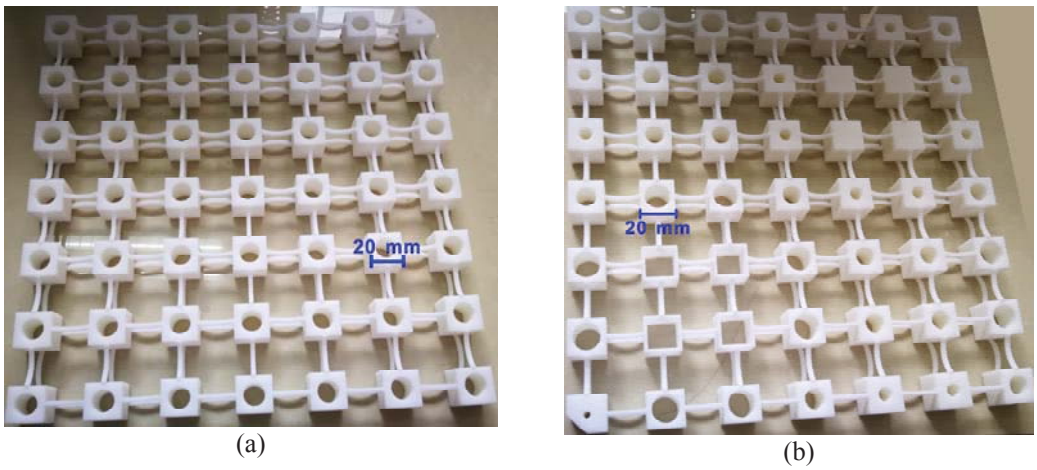
The structural samples were fabricated using PA12 material. The printer employed a CO2 laser having a scan speed and hatch spacing of 0.35m/s and 0.3 mm, respectively. We note the nominal spot size of the laser was 0.46 mm and the layer thickness 0.12 mm. PA12 powder was used to fill the powder bed having dimensions 375 mm×375 mm×430 mm at a temperature of 170 °C. The theoretical size threshold below which the metamaterial manufacturing would present deviations from the designed CAD geometry was determined by the accuracy of the printer. The printer properties that affect manufacturing precision include the laser spot size, the layer thickness, the size of the powder and the laser scanning strategy. Features of sizes below 0.8 mm are expected to be fabricated with considerable mechanical properties [28].



(a) (b)

Figure 3: Photographs of the manufactured (a) periodic PnC, and (b) rainbow PnC by laser sintering.

Photographs of the printed rainbow and periodic PnCs are shown in Figs. 3(a) and (b). The Young's modulus and material density of the printed structures were measured on small fabricated samples based on the ASTM standard and found to be 1.75GPa and 1000kg/m^3 respectively. The printed structures are composed of 7×7 cubic blocks. The side length of cubic blocks is $Q=20$ mm, the distance between blocks is $S=20$ mm, the curvature radius of the connection beam is $R=20$ mm, cross section dimensions of the curved beams are $C_a=C_b=2.5$ mm, the mass of the blocks are sinusoidally distributed in 2 directions as:

$$m_{ij}=\left(0.76+0.19\sin\left((i-1)\pi/3\right)+0.19\sin\left((j-1)\pi/3\right)\right)M \tag{1}$$

where M is the mass of original non-opening blocks, and $i, j = 1, 2, ..., 7$ represent the number of blocks in x and y directions. The block mass of corresponding periodic PnC is equal to the average block mass of the rainbow PnC, e.g. $m_{ij} = 0.76M$.

3.2 Experimental system

The samples were tested with the experimental setup presented in Fig. 4. Due to the large dimensions and masses of the structures, the PnCs were suspended on a metallic truss using rubber bands and plastic hooks to simulate free boundary conditions as shown in Fig. 5(a). The approach of suspending the tested structures has been proved effective by Elmadih *et al*. [29]. A mechanical shaker (Modal Shop 2060E) was employed to excite the PnCs with a chirp wave over the frequency range of 20~1000 Hz. The excitation signal was first generated by the computer and then sent to a junction box (Polytec VIB-E-400), afterwards it was amplified by the amplifier (Modal Shop 2050E09 amplifier) and sent to the shaker. The excitation forces on the PnCs were tested by an impedance head (PCB 288D01) which was bolted to the mechanical shaker on the opposite end. Displacements in two directions at the diagonal corner of the excitation point were measured with the laser Doppler vibrometer (Polytec PSV-400). The collected displacements and forces were sent back to the junction box and calculated by the software to solve out the FRFs. All measurements were taken with a frequency resolution of 1.25 Hz and are complexly averaged over 100 spectral sweeps. Schema of the complete experimental setup system can be seen in Fig. 5.

Figure 4: Photograph of experimental setup for FRFs test of 2D PnC

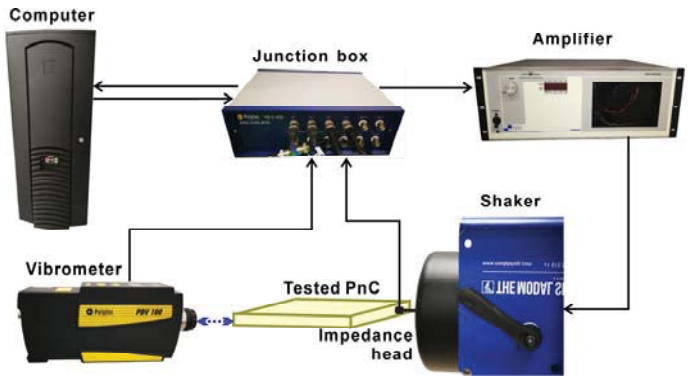


Figure 5: Schema of the experimental setup

3.3 Experimental results

The measured receptance values of the two PnCs are shown in Figs. 6(a)-(f). It can be seen that the rainbow PnC has broader bandgaps than that of the periodic structure of the same mass in x and y directions. The bandgaps of the rainbow PnC occur at the frequency range 470~550 Hz in two directions, within which the receptance values are significantly reduced by 20 dB. By contrast, the periodic PnC has bandgaps within the frequencies 420~470 Hz. Wavelengths at bandgaps are much larger than the lattice dimensions for both PnCs. The rainbow PnC has enhanced bandgaps by 60% than the periodic one. Meanwhile, it also can be seen that the reduction of receptance values within the bandgaps of the rainbow PnC is smaller than that of the periodic PnC. As discussed by Meng *et al*. [23], the enlarged bandwidth could cause smaller attenuation amplitude and thus smaller reduction of receptance values.

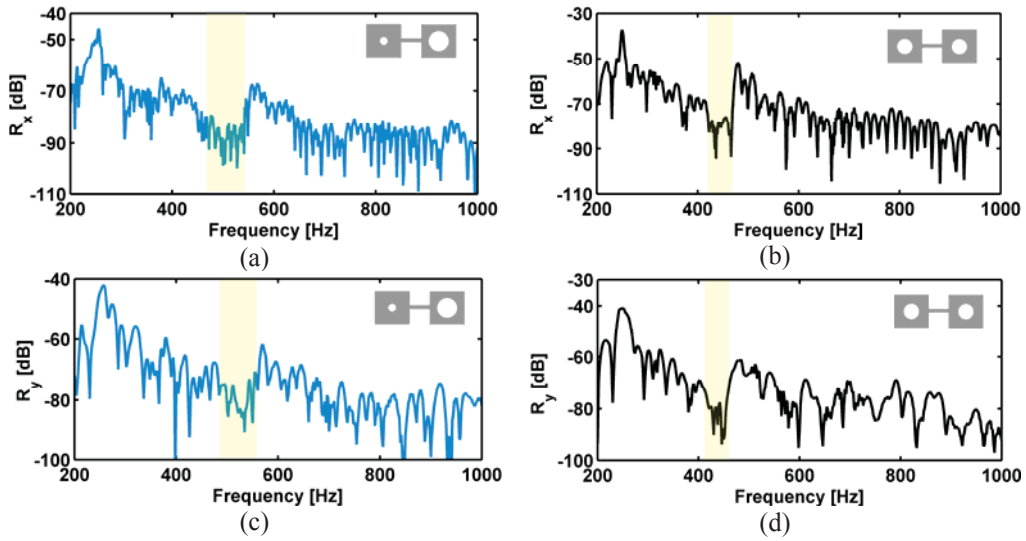

Figure 6: Experimental displacement FRFs of the rainbow PnC in x (a) and y (c) directions, and the periodic PnC in x (b) and y (d) directions

4 CONCLUSIONS

In this paper, the attenuation performance of 2D rainbow PnCs were investigated. Two PnCs with rainbow and periodic unit cells were manufactured by AM method. The PnCs were composed of spatially distributed blocks connected by curved beam. Internal voids were implemented to the blocks to adjust the local masses and generate nonperiodicity. The rainbow PnC contained blocks with masses sinusoidally varying in two directions. FRFs of the PnCs were measured experimentally. Results showed that the introduced rainbow PnC can have low frequency bandgaps much broader than periodic PnCs of equal mass. The method of introducing nonperiodicity displays a great potential for the designing of PnCs with enhanced attenuation performance.

Keywords: noise control, acoustic panel, sound transmission loss, KDamper

Abstract. *In order to encounter the challenges of low frequency noise absorption below 100 Hz, primarily emitted from the engines in air and ground vehicles, a method of acoustic panel mounting is proposed based on the KDamper concept which utilizes the negative stiffness damping effect. The practical constraints in such applications relating to the thickness of the panel for adequate noise absorption, are compensated through the unique damping properties of the KDamper and the ability to attenuate low frequency excitation in a considerable range. Therefore, a preliminary implementation of an acoustic panel with appropriately designed elastic mounts incorporating negative stiffness elements, is evaluated in terms of acoustic performance. During the design stage of the mounting, the problem is approached as in the case of classic vibration isolation of a rigid mass, due to the nature of the low frequency excitation. However, the elasticity of the deformable thin plate is taken into account by modeling its dynamic behavior using generalized modal values. The investigation consists in establishing the theoretical framework of the problem for the examination of metrics such as the sound transmission loss (STL) and the optimization of the mounting in order to maximize the STL performance, accompanied by FEM simulations. Additionally, comparisons with conventionally mounted panels is provided for reference and to highlight the advantages of the proposed solution. Early results regarding the noise control capabilities of such a panel configuration, indicate the potential of this proposition in specific applications.*

1 INTRODUCTION

Researchers have reported several hazardous impacts of low-frequency noise on human health such as annoyance, headache, city-fatigue [5], etc. To attenuate low frequency sound, passive solutions such as foam layers, sound diffusing panels and blocks, sandwich panels and many others [14], constitute the most widespread means for acoustic treatment in a vast range of applications from room acoustics, to loudspeaker enclosures etc.. However, these means present certain limitations in the low frequency range, namely below 500 Hz approximately, which is very important regarding noise control in transportation media and inside buildings, among other applications. Traditional materials follow the mass density law for sound shielding. According to the mass-density law, sound transmission through a substance [19] is given by $T = \frac{1}{\rho t f}$, where ρ is density, t is thickness of the medium, and f is the sound wave frequency. Thus, for a particular frequency, doubling the thickness of the sound insulator would result in an increment of only 6 dB STL. Therefore, a thicker porous material is required for shielding of low frequency noise [11], but even a thick concrete wall fails to attenuate low levels of low frequency noise. To encounter these issues, other types of solutions have been proposed in the form of local dampers [13], perforated plates [4], meta- surfaces or meta-diffusers [8] and acoustic/elastic meta-materials [3] among others.

Lightweight single or double walls are very common solutions for partitioning in dwellings. They are typically composed of two leaves mounted on a wood or steel frame. The cavity between these leaves is filled by absorbing material to improve the acoustic performance in mid-to-high frequencies. The limited capability of the aforementioned conventional passive means at low frequencies, introduces a dilemma, provided that improvement of their performance is generally associated with an increase in weight and volume. Additionally, other solutions such as conventional passive vibration dampers have the ability to absorb at very specific frequencies, and they can also be very heavy.

Owing to the need of low frequency sound absorption, it is desired to develop a new generation of partitions capable of attenuating noise in low-to-high frequency range. To contribute to the solution the paper considers the application of the KDamping concept towards the design of highly dissipative low-frequency mounts. The KDamper is a novel passive vibration isolation and damping concept, based essentially on the optimal combination of appropriate stiffness elements, which include a negative stiffness element [1, 2]. In order to propose a solution to this problem, the STL of panels is initially examined, considering the sound propagation through a single, finite, rectangular thin plate. The acoustic behavior of a simply supported plate in this low frequency range, may be treated as a case of classic vibration control. The mounting of this plate is investigated and the way it participates in its STL performance. An equivalent analytical framework is presented describing the behaviour of a conventional panel supported by KDamper mounts incorporating the effect of the panel flexural stiffness. it is worth

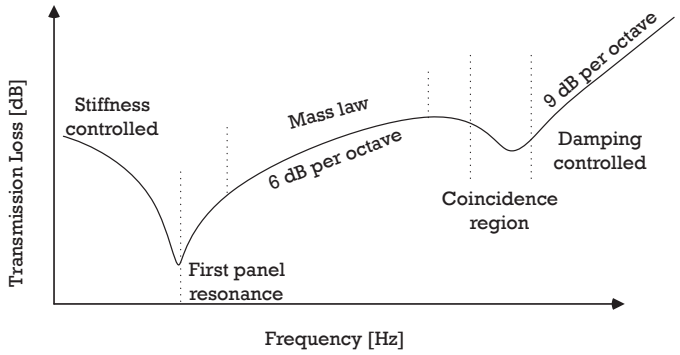

Figure 1: Typical STL profile of a panel.

noting that, the previous approaches considered the problem as in the case of classical vibration of a rigid mass ignoring any contribution of the plate's modes [17].

2 SOUND TRANSMISSION LOSS OF PANEL

In this section the theory of Sound Transmission Loss (STL) through a single panel is briefly presented. Various ways have been proposed regarding the modeling and simulation of the sound propagation through obstacles and the resulting STL [20, 15, 9]. In this work, the fundamental physics of the problem are investigated via an impedance based approach. According to this approach Transmission loss of sound occurs when there is an impedance mismatch between the propagation media of the traveling sound waves, thus sound is reflected and/or absorbed [9]. Direct sound transmission through thin panels depends on the mass, stiffness and damping of the system plate-support.

Figure 1 shows a typical form of the STL curve for sound propagation through a thin plate [7]. This curve presents five distinct regions in corresponding frequency ranges, depending on the properties of the system.

In a general case as in Fig. 2a, the STL is investigated via the assumption of a propagating plane wave between two different media. The impedance mismatch comes from the difference of impedance that the propagation medium of the incident waves Z_0, has from the propagation medium of the transmitted waves Z_1. In order to quantify the consequences of this mismatch, the transmission coefficient τ is introduced, defined as the ratio of the complex amplitude of the transmitted sound pressure to the complex amplitude of the incident sound pressure:

$$\frac{\tilde{p}_t}{\tilde{p}_i} = \tau = 2\frac{\tilde{Z}_1}{\tilde{Z}_1 + \tilde{Z}_0} \tag{1}$$

Figure 2 illustrates a wall, a rigid flat surface that consists only on mass, oscillating in an infinite rigid baffle with air on both sides, subjected to normal incident plane waves $\mathbf{p}_i = \tilde{p}e^{\jmath(\omega t - \kappa_0 z)}$. This particular case is refereed to as the "limp wall" assumption and the resulting frequency response of the STL is known as the "mass law".

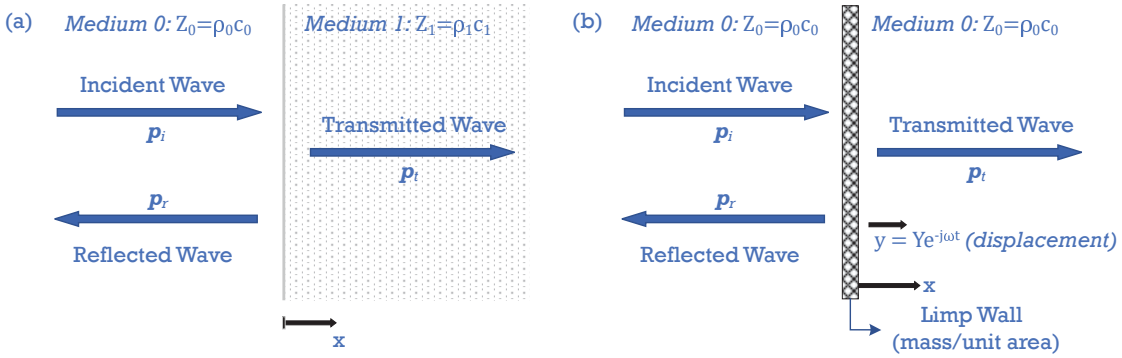

Figure 2: (a) Wave propagation in the presence of impedance mismatch (b) Limp wall assumption.

For frequencies higher than the natural frequency f_0, the STL is controlled by the mass per unit area of the panel. This corresponds to a 6 dB per octave increase of STL, while doubling the mass per unit area leads to a 6 dB per octave increase. Specifically, for a thin panel, neglecting stiffness and damping (limp wall):

$$STL = 10log\Big[\frac{\omega^2\overline{m}^2}{4(\rho_0 c_0)^2/cos^2\theta}\Big] \tag{2}$$

where θ is the angle of incidence of the propagated sound waves, c_0 is the speed of sound in air, ρ_0 the air density and $\overline{m}$ $[kg/m^2]$ is the mass per unit area of the panel. In the case of normal incident waves, $\theta = 0$.

Now, assuming that the same laws apply in case of a partition as illustrated in Fig. 3, by applying pressure and velocity continuity conditions at the interface of air and plate, the transmission coefficient comes as

$$\tau = \frac{2\tilde{Z}_0}{-\jmath(\omega m - k/\omega) + (2\tilde{Z}_0 + c)} \tag{3}$$

The imaginary part in the denominator of Eq. (3), indicates that the mass contribution ωm and the spring contribution $-k/\omega$ have a phase difference of 180° while the term $2\tilde{Z}_0$ indicates the radiation at both sides of the wall. The transmission coefficient can also be written as

$$\tau = \frac{\tilde{Z}_f}{\tilde{Z}_p + \tilde{Z}_f} \tag{4}$$

where $\tilde{Z}_p = -\jmath(\omega m + \jmath c - k/\omega)$ is the partition (mechanical) impedance and $\tilde{Z}_f = 2\tilde{Z}_0$ is the fluid loading impedance in both directions [9]. The

For the calculation of the Sound Transmission Loss (STL) in the case of a thin plate using the single DOF model as in Fig. 3, the expression of the mechanical impedance

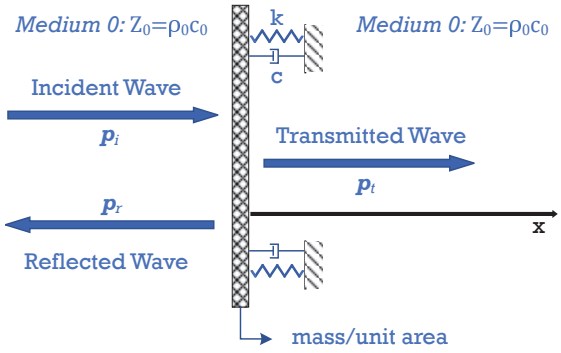

Figure 3: Wave propagation at a partition.

$\tilde{Z}_p$ can be rearranged to include the transfer function of the displacement as to the excitation, namely

$$\tilde{Z}_p = -\frac{1}{\jmath\omega}\frac{|\tilde{T}_{XF}|^{-1}}{A} \tag{5}$$

where A is the surface of the plate subjected to the excitation. Therefore, the STL is calculated as

$$STL = 10\log_{10}\frac{1}{|\tau|^2}\,[dB] \tag{6}$$

3 THE KDAMPER CONCEPT

The KDamper, which can be considered as an extension of the traditional Tuned Mass Damper (TMD), is a novel passive vibration isolation and damping concept, based essentially on the optimal combination of appropriate stiffness elements, including a negative stiffness element [1]. The KDamper supplements the inertial forces of the added TMD mass with the stiffness force of the negative stiffness element. This negative stiffness element can be realized by a number of ways such as pre-stressed disc (Belleville) springs, arranged in appropriate geometrical configurations [3]. Among others, this can provide significant comparative advantages, especially in the very low frequency range, such as better damping characteristics without the need of heavy additional masses.

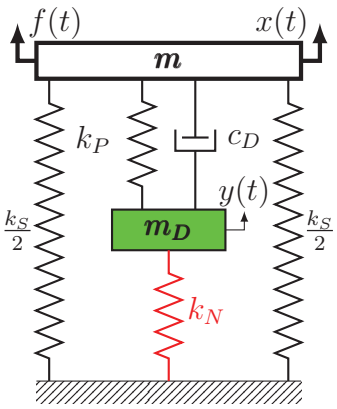

Figure 4: Schematic diagram of the KDamper oscillator.

The KDamper elements are calculated for a specific mass around a desired frequency f_0 or $\omega_0 = 2\pi f_0$ and the overall static stiffness comes as $k_0 = m\omega_0^2$, which also equals to

$$k_0 = \frac{k_P k_N}{k_P + k_N} + k_S \tag{7}$$

The overall static stiffness k_0 of the system is maintained.

Next, the basic parameters of the KDamper concept μ,κ and ρ, are defined as

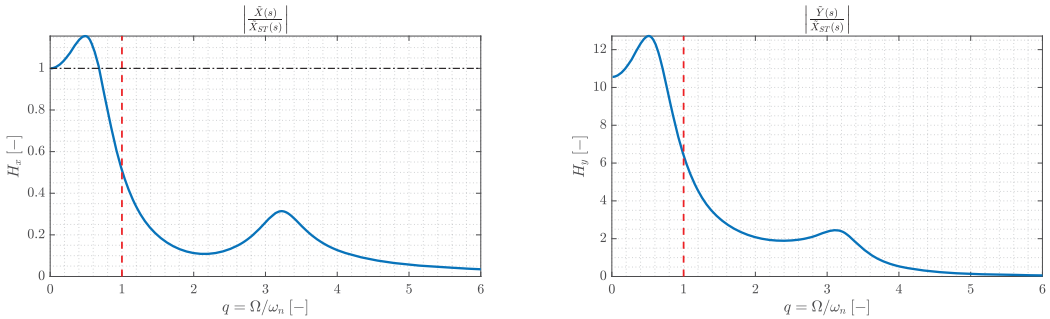
$$\mu = m_D/m \tag{8}$$
$$\rho = \omega_D/\omega_0 \tag{9}$$
$$\kappa = -k_N/(k_P + k_N) \tag{10}$$

Finally, the non-dimensional parameters of the stiffness elements of the KDamper are defined as

$$\kappa_S = \frac{k_S}{k_0} = 1 + \kappa(1+\kappa)\mu\rho^2 \tag{11}$$
$$\kappa_P = \frac{k_P}{k_0} = (1+\kappa)\mu\rho^2 \tag{12}$$
$$\kappa_N = \frac{k_N}{k_0} = -\kappa\mu\rho^2 \tag{13}$$

leading to the calculation of the stiffness elements (k_S, k_P, k_N) of the oscillator. Furthermore k_D is defined as $k_D = k_P + k_N$, thus, for a specific damping ratio ζ_D, the damping constant is calculated as:

$$c_D = 2\zeta_D\sqrt{k_D m_D} \tag{14}$$



(a) Frequency response of $|\tilde{T}_{XK}|$.

(b) Frequency response of $|\tilde{T}_{YK}|$.

Figure 5: Frequency response of of the transfer functions of the KDamper.

Figures 5a and 5b, present the frequency response of the transfer functions of the dynamic magnification factor for both degrees of freedom (DOFs) x and y of the KDamper respectively, for an indicative set of parameters $\mu,\ \kappa$ and ρ. More information regarding the design of the KDamper can be found in [16].

4 SOUND TRANSMISSION LOSS OF DEFORMABLE THIN PLATE

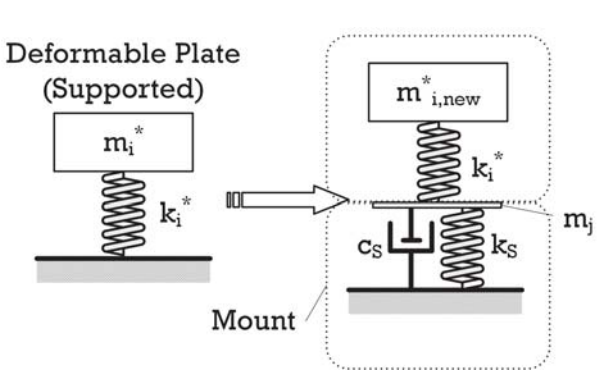
The investigation in this paper is an extension of previous work [17, 16]. However, a slightly different approach is taken here, where the thin plate is now considered as elastic/deformable instead of rigid as before. The goal is to examine how this property of the plate, participates in the dynamics of the system and consequently, the acoustic performance.

In order to do that, the assumption that the bending stiffness of the deformable plate is in a way in series with the stiffness of the mounting, is formulated. This assumption is also investigated through modal analysis and frequency response with FEM. This is achieved by utilizing the generalized values of the structure, namely generalized mass and the corresponding generalized stiffness for the appropriate modes, calculated from modal analysis and FEM simulations, in order to construct a corresponding single degree of freedom (SDOF) model representing the dynamic behavior of the deformable thin plate.

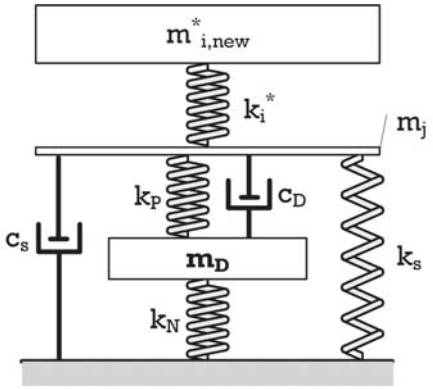
4.1 THEORETICAL FORMULATION

In this section the KDamper theoretical framework is extended to include the case where the rigid mass is replaced by a deformable plate. Figure 6a, shows the equivalent dynamic SDOF model of a deformable plate and the approximate modification when the plate is mounted on elastic mounts.

Figure 6b, shows the equivalent model when the simple elastic mount is replaced with an elastic mount based on the design of the KDamper.



(a) Deformable plate on elastic mounts with stiffness k_S.



(b) Implementation of the mounting based on the KDamper.

Figure 6: Modelling of a mounted deformable plate.

The equation of motion of the equivalent SDOF model is

$$m_i^* \ddot{u} + c_i^* \dot{u} + k_i^* u = f(t) \tag{15}$$

while in the case of the simple elastic mount becomes

$$m_{i,new}^* \ddot{u}_1 + k_i^* (u_1 - u_2) = f(t) \tag{16}$$

$$m_j \ddot{u}_2 + c_S \dot{u}_2 + k_S u_2 + k_i^* (u_2 - u_1) = 0 \tag{17}$$

where m_j is the connecting mass which is assumed as neglible in order to act just as a connector, namely an additional DOF and k_S is the stiffness of the elastic mount which needs to be calculated.

In the case of the KDamper elastic mount, the equation of motion in matrix formulation comes as

$$\mathbf{M}\, \vec{\ddot{u}}(t) + \mathbf{C}\, \vec{\dot{u}}(t) + \mathbf{K}\, \vec{u}(t) = \vec{F}\, f(t) \tag{18}$$

where the mass ($\mathbf{M}$), damping ($\mathbf{C}$) and stiffness ($\mathbf{K}$) matrices, come as

$$\mathbf{M} = \begin{bmatrix} m_i^* & 0 & 0 \\ 0 & m_j & 0 \\ 0 & 0 & m_D \end{bmatrix}, \ \mathbf{C} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & c_S + c_D & -c_D \\ 0 & -c_D & c_D \end{bmatrix}$$

$$\mathbf{K} = \begin{bmatrix} k_i^* & -k_i^* & 0 \\ -k_i^* & k_i^* + k_P' + k_S' & -k_P' \\ 0 & -k_P' & k_P' + k_N \end{bmatrix}, \ \mathbf{F} = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \tag{19}$$

At this point, it should be highlighted that the Dashpots ($\mathbf{c_s}$,$\mathbf{c_D}$) shown in Figure 6a denote schematically the systems' hysteretic damping and they should not be confused

with the parallel dashpots that are usually employed when viscosity is considered. The loss factor η, can represent more accurately the dynamic response of nonlinear systems compared with the damping ratio which is defined on the grounds of the linear single degree of freedom (SDOF) viscous model [10, 6].

Therefore, the damping matrix is empty $\mathbf{C} = \begin{bmatrix} 0 \end{bmatrix}$ $(\mathbf{c_s} = \mathbf{c_D} = 0)$ and the hysteretic damping is introduced indirectly in the stiffness matrix $\mathbf{K} = \begin{bmatrix} \ \end{bmatrix}$,

where

$$k'_S = k_S \left(1 + \jmath n\right) \tag{20}$$

$$k'_P = k_P \left(1 + \jmath n\right) \tag{21}$$

The transfer matrix relative to the excitation, for each frequency ω, is calculated from the following expression:

$$\mathbf{TRF} = (-\omega^2 \mathbf{M} + \mathbf{K})^{-1} \mathbf{F} \tag{22}$$

where

$$\mathbf{TRF} = \left\{ \frac{\tilde{u}_1}{\tilde{F}} \quad \frac{\tilde{u}_2}{\tilde{F}} \quad \frac{\tilde{u}_3}{\tilde{F}} \right\}^T \tag{23}$$

Finally, the transfer function of the deformable plate mounted on KDamper mounts, is taken as $T_{XF_{KD}} = \frac{\tilde{u}_1}{\tilde{F}}$.

4.2 OPTIMIZATION OF THE KDAMPER PARAMETERS

The aim is the selection of the optimal values for the KDamper elements, in order to obtain the maximum possible STL performance, especially in the resonance region of the system in comparison to the initial case where the plate is simply supported on its edges.

4.2.1 OPTIMIZATION ALGORITHM

For the optimization, the "$fmincon$" function of the MATLAB software for local minimization of non-linear functions and constraints, is utilized. The optimization algorithm is formulated as follows:

$$\min_{\mathbf{x}} f(\mathbf{x}) \; s.t. \begin{Bmatrix} c(x) \leq 0 \\ c_{eq}(x) = 0 \\ \mathbf{A}\,\mathbf{x} \leq b \\ \mathbf{A_{eq}}\,\mathbf{x} = b_{eq} \\ lb \leq \mathbf{x} \leq ub \end{Bmatrix} \tag{24}$$

where $\mathbf{x}$ is the vector containing the optimization variables and $f(\mathbf{x})$ is the objective function to be minimized. In this case the vector $\mathbf{x}$ is

$$\mathbf{x} = \begin{Bmatrix} k_N & k_P & k_S \end{Bmatrix}^T \tag{25}$$

Regarding the objective function, the algorithm maximizes the minimum value of the STL of the model in Fig. 6b, namely

$$f(\mathbf{x}) = -\min(STL_{KD}) \tag{26}$$

Initially, the only constraint to which the optimization is subjected has to do with the static stability margin of the KDamper, which is defined as

$$\epsilon = \frac{k_{N_{lim}} - k_N}{k_N} \tag{27}$$

where

$$k_{N_{lim}} = \frac{k_P k_S}{k_P + k_S} \tag{28}$$

and is set to have a minimum value of 10%.
Therefore, the optimization problem becomes

$$\min_{\mathbf{x}} f(\mathbf{x}) \; s.t. \begin{Bmatrix} 0.1 - \epsilon \leq 0 \\ lb \leq \mathbf{x} \leq ub \end{Bmatrix} \tag{29}$$

with the optimization variables between the lower bounds

$$\mathbf{lb} = \begin{Bmatrix} -1 \times 10^6 & 0 & 0 \end{Bmatrix}^T \tag{30}$$

and the upper bounds

$$\mathbf{ub} = \begin{Bmatrix} 0 & 15 \times 10^5 & 1 \times 10^7 \end{Bmatrix}^T \tag{31}$$

The starting point $\mathbf{x}_0$ of the algorithm, is selected such that the stiffness element k_S is of the same order of magnitude as the stiffness element k_i^* of the deformable plate model.

4.2.2 CASE EXAMINATION: RECTANGULAR DRYWALL

A $0.625 \times 1.6\ m$ rectangular drywall is considered, according to real-life masonry applications. The width corresponds to the horizontal distance between the upright supporting beams providing the stable frame of the drywall. Typically, the height of such a drywall is around $3.2\ m$, meaning that it can be covered by two pieces with the

Table 1: Drywall properties.

$\overline{m}\ [kg/m^2]$	$W\ [m]$	$H\ [m]$	$t\ [m]$	$m\ [kg]$	$E\ [MPa]$	ν
8.35	0.625	1.6	12.5×10^{-3}	8.35	2900	0.31

dimensions consider here. The selected dimensions correspond also to a frontal surface of $1\ m^2$. The relevant properties of the drywall are summarized in Table 1.

Modal analysis via the finite element method (FEM), assuming simply supported boundary conditions as in Fig. 7a, gives the following generalized values for the fundamental mode of the plate, shown in Fig. 7b:

$$f_1^* = 31.39\ [Hz] \quad m_1^* = 2.82\ [kg] \tag{32}$$

In case of a simply supported rectangular thin plate this frequency may also be estimated accurately by the theoretical expression

$$\omega_{mn} = \sqrt{\frac{D}{\rho t}}\Big[\Big(\frac{m\pi}{l_x}\Big)^2 + \Big(\frac{n\pi}{l_y}\Big)^2\Big] \tag{33}$$

for $m = n = 1$ which corresponds to the 1^{st} mode and

$$D = \frac{Et^3}{12(1-\nu^2)} \tag{34}$$

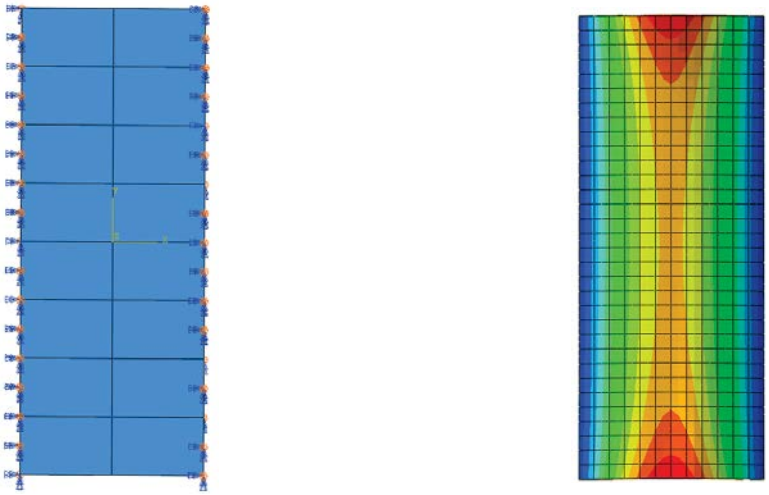
where D is the plate flexural rigidity, t is the plate thickness, E the Young's modulus and ν is Poisson's ratio. The corresponding generalized mass and stiffness [18] are defined as

$$m_{11}^* = m/4 \tag{35}$$

$$k_{11}^* = \frac{1}{4} l_x l_y D \pi^4 \Big(\frac{1}{l_x^2} + \frac{1}{l_y^2}\Big)^2 \tag{36}$$

Based on these values an equivalent generalized stiffness is calculated for the formulation of the corresponding SDOF model. Based on expression (36), it can be easily shown that the generalized stiffness is minimized when $l_x = l_y$, i.e for a square plate. However, as it will be shown hereinafter, acoustic performance is optimized when stiffness is maximized; in that terms the square plate constitutes the less attractive configuration .

Next, it is assumed that the plate will be supported on fifteen (15) elastic mounts in a configuration that essentially divides the plate into two equal parts of $0.3125\ m \times 1.6\ m$, as presented in Fig. 8a. Initially, this configuration as a simply supported plate



(a) Initial boundary conditions.

(b) Mode under consideration.

Figure 7: Simply supported drywall $0.625 \times 1.6\ m,\ A = 1\ m^2$.

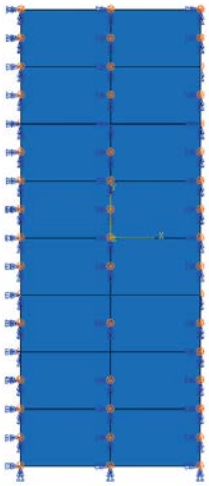
is considered, in order to obtain a more indicative set of generalized values for the following case of the mounted plate, which come as:

$$f_1^* = 196.92\ [Hz] \quad m_1^* = 1.91\ [kg] \tag{37}$$

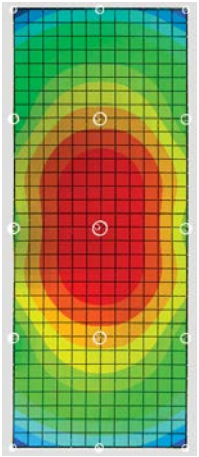
Using the objective function of Eq. (26), the algorithm searches for a solution in the frequency range $f_e = 1 : 1000\ Hz$. After the optimal set of parameters is calculated, the resulting stiffness k_S is divided into 15 springs and the FEM simulation is repeated in order to calculate the new generalized mass $m^*_{i,new}$. This procedure repeats a few times until there is a convergence of this value within a margin of error where any deviations become insignificant to the final results.

Then, for the generalized mass $m^*_{1,new}$ of the mounted plate, the corresponding element values of the KDamper come as in Table 2. The effect of the hysteretic behavior of KDamper is investigated parametrically for four (4) different loss factor η values and the results are illustrated in Fig. 9. The total loss factor η of a structure is the ratio of lost to reversible mechanical energy per radian cycle in a dynamic system. Nowadays, someone can easily find industrially produced rubber materials with specified loss factor values higher than $\eta = 0.4$ [12].

Figure 10, essentially compares the STL performance of the panel when utilizing elastic mounts - red-dashed line for simple elastic mounts and blue line for the optimized KDamper mounts - with the initial case as in Fig. 7, which is represented by the green line. Additionally, the mass law curve is represented for reference with the black-dashed line. When using elastic mounts the new generalized mass of the corresponding mode is higher, namely $m^*_{new} = 4.156\ kg$ compared to the initial $m^* = 2.819\ kg$. The same



(a) Mounting points for the elastic mounts.



(b) Mode under consideration.

mass m_{new}^* is also used for the mass law. Therefore, this fact alone is expected and it shows to improve the STL performance of the initial panel.

5 DISCUSSION

An increase in the loss factor, improves the acoustic performance of the panel at the design frequency and the uniformity of STL at the resonance frequency range. However, the design frequency shifts to lower values and at the same time, higher damping also translates to smaller oscillation amplitude for the added mass. Of course, arrangements with extraordinary high loss factors are not easily realized practically and that is something that has to be considered. For example, in this contribution the loss factor is selected η=0.2.

The resulting STL curves for the four cases are compared in Fig. 10. The STL curve of the ”mass law” (limp wall approximation) is presented as a reference for the performance in these cases. The obvious advantage of the proposed KDamper configuration is

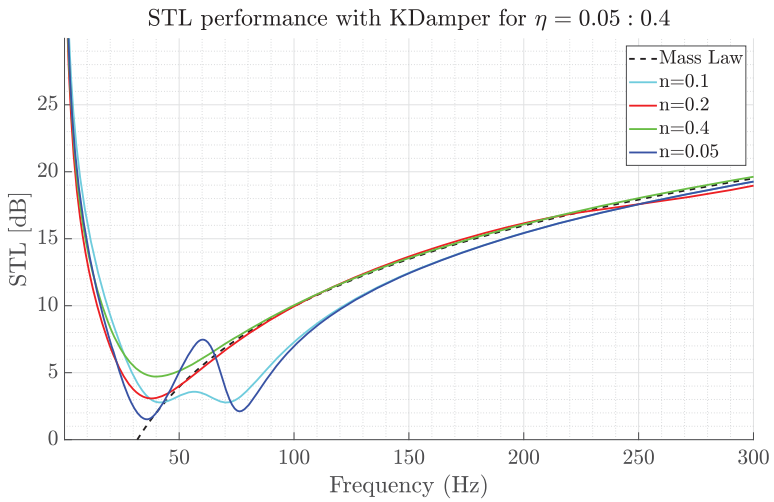

Figure 9: Resulting STL curves comparison with optimized $KDamper$ mount for different Loss factor η values.

the higher level of STL in the resonance region and the coincidence with the "mass law" curve for higher frequencies. On the other hand, the simple elastic mount configuration revealed little or no improvement in low frequencies compared with the simply supported panel, especially in the case of low damping but exhibited a similar behavior with the KDamper mounted panel for higher frequencies.

This impedance based approach for the calculation of the STL performance of a panel, demonstrates the viability and advantages of a KDamper based, mounted plate over conventional mounting mechanisms. The addition of the elastic mounts on a deformable plate, increases the generalized mass, therefore improves its acoustic performance. Compared to the simple elastic mounts, the KDamper provides an additional improvement in the resonance region. The main observation as shown in Fig. 6, is that the equivalent dynamic stiffness of the deformable plate and the stiffness of the mounting, operate approximately in series. Consequently, as it comes from the expression

$$k_{tot} = \frac{k_i^* k_S}{k_i^* + k_S} \tag{38}$$

the total stiffness of the model is restricted by the initial equivalent dynamic stiffness of the plate. An indicative graphical representation of Eq. (38), is shown in Fig. 11.

This implies that in order to utilize stiffer mounting -therefore increasing the eigenfrequency of the model where the total STL level is higher and the effect of the KDamper is more prevalent- requires a stiffer plate. To achieve that, either the mounting has to be more dense, namely dividing the plate into smaller "pieces" or the material of the

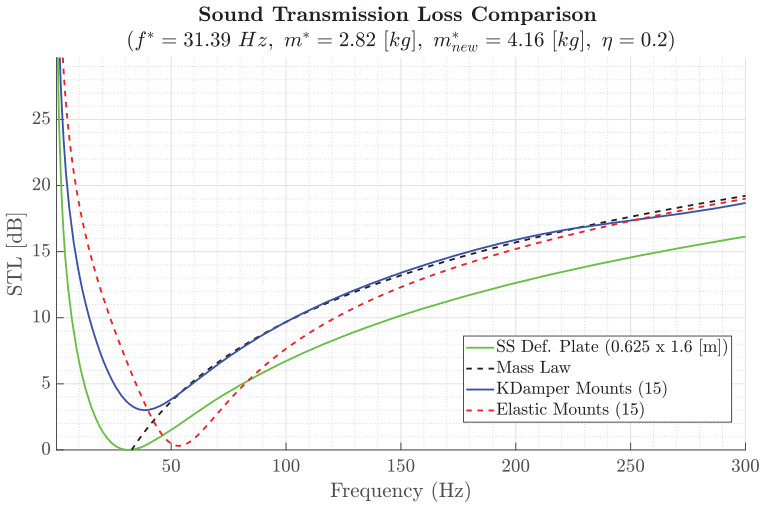

Figure 10: Comparison of the resulting STL curves with the optimized KDamper mount.

plate itself has to have higher Young's Modulus, thus higher bending stiffness D, or/and higher mass per unit surface.

6 CONCLUSIONS

A novel mount for acoustic panels was presented based on the KDamper concept, incorporating a negative stiffness element. The application of the mount in flexible panels was investigated based on analytical formulas and an equivalent "KDamper-Flexible panel model" was developed, to approximate more accurately the acoustic performance of the configuration compared to the "rigid mass" approach. The optimization algorithm of the system's parameters was described and an iterative procedure was followed to define the optimized set of parameters aiming to maximize the STL.

Then, a real-case scenario of a $0.625 \times 1.6\ m$ rectangular drywall was studied, comprising the reference arrangement for all the subsequent comparisons. The hysteretic behavior of the mount was examined for a range of loss factor (η) values, which control the design frequency, revealing the importance of a suitable rubber material to the system's performance. Finally, the superiority of the KDamper mounts was shown by comparison with the Simply-Supported panel and the simple elastic mounts. In case of the elastic supports an increase was observed at oscillating panel effective mass, resulting to an improved sound attenuation. The KDamper mounts proved advantageous compared with the simple elastic mounts improving at least four (4)dB the STL curve in the low frequency region. To the authors knowledge this improvement has not been observed in any other product being available on the market. Additionally, it was observed that the equivalent dynamic stiffness of the panel and the stiffness of the mounting, operate approximately in series. Hence, the total stiffness of the model is bounded by the

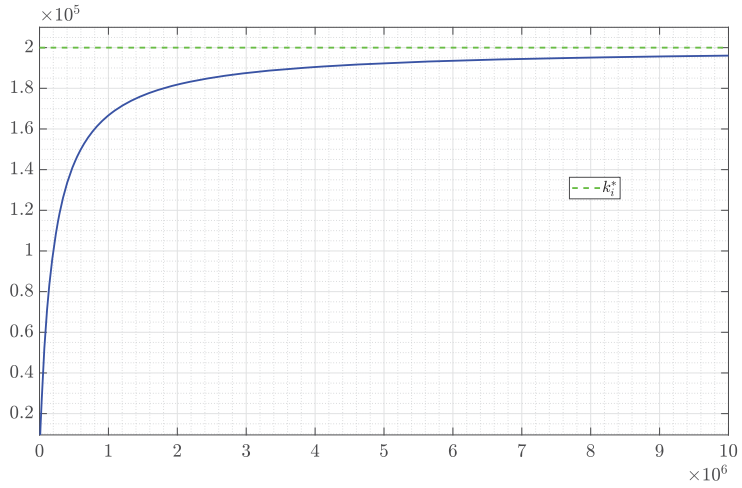

Figure 11: Springs in series configuration.

initial equivalent dynamic stiffness of the panel.

It should be noted that the approach followed in this paper, considers an equivalent mount-flexible panel model where the total system stiffness is calculated by applying a heuristic approach. Therefore, a topic for future work, is the calculation of the STL via a full numerical coupled structural-acoustic FE model and validate the performance experimentally.

Keywords: Vibration isolation, KDamper, Low frequency, Negative Stiffness.

Abstract. *The advantages of the negative stiffness damping effect for vibration absorption in very low frequencies (below 10 Hz) are utilized in this implementation in the form of a mounting mechanism based on the KDamper concept. Specifically, the mount is designed for the absorption of vertical vibrations for machines with mass in the order of 100 kg and rotational speeds in the area of 500 RPM. The design consists in the selection of the appropriate stiffness elements according to the KDamper concept, optimized for minimizing the displacement amplitude of the seismic mass. The included negative stiffness element is realized via a simple configuration of pre-stressed disc (Belleville) springs. Initial experimental measurements of an early prototype are used for comparison with the theoretical investigation and evaluation of the absorption capacity of the mounting mechanism. The results are compared with the predictions of the corresponding models. At the same time, the effects of the non-linear nature of the negative stiffness element are documented, among certain constraints and conditions required for the optimal operation of the system. This examination is demonstrated through the frequency response of the non-linear system using the theoretical models and experimental setup, its potential advantages compared to conventional elastic mounts.*

1 INTRODUCTION

Regarding vibration isolation with conventional elastic mounting, generally in the case of systems subjected to periodic excitation the resonant frequency has to be lowered by adjusting the stiffness of the mounting. Consequently, the frequency of the excitation falls in the isolation range. However, especially in cases where the excitation frequency is already very low, this could mean that the stiffness has to be decreased so much that it compromises the structural integrity of the system. Very low stiffness could also translate to prohibitive amplitude values of the response, especially since high damping ratios are not always easily achievable in a lot of cases.

For this reason, several different concepts have been proposed and implemented over the years, encountering the difficulties in low frequency vibration isolation. Some examples are the general concept of the Tuned Mass Damper (TMD), quasi-zero stiffness oscillators, the inerter and other concepts and variations of the aforementioned.

The design of a mounting mechanism for the absorption of vertical vibrations of rotating machines and all kinds of critical configurations, is examined in this paper. The seismic mass is considered to be 100 kg and the rotational speed around 500 RPM. This mount is based on the KDamper concept [1, 2], the schematic diagram of which is presented in Fig. 1.a.

The KDamper, which can be considered as an extension of the traditional Tuned Mass Damper (TMD), is a novel passive vibration isolation and damping concept, based essentially on the optimal combination of appropriate stiffness elements, including a negative stiffness element [1]. The KDamper supplements the inertial forces of the added TMD mass with the stiffness force of the negative stiffness element. This negative stiffness element can be realized by a number of ways such as pre-stressed disc (Belleville) springs, arranged in appropriate geometrical configurations [3]. Among others, this can provide significant comparative advantages, especially in the very low frequency range, such as better damping characteristics without the need of heavy additional masses and without sacrificing the static loading capacity of the structure by using very soft elastic mounting.

The KDamper elements are calculated for a specific mass around a desired frequency f_0 or $\omega_0 = 2\pi f_0$ and the overall static stiffness comes as $k_0 = m\omega_0^2$, which also equals to

$$k_0 = \frac{k_P k_N}{k_P + k_N} + k_S \tag{1}$$

The overall static stiffness k_0 of the system is maintained.

Next, the basic parameters of the KDamper concept μ,κ and ρ, are defined as

$$\mu = m_D/m \tag{2}$$
$$\rho = \omega_D/\omega_0$$
$$\kappa = -k_N/(k_P + k_N)$$

Finally, the non-dimensional parameters of the stiffness elements of the KDamper are defined as

$$\kappa_S = \frac{k_S}{k_0} = 1 + \kappa(1+\kappa)\mu\rho^2 \tag{3}$$
$$\kappa_P = \frac{k_P}{k_0} = (1+\kappa)\mu\rho^2$$
$$\kappa_N = \frac{k_N}{k_0} = -\kappa\mu\rho^2$$

leading to the calculation of the stiffness elements (k_S, k_P, k_N) of the oscillator. Furthermore k_D is defined as $k_D = k_P + k_N$, thus, for a specific damping ratio ζ_D, the damping constant is calculated as:

$$c_D = 2\zeta_D\sqrt{k_D m_D} \tag{4}$$

Figure 1 presents the schematic diagrams of the classic "m-c-k" and "TMD" oscillators along with the KDamper. For a direct comparison between the three concepts, it is appropriate to consider the same static stiffness k_0 for all. However for the TMD is taken that $f_{D,TMD} = f_{0,mck} = f_{0,KD}$. This modification makes the static stiffness of the TMD slightly higher and the reason for this is to exploit the anti-resonance nature of the oscillator. As for the stiffness elements, it is considered that $k_{S,TMD} = \omega_0^2 m_D$ and $k_{P,TMD} = \omega_D^2 m_D$.

The frequency response of the transfer functions for the three oscillators are compared in Fig.2. For a harmonic excitation, the KDamper minimizes the amplitude of the response $x(t)$ in a frequency band defined by the selection of its individual parameters, much more effectively than the TMD for a broader range of frequencies while utilizing much lighter added mass. The depth of the narrow band where the transfer functions of the TMD drop, is proportionate to its added mass and inversely proportionate to the damping element c_D, but of course c_D cannot be too low due to practical amplitude constraints of the internal mass.

2 EXPERIMENTAL IMPLEMENTATION OF KDAMPER

For this particular implementation, a conservative approach is taken, meaning that parameter κ is taken as just 45% of κ_{max} in order to ensure a static stability margin ϵ above 10%.

2.1 NEGATIVE STIFFNESS ELEMENT REALIZATION

There are various structural configurations by which negative stiffness can be achieved, using either post-buckled beams or shells, pre-stressed spring configurations and many others [5]. In this implementation, the negative stiffness element of the oscillator is realized utilizing disc (Belleville) springs. The exerted force and the equivalent stiffness of this type of springs, are non-linear functions of the vertical displacement s of the inner diameter D_i. The height of the spring is denoted by l_0, D_e is the external diameter and $h_0 \approx l_0 - t$, where t is the thickness. The relevant notation is demonstrated in Fig. 4. More specific information about disc springs are provided by manufacturers [4]. Specifically, for the calculation of the exerted force of an individual spring as function

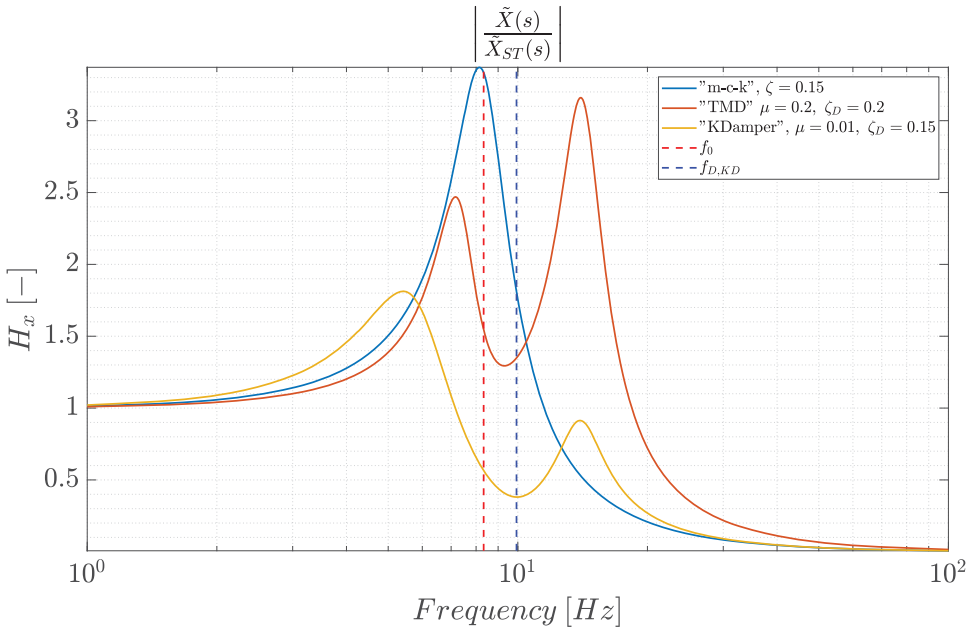

Figure 2: Magnification factor comparison of the three oscillators.

of the deformation s holds:

$$F(s) = F_c\Big[K_4^2\Big(\frac{h_0}{t} - \frac{s}{t}\Big)\Big(\frac{h_0}{t} - \frac{s}{2t}\Big) + 1\Big]s \tag{5}$$

where $F_c = F(s = h_0)$ is the exerted force when the disc is at its flattened position and is estimated as

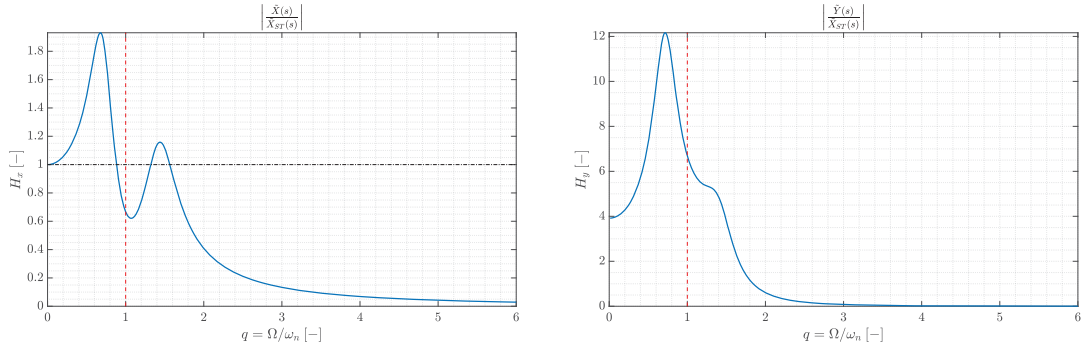
$$F_c = \frac{4E}{1-\nu^2}\frac{t^3 h_0}{K_1 D_e^2}K_4^2 \tag{6}$$

By setting $\delta = D_e/D_i$ as the ratio of outer to inner diameter of the disc, parameters K_1 is defined as

$$K_1 = \frac{1}{\pi}\frac{\Big(\frac{\delta-1}{\delta}\Big)^2}{\frac{\delta+1}{\delta-1} - \frac{2}{ln(\delta)}} \tag{7}$$

while parameter K_4 depends on the type of the contact surfaces of the disc spring. In this particular case where $t < 1.25\ mm$, no contact surfaces (rounded edges) or reduced thickness are taken into account which corresponds to $K_4 = 1$.

Standard disc springs dimensioned in accordance with DIN 2093, have ratios of h_0/t up to 1.3. However, in order for such a disc to demonstrate negative stiffness behaviour, this ratio needs to be $h_0/t > \sqrt{2}$. Disc springs with a ratio above this value are categorized as non-standard. Furthermore, for $h_0/t > \sqrt{8}$ the disc becomes a bistable element, meaning that in a certain range of deformation s (snap-through region), the exerted force becomes negative, thus these type of discs may act as switch elements.



(a) Frequency response of $|\tilde{T}_{XK}|$. (b) Frequency response of $|\tilde{T}_{YK}|$.

Figure 3: Frequency response of the KDamper transfer functions.

On the other hand it has to be taken into account that as this ratio increases, considering all other parameters constant, the force F_c increases too and the developing stresses are getting higher. This fact would be problematic, especially for cyclic operation as in this case, due to low fatigue strength.

The range of the vertical displacement s where the disc exhibits the desired negative stiffness characteristics, is centred around the flat position of the disc where the exerted force is F_c and the negative stiffness value is at its maximum. This of course, translates to the application of a certain pre-stress condition on the spring, so that its stiffness falls in the negative stiffness region, at the equilibrium state of the oscillator.

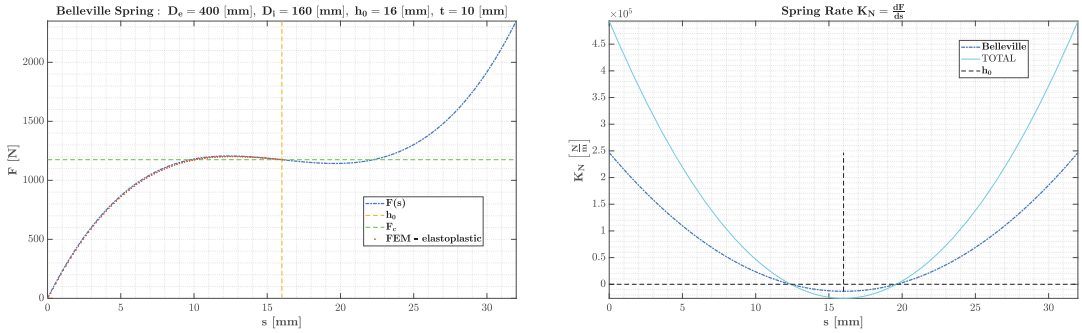
Figure 5.a shows the resulting Force - Displacement curve for the selected disc spring, while Fig. 5.b demonstrates the equivalent stiffness of the spring as a function of the vertical displacement s. The dotted black line, indicates the zero value of k_N namely the threshold of negative stiffness. In order to achieve the required negative stiffness value, a total number of two such disc springs have to be configured in parallel. The resultingstiffness in this case is demonstrated in Fig. 5.b in comparison with the single spring curve.



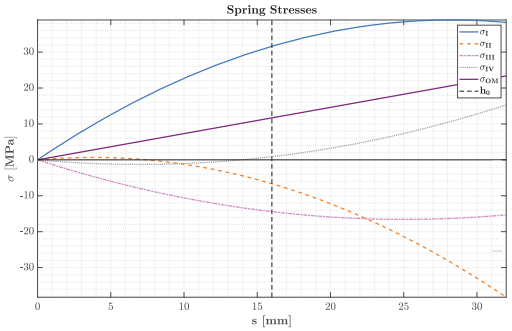
(a) Force-deformation curve of disc spring. Comparison with FEM simulation.

(b) Equivalent stiffness of the disc spring and of the parallel configuration.

Figure 5: Force-Displacement curves of "Belleville" disc springs.

Another aspect to be considered, concerns the generated stresses of the disc spring. Figure 6.a, shows the stresses as function of deformation s, at the five characteristic points of the spring. According to manufacturers, depending on the application, the value of the resulting stress σ_{OM} must be between certain limits to ensure smooth, as intended operation. Especially in dynamic applications this stress defines a nominal number of cycles of operation for the disc spring provided via endurance and fatigue strength diagrams.

Furthermore, due to the unstable nature of negative stiffness, once the pre-stressed flattened disc are attached inside the rest of the configuration, the exerted forces will produce deformation of the k_P stiffness element and consequently the k_S element leading to displacement of the internal and seismic mass up to a static equilibrium position.



(a) Stresses during deformation of the disc spring.

(b) Disc springs in parallel configuration.

Figure 6: Stress development of the disc springs, and the configuration for the NSE.

2.2 ANALYTIC INVESTIGATION

In order to perform an initial evaluation of the performance of the system, two analytical models were formulated. The first, linear model, considers the value of the NSE k_N to be constant, as calculated by the initial dimensioning from the KDamper design. Utilizing this model, the transfer functions of the oscillator may be calculated along with indicative time response of the x and y DOFs and other important variables. This is important in order to have a frame of reference by which the non-linear response of the second model is evaluated and to calculate the expected order of magnitude of displacement, especially regarding the internal mass. The aforementioned second non-linear model considers the time-varying nature of the NSE, by incorporating the corresponding equations of the disc springs.

Considering a harmonic excitation of the form

$$F(t) = \tilde{F}e^{\jmath\Omega t} = \hat{F}e^{\jmath\Omega t} \tag{8}$$

where the amplitude of the force is taken as

$$\hat{F} = k_0 X_{ST} \tag{9}$$

which for $X_{ST} = 0.1\ mm$ results to $\hat{F} = 27.4\ N$.

As observed in Fig. 8.a, the response x of the initial mass and y of the internal mass of the non-linear model to a harmonic excitation of frequency $\Omega = \omega_0$, show negligible deviations from the linear response, both in phase and amplitude.

Figure 9.a shows the velocity response of both degrees of freedom x and y of the non-linear model, while Fig. 9.b shows the corresponding accelerations.

This velocity response can be used for direct comparison with the experimental measurements.

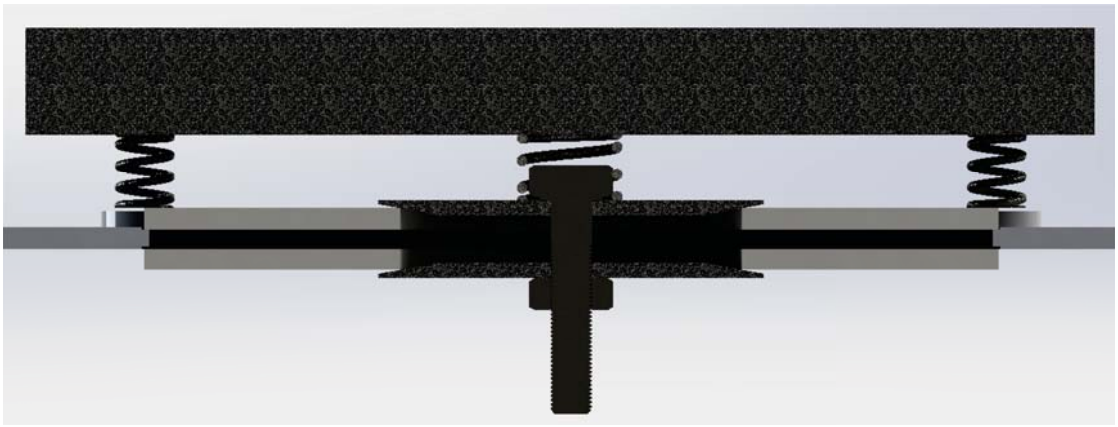


Figure 7: Design of the practical implementation of the mount. Cross section of front view.

3 EXPERIMENTAL TEST

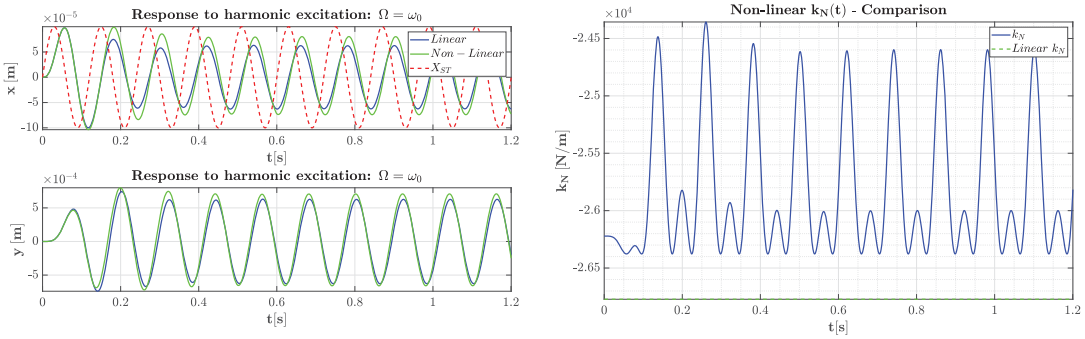
A first prototype of the design presented thus far was structured and a preliminary run of experimental tests was performed in order to validate the analytical results and calculations. It should be noted that at that preliminary stage, no damping elements were added to the configuration, therefore the only dissipative mechanisms during these first tests were the structural damping of the various elements along with any frictional effects.

Figure 10.a presents the shape of the base acting as the ground where the disc springs of the NSE are positioned. This picture also shows the lower half of the NSE, namely the lower disc spring with its corresponding conical force-applying element and the screw via which the equivalent top part is later tied together. The surrounding helical springs implementing the k_S stiffness element of the KDamper can also be seen, positioned in the four corners around appropriate guides for the oscillating seismic mass in order to ensure proper vertical oscillation and avoid any slipping.

Figure 10.b shows the completed setup with the seismic mass on top, the NSE in its appropriate pre-stressed state where the disc springs are flat and the helical spring representing the k_P stiffness element of the KDamper, in between. The guide shown on the side, connects the exciter with the seismic mass in order to provide the necessary excitation for the tests.

Initially, the system is subjected to an impulse excitation, in an attempt to evaluate the eigenfrequency of the system along with its damping capacity. The measurements were undertaken by using appropriately positioned laser velocimeters. The response of the seismic mass, representing the x DOF of the KDamper, is presented in Fig. 11 along with the corresponding double-sided frequency spectrum $P_2(f)$.

The response of the internal mass, representing the y DOF of the KDamper, is pre-



(a) Response of x and y to harmonic excitation with $\Omega = \omega_0$.

(b) Corresponding stiffness value response of the NSE.

Figure 8: Linear and non-linear models time response comparison to harmonic excitation.

sented in Fig. 12 along with the corresponding double-sided frequency spectrum $P_2(f)$. The spectra of these measurements show clearly a peak very close to the theoretical design frequency of $500RPM \approx 8.33\ [Hz]$. Specifically the response of the seismic mass shows the eigenfrequency of the system at $f = 8.582\ [Hz]$, while the response of the internal mass positions the eigenfrequency $f = 8.772\ [Hz]$, variations well within the margin of error.

Next, a frequency sweep was gradually applied, namely a harmonic excitation with varying frequency up to $50\ [Hz]$, in order to acquire a frequency response of the two DOFs for comparison with the theoretically estimated transfer functions.

The shape of the two spectra present some resemblance to the expected behavior, compared to Figs. 3.a and 3.b. The analytical model provides the two eigenfrequencies of the KDamper as $f_1 = 6.08\ [Hz]$ and $f_2 = 12.07\ [Hz]$ which appear to be comparable to the corresponding peaks of the measurements. Furthermore, the expected dip in amplitude is observable between these two frequencies. However, without exact knowledge of the excitation amplitude at each frequency, it is not possible to evaluate with any degree of certainty the level of isolation achieved by the system. For the same reason, it is difficult to extract definitive conclusions for the amplitude of the velocity response by comparing them to the theoretically calculated ones.

4 CONCLUSIONS

A machine mounting mechanism was designed based on the concept of the KDamper, for vertical vibration absorption of a 100 kg seismic mass at a frequency of interest approximately $8.33\ [Hz]$. Appropriate analytical models were formulated, simulating the expected performance of the mount and to be used for comparison with future experimental measurements. A first experimental setup has been constructed based on the

above design and a preliminary set of measurements was undertaken in order to validate the projections of the theoretical analysis. However, various technical difficulties and the limited number of tests performed at this initial stage, cannot provide definitive conclusions as to the performance of the setup, although some values were verified, including some basic frequencies of the system.

The experimental setup is currently being updated and further tests will be performed in the near future to provide a clearer picture. Necessary future steps include the addition of either viscous or elastomeric damping elements in the appropriate positions of the system, along with more precise and targeted measurements.

Abstract. *Elastic metamaterials enable to generate phononic band gaps below the Bragg limit. Most metamaterials in the literature are based on vibration absorption (local resonance) principle. In this study, a two dimensional elastic metamaterial is designed, which utilizes inertial amplification principle. This principle allows generating wide band gaps at low frequencies. Firstly, the theory of phononic gaps induced by inertial amplification in finite structures is discussed briefly utilizing a lumped parameter model. Afterwards, a compliant inertial amplification mechanism is introduced, which is the building block of the metamaterial designed in this paper. Topology optimization is performed on this mechanism to obtain a wide vibration stop band for a given mass constraint. Then, vibration transmissibilities of one dimensional finite periodic structures with various number of unit cells are presented. Subsequently, a two dimensional metamaterial is constructed by incorporating the topologically optimized compliant inertial amplification mechanisms. Finally, in-plane vibration isolation performance of this two dimensional system is demonstrated via vibration transmissibility plots.*

1 INTRODUCTION

Periodic structures are extensively studied for almost three decades since they can mitigate vibration transmission and can act as passive vibration isolation systems. Periodic structures which can inhibit wave propagation by generating phononic band gaps are generally known as phononic crystals. If band gaps can be generated below the Bragg limit then these structures are called elastic metamaterials. In the literature, there exist three methods to create band gaps (stop bands): Bragg scattering [1, 2], resonance scattering (local resonances) [3, 4], inertial amplification [5–7]. In Bragg scattering, stop band is created via employment of periodically varying mass and stiffness elements in the structure. However, in order to obtain band gaps at low frequency region, low stiffness and large mass elements are required. In resonance scattering (local resonances), periodic local resonators are added to the structure. Nevertheless, to have band gaps at low frequencies, one has to utilize large local resonators. In inertial amplification, displacement amplification mechanisms are employed to create inertial coupling induced vibration stop bands. In this method, effective dynamic inertia of the system is increased, thus low frequency band gaps can be attained without decreasing stiffness or increasing total mass of the structure.

Elastic metamaterials are formed by periodic inclusion of the smallest repeating constructive elements called unit cells. Unit cell design is quite important, since it determines the vibration stop band limits, i.e., vibration isolation frequency range. Hence, in order to obtain the widest possible stop band, structural optimization should be considered when designing a unit cell. To that end, topology optimization will be a proper choice since it determines optimum topology, shape and size of a structure simultaneously. On the other hand, vibration isolation level achieved with an elastic metamaterial depends on the number of unit cells used in the periodic structure. As the number of unit cells employed increases, vibration transmission through metamaterial decreases, hence vibration isolation performance increases.

In this paper, a two dimensional broadband elastic metamaterial is proposed to inhibit in-plane low frequency vibration transmission for a wide frequency range. The elastic metamaterial is constructed via incorporating topologically optimized compliant inertial amplification mechanisms (unit cell) in hexagonal form. Vibration transmissibility plots for several periodic designs are calculated and satisfactory levels of vibration isolation performances are demonstrated.

2 THEORY

2.1 Inertial Amplification

Inertial amplification [5, 6] is a phononic band gap generation method, in which broadband phononic band gaps can be attained at low frequency regions without decreasing stiffness or increasing mass of the structure. In order to show the effectiveness of the method, a lumped parameter inertial amplification mechanism model is provided in Fig. 1. In this model, the two masses denoted as m are connected with each other with an elastic spring which has stiffness k. On the other hand, the masses m and the mass m_a are connected with massless rigid rods. The mechanism has an isosceles triangle configuration, i.e., the angle between the rigid rods and the spring is θ. For this lumped parameter model, the input displacement is provided from the left side as y and the output is taken from the right side as x. Besides, the horizontal and the vertical displacements of the mass m_a are provided in terms of the input (y) and the output (x) displacements as $(x + y)/2$ and $(y - x)\cot(\theta)/2$, respectively.

The equation of motion of the lumped parameter inertial amplification mechanism shown in

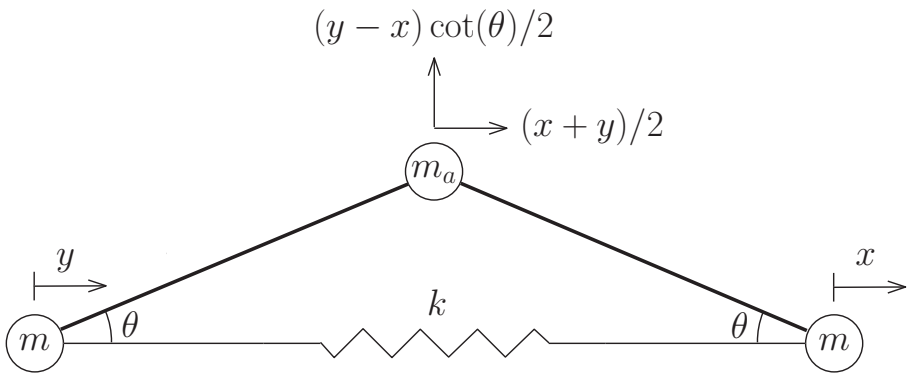

Figure 1: Lumped parameter inertial amplification mechanism.

Fig. 1 can be obtained by employing the Lagrange method as [8, 9]:

$$\left[m_a(\cot^2\theta+1)/4+m\right]\ddot{x}+kx=\left[m_a(\cot^2\theta-1)/4\right]\ddot{y}+ky \tag{1}$$

Equating the right hand side of Eq. 1 to zero and solving the resulting ordinary differential equation for the output x, one can find the resonance frequency as:

$$\omega_p=\sqrt{\frac{k}{m_a(\cot^2\theta+1)/4+m}} \tag{2}$$

Similarly, when one equates the left hand side of Eq. 1 to zero and solves for the input y, the antiresonace frequency can be found as:

$$\omega_z=\sqrt{\frac{k}{m_a(\cot^2\theta-1)/4}} \tag{3}$$

As can be seen from Fig. 1, the total mass of the structure (static mass) is:

$$m_s=2m+m_a \tag{4}$$

On the other hand, Eq. 2 can be rewritten as:

$$\omega_p=\sqrt{\frac{k}{m_d}} \tag{5}$$

Therefore, one can calculate the effective dynamic mass of the structure from Eq. 2 and Eq. 5 as:

$$m_d=\frac{4m+m_a(\cot\theta^2+1)}{4} \tag{6}$$

Similarly, antiresonance frequency can be redefined in terms of k, m_s and m_d as:

$$\omega_z=\sqrt{\frac{k}{m_d-m_s/2}} \tag{7}$$

The lumped parameter inertial amplification mechanism presented in Fig. 1 is a single degree of freedom low pass filter type vibration isolator. Hence, its displacement transmissibility for a given excitation frequency ω can be calculated as [8, 9]:

$$TR(\omega) = \frac{|x(\omega)|}{|y(\omega)|} = \frac{|1 - (\omega/\omega_z)^2|}{|1 - (\omega/\omega_p)^2|} \tag{8}$$

Vibration stop band is defined for the frequencies where transmissibility value obtained in Eq. 8 is less than 1 [8, 10]. Consequently, stop band starting frequency (ω_s) can be found by solving the expression below:

$$TR(\omega_s) = \frac{|x(\omega_s)|}{|y(\omega_s)|} = \frac{|1 - (\omega_s/\omega_z)^2|}{|1 - (\omega_s/\omega_p)^2|} = 1 \tag{9}$$

Solving Eq. 9 for ω_s, one can find the stop band starting frequency as:

$$\omega_s = \sqrt{\frac{2\omega_p^2\omega_z^2}{(\omega_p^2 + \omega_z^2)}} \tag{10}$$

Now, consider a situation in which angle θ is small. For small θ values, $\cot\theta^2$ term in the denominator of Eq. 6 becomes quite large. As a result, the effective dynamic mass of the lumped parameter inertial amplification mechanism becomes quite large. As the dynamic mass of the structure increases, the resonance and the antiresonance frequencies decrease to lower frequency region. Finally, following Eq. 10, the stop band starting frequency decrease, as well.

In order to give a clear view on the inertial amplification concept, a simple numerical example can be considered. Suppose that all masses are 1 kg, spring stiffness value is 1 N/m and consider a small θ value of 10° ($\pi/18$ rad). Then, static mass (m_s) of the model becomes 3 kg and effective dynamic mass (m_d) of the structure becomes 9.29 kg. Hence, the effective inertia of the system increases more than 3 fold. If the whole 3 kg mass was on the right side of the spring and there wasn't any amplification mechanism, the resonance frequency would be 0.577 rad/s and stop band would start at $\sqrt{2} \times 0.577 = 0.816$ rad/s. For the system with inertial amplification mechanism, the resonance and antiresonance frequencies are calculated as 0.328 rad/s and 0.358 rad/s, respectively. Hence, the stop band starts at 0.342 rad/s, which is less than half of 0.816 rad/s. As this simple example demonstrates, by employing inertial amplification method, one can obtain a vibration stop band at low frequency regions without sacrificing stiffness or increasing total mass of the structure.

2.2 Topology Optimization

Topology optimization [11] is a structural optimization method, in which optimum material layout is sought to obtain a structure that satisfies a certain mechanical performance in a given finite element design space. In the literature, there exist several topology optimization methods [12]. However, in this study, widely utilized modified solid isotropic material with penalization (modified-SIMP) [13] is employed. In this method, an individual finite element's stiffness value is defined as:

$$E_e(x_e) = E_{min} + x_e^p(E_0 - E_{min}) \qquad x_e \in [0, 1] \tag{11}$$

where x_e denotes the element's density which can take any value between 0 and 1, E_e denotes element's elastic modulus, E_{min} denotes a small elastic modulus value to prevent stiffness ma-

trix singularity, E_0 denotes the elastic modulus of the material, p denotes the penalization factor for stiffness.

Similarly, an individual element's physical density value can also be defined as [14]:

$$\rho_e(x_e) = \begin{cases} \rho_{min} + x_e(\rho_0 - \rho_{min}) & \text{if } x_e > 0.1 \\ \rho_{min} + x_e^d(\rho_0 - \rho_{min}) & \text{if } x_e \leq 0.1 \end{cases} \tag{12}$$

where x_e is the density of element e, ρ_e is the physical density of element e, ρ_{min} is a small density value to prevent mass matrix singularity, ρ_0 is the physical density of the material, d is the penalization factor for mass.

Using Eq. 11, global stiffness matrix $\boldsymbol{K}$ is defined as:

$$\boldsymbol{K} = \sum_{e=1}^{N} E_e(x_e)\boldsymbol{K_0} \tag{13}$$

where $\boldsymbol{K_0}$ is the stiffness matrix of an element that has unit elastic modulus and N is the total number of finite elements in the design domain. Here, the summation notation indicates the usual finite element notation to form global matrices from local matrices.

Similarly, using Eq. 12, global mass matrix $\boldsymbol{M}$ is defined as:

$$\boldsymbol{M} = \sum_{e=1}^{N} \rho_e(x_e)\boldsymbol{M_0} \tag{14}$$

where $\boldsymbol{M_0}$ is the mass matrix of an element that has unit density.

Moreover, the material volume is defined as:

$$V(\boldsymbol{x}) = \sum_{e=1}^{N} x_e \tag{15}$$

In this study, the objective of the topology optimization problem is maximization of the band gap width for a given mass constraint. For that purpose, $-\omega_2/\omega_1$ ratio is minimized, where ω_1 and ω_2 are the first two natural frequencies of the unit cell mechanism and the band gap resides between these frequencies. Hence, the topology optimization problem is given as [15]:

$$\begin{aligned} \text{min.}_{\ \boldsymbol{x}} \quad & f(\boldsymbol{x}) = -\frac{\omega_2(\boldsymbol{x})}{\omega_1(\boldsymbol{x})} \\ \text{s.t.} \quad & \boldsymbol{K u_1} = \omega_1^2 \boldsymbol{M u_1} \\ & \boldsymbol{K u_2} = \omega_2^2 \boldsymbol{M u_2} \\ & V(\boldsymbol{x}) = aV_0 \\ & 0 \leq x_e \leq 1 \qquad \text{for } e = 1, 2, ..., N \end{aligned} \tag{16}$$

where V_0 denotes the total design space area, a denotes the volume fraction defined as the ratio of solid area over total area, u_1 and u_2 are the eigenvectors for the 1st and the 2nd modes, respectively.

The topology optimization problem presented in Eq. 16 can be solved via optimality criteria (OC) [15, 16] method.

In a topology optimization problem, if an individual element's density value (i.e., x_e) is 0, then no material exists in that element. On the contrary, if an element's density value is 1, then it means that element is solid. At the end of the optimization process, the aim is to obtain a solid-void (1-0) type of design, which can be achieved via employing a sensitivity [17] and a post processing filter [18].

3 RESULTS

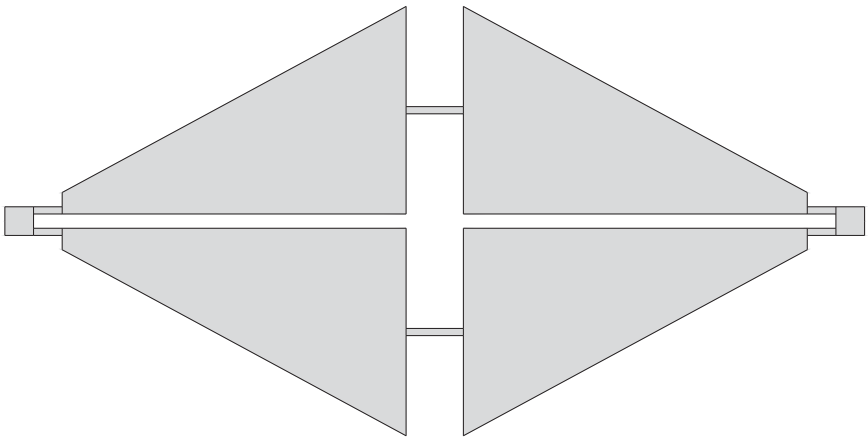
Topology optimization is conducted on the compliant inertial amplification mechanism shown in Fig. 2. The horizontal length of the mechanism is 120 mm, whereas the vertical length is 60 mm. The small square blocks that are found at the rightmost and leftmost ends have 4 mm by 4 mm dimensions. Four small flexure hinges that connect small square blocks and large triangular amplifier blocks have 4 mm horizontal and 1 mm vertical dimensions. Two long flexure hinges that reside at the center of the mechanism and connect large triangular amplifier blocks to each other have 8 mm horizontal and 1 mm vertical dimensions. Each of the large triangular amplifier blocks have 48 mm horizontal length and 29 mm vertical length. Two long flexure hinges at the center of the mechanism are connected at the middle to the large triangular blocks. Moreover, the slope of the hypotenuse of the triangular blocks is determined as 28° (0.489 rad), a value that prevents contact when a two dimensional periodic structure is constructed in hexagonal incorporation of compliant mechanisms with 60° ($\pi/3$ rad) angles. Finally, the isotropic material of construction is steel with elastic modulus $E_0 = 210$ GPa, density $\rho = 7800$ kg/m^3 and Poisson's ratio $\nu = 0.3$.

Topology optimization is performed on the compliant inertial amplification mechanism to obtain wide vibration stop bands for a given mass constraint. To that end, the topology optimization problem given in Eq. 16 is solved in the design space provided in Fig. 3 for roller-roller boundary conditions. Topology optimization is performed on the grey parts of the mechanism. Whereas, black solid parts of the mechanism are exempted of the optimization process, i.e., for the black solid parts element density value is fixed to 1 and can not be altered. In order to maintain the structural integrity [15] during the optimization process, a diagonal stair type solid framework, which is also exempted of the optimization routine, is utilized. According to the numerical studies performed, a volume fraction value of $a = 0.35$ is selected, since it is the optimum volume fraction value that provides the widest possible stop band. For the topology optimization finite element model, four node, quadrilateral, square, plane stress finite elements are employed. Finite element model discretization is 120 elements in horizontal by 60 elements in vertical, i.e., 7200 elements in total.

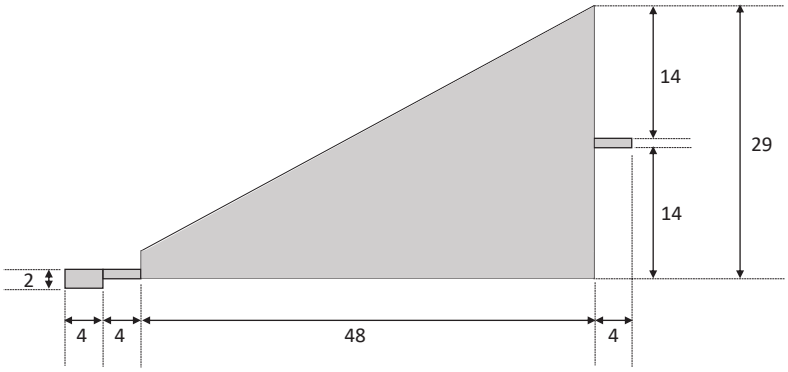
At the start of the optimization (i.e., for the mechanism in Fig. 3), first (non rigid mode) resonance frequency f_1 is found as 215.4 Hz, second (non rigid mode) resonance frequency is found as 1392 Hz, and f_2/f_1 ratio (an indicator of stop band width) is calculated as 6.46. As a result of topology optimization process, the design demonstrated in Fig. 4 is obtained. The topologically optimized design has its first resonance frequency f_1 at 200.2 Hz, second resonance frequency f_2 at 1594 Hz, thus, f_2/f_1 ratio is calculated as 7.96. As a result of topology optimization, f_2/f_1 ratio is increased by 23.2 %.

3.1 Unit Cell Mechanism

The unit cell mechanism of the two dimensional elastic metamaterial is obtained from the design provided in Fig. 4 by smoothing the sharp edges. To that end, the unit cell mechanism shown in Fig. 5 is obtained. For a fine mesh with 14050 four node, quadrilateral, plane stress



(a)



(b)

Figure 2: The compliant inertial amplification mechanism that is going to be topology optimized. (a) The whole mechanism, (b) the quarter mechanism showing the dimensions in mm.

finite elements, the first resonance frequency is observed at $f_1 = 172$ Hz and the second resonance frequency is observed at $f_2 = 1409$ Hz, whereas f_2/f_1 ratio is calculated as 8.19. Shift in resonance frequencies is an expected result, since the preliminary design in Fig. 4 has coarse mesh. However, the difference in f_2/f_1 ratios for both designs given in Fig. 4 and Fig. 5 is insignificant.

In order to see the vibration isolation performance of the compliant inertial amplification unit cell mechanism provided in Fig. 5, one has to perform frequency response function analysis. Consequently, vibration transmissibility of the unit cell structure given in Fig. 5 is calculated for roller-roller boundary conditions. In transmissibility analysis, a horizontal displacement input is provided from the left end of the structure, whereas horizontal output is taken from the right end. The vibration transmissibility plot for axial input and axial output case is shown in Fig. 6. As can be seen, between 171-1432 Hz, transmissibility value is below 1, hence this is the vibration isolation frequency range. The minimum vibration isolation amount achieved via one mechanism is calculated as 18 % within this frequency range (maximum vibration transmissibility of 82 %).

As the periodicity of the elastic metamaterial increases, vibration isolation level increases,

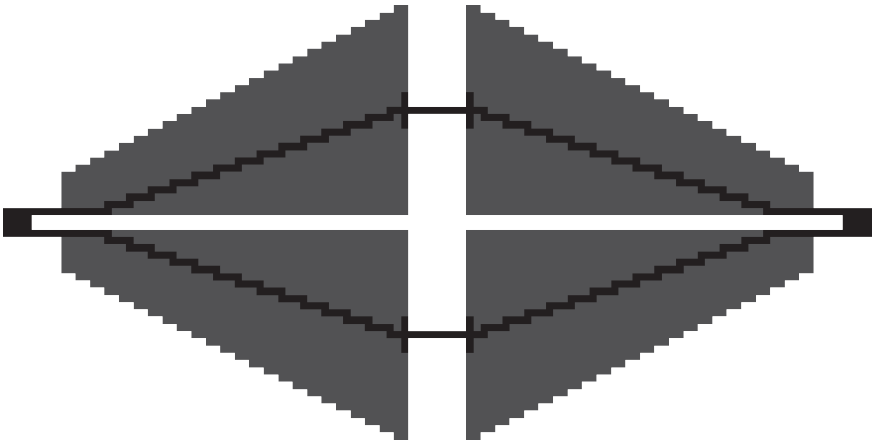


Figure 3: Topology optimization design space of the compliant inertial amplification mechanism. ($f_1 = 215.4$ Hz, $f_2 = 1392$ Hz, $f_2/f_1 = 6.46$).

as well [8, 10, 19, 20]. To that end, in order to observe how vibration isolation performance changes with the number of unit cell mechanisms employed in the elastic metamaterial, one dimensional periodic structures are formed utilizing various number of unit cell mechanisms. A one dimensional periodic structure constructed with four unit cells is given in Fig. 7 as an example. As in the case of the unit cell mechanism, for all of the one dimensional periodic structures, input displacement is provided from left end and output displacement is taken form right end. In Fig. 8, vibration transmissibility plots for one dimensional periodic structures that have 2, 4 and 6 unit cells are shown. As observed, vibration stop band occurs for the same frequency range (between 172-1418 Hz) for all of the periodic structures, a result which is encountered in the literature [8, 10, 19], as well. On the other hand, as the number of unit cells used in the periodic structure increases, vibration isolation level increases, as well. For the one dimensional periodic structure with two unit cell mechanisms utilized, minimum vibration isolation level achieved is calculated as 47 %. Vibration isolation level for the periodic structure with four unit cells is calculated as 84 %. Finally, vibration isolation level for the periodic structure with six unit cells is found as 96 %. In other words, for the periodic structure with six unit cells only 4 % of input vibration can reach to the output end.

3.2 Two Dimensional Broadband Elastic Metamaterial

A two dimensional elastic metamaterial can be constructed by incorporating the unit cell mechanisms in hexagonal formation as shown in Fig. 9. This two dimensional periodic structure has 483 mm horizontal length and 268 mm vertical length, and it is used to isolate in-plane excitations for a broad frequency range.

Vibration transmissibility plots for the two dimensional elastic metamaterial in Fig. 9 are provided in Figs. 10 and 11 for free boundary conditions. In Fig. 10, displacement transmissibility performance of the two dimensional periodic structure is demonstrated for an input provided from the left end and output displacement is taken from the right end (axial input vs axial output case). As can be seen, for a broad frequency range between 173-1420 Hz, less than 0.7 % of input vibration can reach to the output end. That is to say, by using the elastic metamaterial presented in Fig. 9 more than 99.3 % vibration isolation can be achieved between

Figure 4: Topologically optimized compliant inertial amplification mechanism. ($f_1 = 200.2$ Hz, $f_2 = 1594$ Hz, $f_2/f_1 = 7.96$).

173-1420 Hz for axial excitations. This result is also valid for transverse excitations, as well, considering the transmissibility data provided in Fig. 11. For the case shown in Fig. 11, an oblique in-plane displacement input that has both axial and transverse components is supplied to the two dimensional periodic structure from the left end whereas the axial and transverse output displacements are taken separately from the right end of the elastic metamaterial. As can be seen from Fig. 11, axial and transverse transmissibility plots show similar behavior with the axial input vs axial output case discussed in Fig. 10. As observed from Fig. 11, both of the axial and transverse excitations are mitigated more than 99 % within 173-1420 Hz frequency range. The transmissibility plots demonstrate that the two dimensional elastic metamaterial proposed in Fig. 9 is able to inhibit in-plane excitations for a broadband frequency region, and consequently can be used as a high performance passive vibration isolator.

4 CONCLUSIONS

In this study, a two dimensional elastic metamaterial which inhibits in-plane vibrations for a broad frequency range is proposed. The suggested two dimensional periodic structure is formed by incorporating topologically optimized compliant inertial amplification mechanisms in hexagonal formation. Vibration transmissibility plots indicate that, the proposed metamaterial can mitigate in-plane excitations for a broad frequency range that resides in the low frequency region. Vibration isolation levels achieved are quite satisfactory, hence, the suggested design can be utilized as a two dimensional passive vibration isolator for the specified broad frequency band.

Keywords: Metamaterials, Impact-dampers, Nonlinear dynamics

Abstract. *In recent years, metamaterials are increasingly used in the field of vibration mitigation due to the unique potential these offer. Periodic placement of appropriately designed resonators, the so-called unit cells, has been shown to arrest the propagation of vibration within a specific frequency range, thus resulting in formation of a bandgap. In rendering metastructures efficient, the breadth of the bandgap should be maximized, while for application in structures, it is also necessary to shift the lower limit of the gap to lower frequencies. One potential solution to this direction is the use of nonlinearity at the unit cell scale. In this direction, the current study investigates finite lattice configurations, which consist of impact damper unit cells. The effectiveness of impact dampers in vibration attenuation has been successfully illustrated in limited degree of freedom systems, and is here extended for use in the metastructure sense, i.e., for multiple degree of freedom systems. For this purpose, a one dimensional lattice of a finite number of unit cells is considered. In order to study and better asses the behaviour of the configuration, variable parameters are taken into account, including the number of unit cells, stiffness and mass ratio, while a comparison to a conventional linear oscillator is further offered. For the evaluation of the system performance, several criteria are utilized, including the oscillation amplitude as well as the energy absorption from the primary system as a result of the individual impacts. The obtained results clearly indicate the ability of impact-based meta-structures to successfully contribute to vibration mitigation under appropriate design.*

1 INTRODUCTION

In recent years, attention has turned to resilience of large-scale civil structures under dynamic loading, and in particular under seismic excitation. In addressing this challenge, the research community has focused on the development of vibration mitigation systems, which are able to ensure structural safety, by minimizing the effects of the excitation onto the structure.

Mitigation of engineering vibration has been widely dealt using linear, passive or active methods. As for the first, several concepts have been developed, among which some take advantage of the favorable effects that increased damping can offer [1, 2, 4], while others influence the nature of the system's dynamic response by introducing secondary devices, which are attached to the main system. Some of the common practices of such methods include oil dampers [5], friction dissipaters [3], tuned mass dampers [8]-[11], as well as tuned liquid dampers [12]. A major disadvantage of such devices, however, lies in the narrow range of frequencies within which their contribution is beneficial. Indeed, there exist frequency regions where the existence of passive devices can even affect the dynamic response in a negative way, as for example in the case of tuned mass dampers. On the other hand, the active control schemes overcome the former difficulties by offering the ability to adapt to diverse loading situations [6, 7, 13, 14]. Nonetheless, considerable disadvantages to such an active approach pertain to the significantly higher costs and the continuous need for maintenance.

A novel idea, which has recently been exploited for civil engineering applications, is based on the concept of metamaterials [17]-[26]. These are configurations, characterized by extraordinary filtering properties, attained as a result of diversified mechanisms, such as their microscopic geometry, periodic arrangement, etc [27]. Appropriately designed resonators, the so-called unit cells, have been shown to arrest the propagation of vibration within a specific frequency range [15]-[16], this resulting in formation of a "bandgap". In rendering metastructures efficient, the breadth of the bandgap should be maximized, while for application in structures, it is also necessary to shift the lower limit of the gap to lower frequencies. One potential solution to this direction is the use of nonlinearity at the unit cell scale. In this direction, following the work of Dertimanis et al. [28], the current study investigates finite lattice configurations, which consist of impact damper unit cells. The effectiveness of impact dampers in vibration attenuation has been successfully illustrated in limited degree of freedom systems [29], and is here extended for use in the metastructure sense, i.e., for multiple degree of freedom systems. The general term used for nonlinear attachments to the primary system is nonlinear energy sinks (NES). Extended research has been carried out regarding several types of NES, including impact dampers [29, 34, 35]. The dynamics of impact phenomena has been investigated in multiple studies [36]-[38]. Significant contribution in the subject of impact dampers has been made in the work of Masri and colleagues on impact dampers, regarding their general motion [30], their stability analysis [31], as well as their dynamic response to random excitation [32]. There is also high relevance between impact dampers and particle dampers, the latter being investigated in the work of Lu et al. [33].

2 META-DAMPER

2.1 Unit cell

The idea of the meta-impactor is inspired by the beneficial effect that a single impact damper can have on a structure, under dynamic loading [29]. The unit cell consists of a rigid container of mass m, containing a laterally unconstrained mass μ, free to impact on the respective bounds (Figure 1).

The nonlinearity in the response results from the contact between the container and the inner mass at the time instances where the relative displacement of the two equals to the free clearance $D/2$. This leads to the outcome of impact realizations, which introduce a highly nonlinear behaviour. Furthermore, since the interaction between the two masses results in sudden changes in their velocity, the phenomenon of impact can be classified as non-smooth.

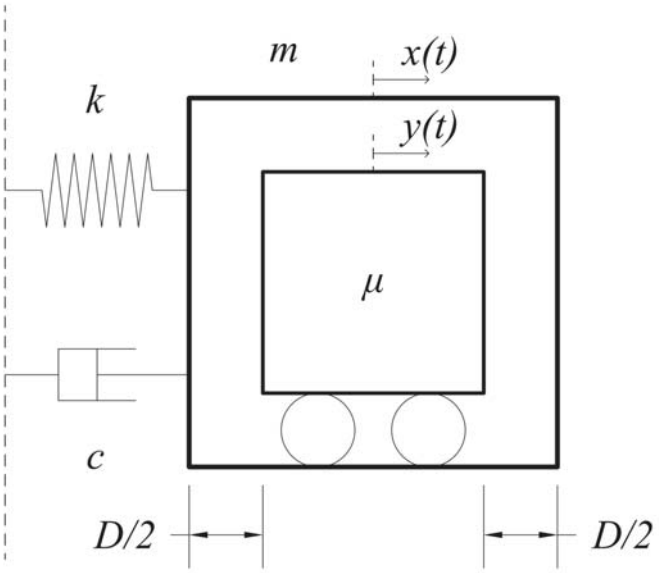

Figure 1: Impact damper unit cell.

2.2 Nonlinear lattice

The goals lies in shielding a target structure via coupling with the metamaterial configuration. The initial oscillator was a single degree of freedom system of mass M, stiffness K and damping C. The concept of the current work is based on the consecutive arrangement of impact damper unit cells. The resonators are connected elastically to each other with stiffness k, as well as to the protected mass on one end, and to a fixed support on the other, while damping c is also applied (Figure 2). In order to better assess the response of the system, excluding misleading effects from complicated input time histories, a harmonic excitation force $F(t)=A\sin(2\pi ft)$ was selected.

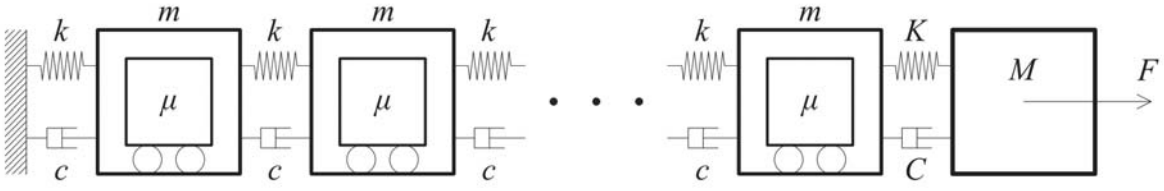

Figure 2: Nonlinear lattice.

2.3 Governing equations

The system is considered to comprise a linear behavior outside the impact events, so it can be described as a conventional, linear multiple degree of freedom system during those instances. It should be mentioned that there is no assumption regarding the number of impacts per cycle at the steady state.

The equations of motion for the first unit cell can be formulated as:

$$\begin{aligned} &m\ddot{x}_1(t)+c\dot{x}_1(t)+kx_1(t)+c[\dot{x}_1(t)-\dot{x}_2(t)]+k[x_1(t)-x_2(t)]=0 \\ &\mu\ddot{y}_1(t)=0,\ \ |x_1(t)-y_1(t)|<D/2 \end{aligned} \tag{1}$$

In the same pattern, the equations of motion for the *i*-th unit cell, $i=2,...,N-1$, are:

$$\begin{aligned} &m\ddot{x}_i(t)+c[\dot{x}_i(t)-\dot{x}_{i-1}(t)]+k[x_i(t)-x_{i-1}(t)]+c[\dot{x}_i(t)-\dot{x}_{i+1}(t)]+k[x_i(t)-x_{i+1}(t)]=0 \\ &\mu\ddot{y}_i(t)=0,\ \ |x_i(t)-y_i(t)|<D/2 \end{aligned} \tag{2}$$

For the last (*N*-th) unit cell the equations of motion are:

$$\begin{aligned} &m\ddot{x}_N(t)+c[\dot{x}_N(t)-\dot{x}_{N-1}(t)]+k[x_N(t)-x_{N-1}(t)]+C[\dot{x}_N(t)-\dot{X}(t)]+K[x_N(t)-X(t)]=0 \\ &\mu\ddot{y}_N(t)=0,\ \ |x_N(t)-y_N(t)|<D/2 \end{aligned} \tag{3}$$

whereas, for the primary structure they are formed as:

$$M\ddot{X}(t)+C[\dot{X}(t)-\dot{x}_N(t)]+K[X(t)-x_N(t)]=F(t) \tag{4}$$

Under the assumption of a sufficiently small duration of impact, it is further reasonable to consider that the post-impact displacement remains unaffected, opposite to the post impact velocities, which are altered discontinuously. In order to determine the latter, the coefficient of restitution *r*, related to the energy loss at every impact, is introduced [29]. Therefore, the additional equations describing the individual impacts can be defined as:

$$\begin{aligned} x_i^+ &= x_i^- \\ y_i^+ &= y_i^- \end{aligned} \tag{5}$$

$$r=-\frac{\dot{x}_i^+-\dot{y}_i^+}{\dot{x}_i^--\dot{y}_i^-} \tag{6}$$

where the coefficient of restitution ranges between $0<r<1$, zero representing purely plastic and unity perfectly elastic impacts [29]. Moreover, the conservation of momentum applies, which indicates:

$$m\dot{x}_i^+ + \mu\dot{y}_i^+ = m\dot{x}_i^- + \mu\dot{y}_i^- \tag{7}$$

Use of Eqs. 6, 7, results in the calculation of post impact velocities for the *i*-th unit cell.

$$\begin{bmatrix} m & \mu \\ 1 & -1 \end{bmatrix}\begin{bmatrix} \dot{x}_i^+ \\ \dot{y}_i^+ \end{bmatrix}=\begin{bmatrix} m\dot{x}_i^- + \mu\dot{y}_i^- \\ -r\dot{x}_i^- + r\dot{y}_i^- \end{bmatrix} \tag{8}$$

2.4 Simulation

In order to solve the system of differential equations, the system is brought into a nonlinear state space form as:

$$\begin{aligned} &\dot{z}(t)=g(z(t),F(t)),\ \text{where} \\ &z=\left[x_1,\dot{x}_1,y_1,\dot{y}_1\ |\ \ \ldots\ \ |x_N,\dot{x}_N,y_N,\dot{y}_N\ |\ X,\dot{X}\right]^T \end{aligned} \tag{9}$$

Subsequently, the derivatives of *z* for the first unit cell are calculated as:

$$\begin{aligned}
&\dot{z}_1(t) = z_2(t)\\
&\dot{z}_2(t) = -\frac{k}{m}z_1(t) - \frac{c}{m}z_2(t) - \frac{k}{m}[z_1(t) - z_5(t)] - \frac{c}{m}[z_2(t) - z_6(t)]\\
&\dot{z}_3(t) = z_4(t)\\
&\dot{z}_4(t) = 0, \quad |z_1 - z_3| < D/2
\end{aligned} \tag{10}$$

Similarly, for the the *i*-th unit cell, $i = 2,...,N-1$, these are:

$$\begin{aligned}
&\dot{z}_{4(i-1)+1}(t) = z_{4(i-1)+2}(t)\\
&\dot{z}_{4(i-1)+2}(t) = -\frac{k}{m}[z_{4(i-1)+1}(t) - z_{4(i-2)+1}(t)] - \frac{c}{m}[z_{4(i-1)+2}(t) - z_{4(i-2)+2}(t)]\\
&\qquad\qquad -\frac{k}{m}[z_{4(i-1)+1}(t) - z_{4i+1}(t)] - \frac{c}{m}[z_{4(i-1)+2}(t) - z_{4i+2}(t)]\\
&\dot{z}_{4(i-1)+3}(t) = z_{4(i-1)+4}(t)\\
&\dot{z}_{4(i-1)+4}(t) = 0, \quad |z_{4(i-1)+1} - z_{4(i-1)+3}| < D/2
\end{aligned} \tag{11}$$

and for the last (*N*-th) unit cell, these are respectively obtained as:

$$\begin{aligned}
&\dot{z}_{4N-3}(t) = z_{4N-2}(t)\\
&\dot{z}_{4N-2}(t) = -\frac{k}{m}[z_{4N-3}(t) - z_{4N-7}(t)] - \frac{c}{m}[z_{4N-2}(t) - z_{4N-6}(t)]\\
&\qquad\qquad -\frac{K}{m}[z_{4N-3}(t) - z_{4N+1}(t)] - \frac{C}{m}[z_{4N-2}(t) - z_{4N+2}(t)]\\
&\dot{z}_{4N-1}(t) = z_{4N}(t)\\
&\dot{z}_{4N}(t) = 0, \quad |z_{4N-3} - z_{4N-1}| < D/2
\end{aligned} \tag{12}$$

while for the linear oscillator are:

$$\begin{aligned}
&\dot{z}_{4N+1}(t) = z_{4N+2}(t)\\
&\dot{z}_{4N+2}(t) = \frac{K}{M}[z_{4N-3}(t) - z_{4N+1}(t)] + \frac{C}{M}[z_{4N-2}(t) - z_{4N+2}(t)] + \frac{1}{M}F(t)
\end{aligned} \tag{13}$$

The post impact velocities are computed as:

$$\begin{bmatrix} m & \mu \\ 1 & -1 \end{bmatrix} \begin{bmatrix} z^+_{4(i-1)+1} \\ z^+_{4(i-1)+2} \end{bmatrix} = \begin{bmatrix} mz^-_{4(i-1)+1} + \mu z^-_{4(i-1)+2} \\ -rz^-_{4(i-1)+1} + rz^-_{4(i-1)+2} \end{bmatrix} \tag{14}$$

3 ANALYSIS

The behaviour of the system was studied parametrically, calculating its response for each set of parameters. The analysis was performed using a MATLAB® environment, with integration carried out by means of the *ode45* function (AbsTol=eps, ReTol=eps$^{(2/3)}$, Refine=4 and MaxStep=0.001/sqrt(K/M), eps corresponding to the machine precision epsilon). Moreover, an event function is used, checking the condition $|x_i(t) - y_i(t)| = D/2$ for all unit cells. If at least one impact is detected, Eqns. 5, 8 are deployed for the calculation of post impact displacements and velocities.

The properties of the linear oscillator were chosen as M=1kg, f_n=1Hz and ζ_n=2%, while the harmonic excitation was chosen as $F(t)=\sin(2\pi t)$, with a unit amplitude and an excitation frequency matching the natural frequency of the linear oscillator. Furthermore, the coefficient of restitution is set constant at r=0.6, the clearance is set at D=0.1m and the damping between unit cells is set at c=0, throughout all parametric studies.

In order to better asses the effect of each parameter given to the system, parametric analyses were performed. Varying mass (m/M, μ/m) and stiffness (K/k) ratios were taken into consideration, in the range of $0.01 \leq m/M \leq 1.00$, $0.10 \leq \mu/m \leq 1.00$ and $10 \leq K/k \leq 100$ respectively.

The response of each system is calculated for the first 10 seconds. For the evaluation of the system's performance, several criteria are utilized, including the oscillation amplitude, maximum absolute acceleration, as well as the energy absorption from the primary system as a result of the individual impacts. The latter is calculated as the ratio between the total energy dissipation, resulting from all individual impacts, and the total energy inserted to the system by the external excitation [29].

$$E_{dis}(t)=\frac{\sum_{i=1}^{N-1}\int_0^t c[\dot{x}_i(\tau)-\dot{x}_{i+1}(\tau)]^2 d\tau+\sum_{p=1}^{P_t}\Delta p}{\int_0^t F(\tau)\dot{X}(\tau)dt} \tag{15}$$

where Δp is the amount of energy dissipation at the p-th impact, p=1,…, P_t and P_t is the number of impacts at any unit cell up to time t. Since in the current investigation c=0, the first part of the numerator is excluded.

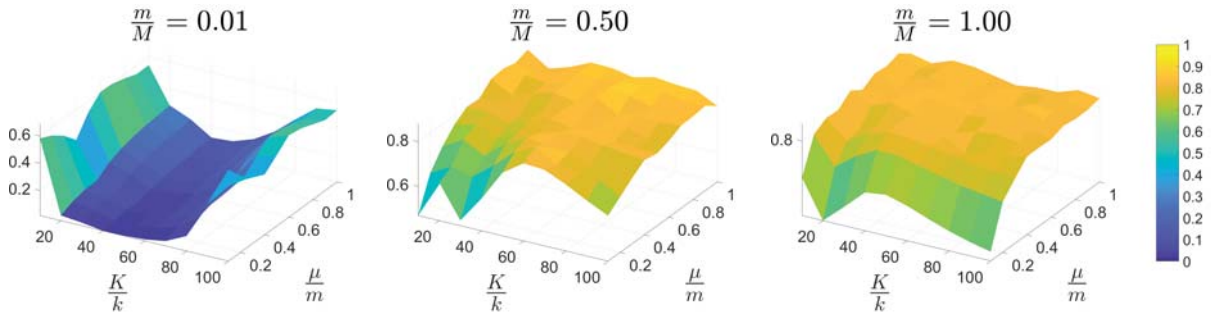

Figure 3: Energy absorption at 1 Hz for N=1 for varying mass and stiffness.

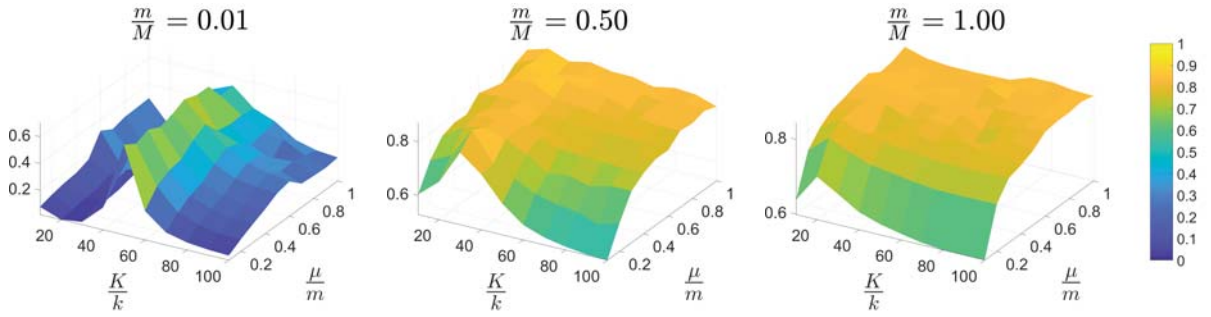

Figure 4: Energy absorption at 1 Hz for N=2 for varying mass and stiffness.

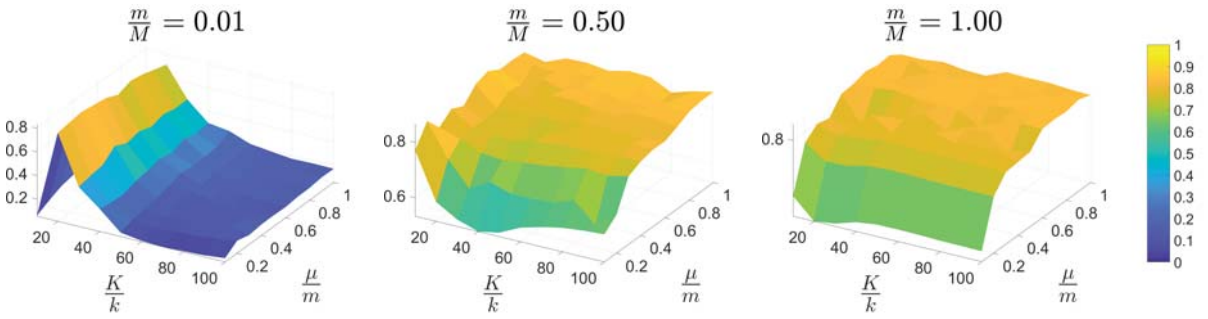

Figure 5: Energy absorption at 1 Hz for N=5 for varying mass and stiffness.

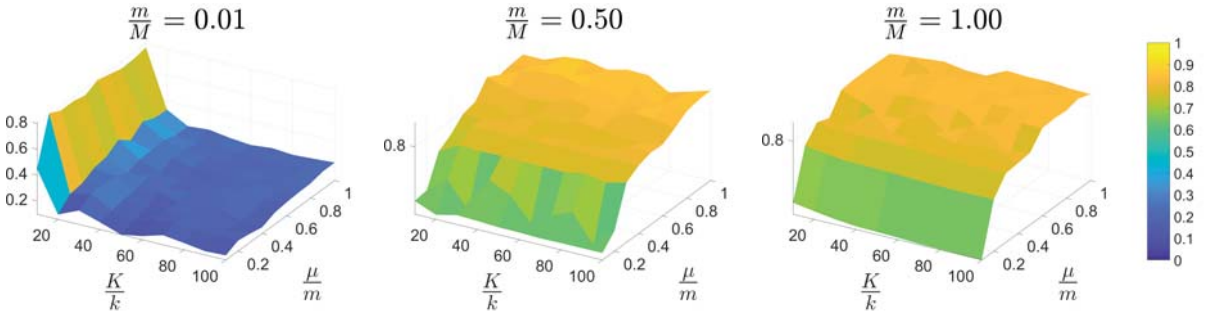

Figure 6: Energy absorption at 1 Hz for N=10 for varying mass and stiffness.

In Figs. 3-6 the results of energy absorption are presented. It is evident that for lower values of external mass ratio m/M the behavior of the system is dominated by the stiffness ratio. In those cases, the variation of the internal mass ratio μ/m does not significantly affect the energy absorption. As the external mass ratio increases, the importance is shifted towards the internal mass ratio as well, while for m/M=1, the internal mass ratio has the principal influence. As the number of unit cells increases, in combination with high values of external mass ratio, the amount of dissipated energy tends to become uniform and unaffected from the variation of the number of unit cells, as it can be inferred from Figs. 5, 6 for m/M=1.

Additional parametric analyses were carried out investigating the influence of the variation in the excitation frequency. For this purpose, the system's parameters were set to m/M=1, μ/m=0.1 and K/k=10. The simulation time is increased to 50s and the maximum absolute displacement and acceleration of the last 40s were recorded for the primary structure. Throughout these analyses, the excitation frequency varies between $0.1 \leq f / f_n \leq 4.0$.

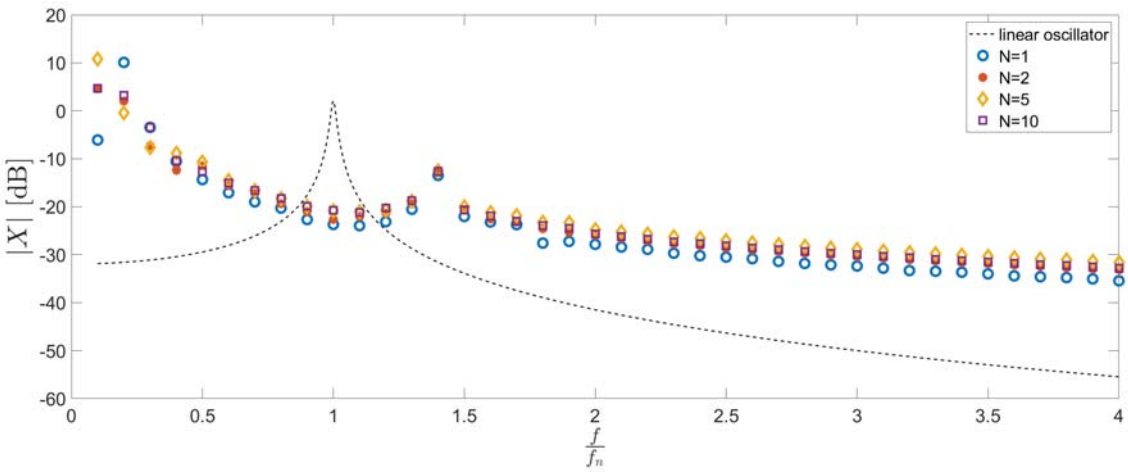

Figure 7: Maximum absolute displacement of the primary structure as a function of the applied frequency ratio.

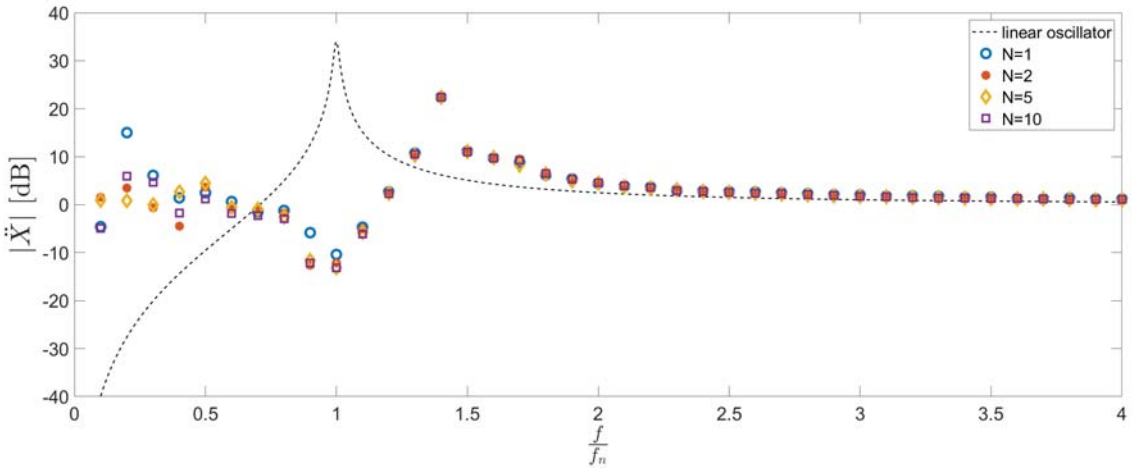

Figure 8: Maximum absolute acceleration of the primary structure as a function of the applied frequency ratio.

As inferred from Figs. 7, 8, a substantial mitigation of the dynamic load effect on the structure is observed for frequency ratios between 0.7 and 1.2. Considering that the damping between unit cells is set to zero, there is an amplification of the system's response in regions away from the resonance frequency. Moreover, it is observed that an increase in the number of unit cells does not have a notable effect on the attenuation properties of the configuration, especially in higher excitation frequencies. However, a distinctive peak at f / f_n=0.2 is indicated for N=1, which is not transferred to lattices with higher unit cell number.

4 CONCLUSIONS

The current study investigates the behavior of a highly nonlinear solution for attenuation of mechanical vibrations. The influence of critical parameters of the system was inspected, including mass and stiffness, number of unit cells, as well as excitation frequency. It is observed that high values of the external mass ratio m/M, as well as of the internal mass ratio μ/m, affect positively the system's vibration mitigation capabilities. Regarding the stiffness ratio, its influence is significant for lower values of the external mass ratio, while for higher values of the latter the amount of energy absorption is less affected by stiffness. The number of unit cells consisting the lattice does not seem to affect the behaviour of the system for high excitation frequencies, while for frequency ratio below unity there are some discrepancies in the behaviour of the system, the most notable being that of the single unit cell attachment. Further investigation is being performed by the authors in exploring this observation, which additionally requires consideration of the free clearance dimension. Moreover, the configuration is able to reduce the dynamic load effect within a frequency range centered around the resonance of the primary system, while some unfavourable effects were observed at adjacent frequencies. The results clearly indicate the effectiveness of the system under specific conditions, while it is also implied that proper adjustment of the metamaterial to specific structures can be challenging.

Abstract. *The aim of this research is to evaluate the effectiveness of a seismic retrofit technique that involves the introduction of energy dissipation devices properly connected to an existing structure through a system of cables and leverisms, which are employed to amplify total or inter-story drift at device end. One of the main topics related to the introduction of energy dissipation devices, lies in the choice of their optimal setting within the structure to maximize the effectiveness without producing functionality limitations. The achievement of these objectives is therefore linked, regardless of the type adopted, to the amount of energy dissipated in each cycle, directly proportional to the displacements magnitude to which the device is subject. Many configurations proposed in the literature and currently adopted in professional practice provide additional dissipation systems variously connected to braces installed inside the structural frame and therefore able to exploit the inter-story drift produced by seismic input. The proposed system exploits top displacements of the structure with respect to the foundation level, transferred to the device through a system of cables properly configured and amplified with leverage. This paper represents the first step of the research, in which after a brief description of equation of motion for a simple SDOF system, it is take into account a existing RC school building in Italy to assess performances of the retrofitted structure equipped with the proposed system.*

1 INTRODUCTION

The introduction of seismic energy dissipation devices within existing structures represents an important seismic protection system widely adopted for framed structures. The deformability of these structures generally allows, in fact, to exploit inter-story drifts to activate the devices and achieve consistent levels of dissipation of input energy. Many configurations and geometrical arrangements [1,2] have been proposed in order to optimize the devices location, generally applied in series to a bracing placed inside the frame mesh and able to transfer to the device a fraction of the inter-story drift, depending on their geometric configuration. It is therefore clear that the deformability of the structure is an essential requirement for the effectiveness of dissipation systems. For situations where structures are not sufficiently flexible, interesting solutions have been developed by several authors, including a cable system solution (Damped cable system, DCS), initially proposed by the research team of the University of Buffalo [3,4], and further developed [5,6,7,8] also as part of a research project funded by the European Commission, named SPIDER (strand prestressing for internal damping of earthquake response). Likewise, dissipation systems designed to increase displacements at the dissipation system end have been proposed by various authors [9,10,11] and generally consist of levers or pulley systems able to amplify inter-story displacement. The system proposed in this paper, uses a system of steel cables capable to transmit a portion of the total roof displacement of the building to the foundation where, by means of a system of displacements amplification, transfer to the damper a resulting amplified displacement. Considering a simple shear frame, the proposed system is configured according to the following scheme in Figure 1: The cable used (6) is fixed with clamps (7) at the upper ends of the floor; the cable, therefore, is arranged in an X configuration along the diagonals of the frame and diverted at the base of the columns by pulleys (4). The cable then runs horizontally along the base of the frame; in this area it is connected to the end of a lever arm (1), to the opposite end of which the dissipation device is connected (2). The particular configuration of the cable, which runs along both diagonals of the building's elevation, continuing without interruption at foundation level, also allows the same to be always active in both directions of seismic loads. The portion of the cable placed on the diagonal in tension (blue wire), in fact, exerts a recall action on the cable portion placed along the compressed diagonal (red wire), not allowing deflection.

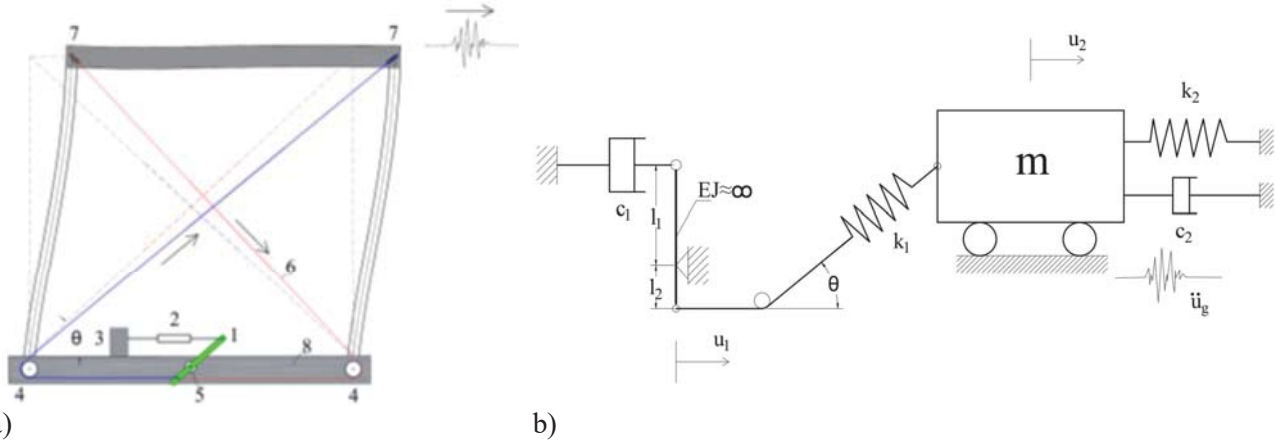

Figure 1 a) Conceptual model of simple 1-floor frame structure equipped with proposed system: 1 lever arm; 2 viscous damper (VD); 3 contrast; 4 pulleys; 5 pin; 6 wire; 7 clamp; 8 foundation; b) Mechanical model of a 2-DOF structure equipped with the proposed system.

The mechanical model of the SDOF system, equipped with the proposed system and reported in Figure 1, has been described in a previous paper by the authors [12], to which we refer you for details.

The model equipped with an additional damping system, with a linear viscous dissipation device, is described by the following general equation:

$$Fd = c_1 \dot{u}_d = \alpha_d \cdot c_2 \cdot \dot{u}_d \tag{1}$$

with $\dot{u}_d$ velocity at the device end and Fd device damping force.

The damping coefficient is then expressed as a function of the internal damping of the structure through the parameter α_d. With reference to the stiffness characteristics of the system, the structure stiffness k_2 and the stiffness of the elements constituting the additional dissipation system, i.e. the cable and the leverages, k_1, are defined; actually, as showed in the follow, the main stiffness component is represented by the cable extensional stiffness. As said, from the examination of the Figure 1 results that, in both directions of displacement, the part of the cable connecting the clamp placed in the direction of displacement with the lever arm is in tension (blue wire), while the remaining ones is not stressed (red wire) if friction in pulleys is neglected. In the evaluation of the extensional stiffness, therefore, it is necessary to refer to a length of the cable equal to half of the whole length. At this research stage the component related to the real viscous device elastic stiffness has been neglected, considering it rigid and neglecting friction in pulleys, pin etc... Added stiffness k_1 has been, then, expressed as a function of the stiffness of the bare structure through the coefficient α_k:

$$Fd = c_1 \dot{u}_d = \alpha_d \cdot c_2 \cdot \dot{u}_d \tag{2}$$

Finally, the amplification ratio produced by the leverage is defined through:

$$\alpha_M = \frac{l_1}{l_2} \tag{2a}$$

Description of the equations of the motion for a SDOF system are reported below:

$$\begin{cases} m\ddot{u}_2(t) + k_2 u_2(t) + \cos\theta\, \alpha_k k_2 \left(u_2(t)\cos\theta - u_1(t)\right) + c_2 \dot{u}_2(t) = -m\, \ddot{x}_g(t) \\ \alpha_M \alpha_d c_2 \cdot \dot{u}_1(t) - \alpha_k k_2 (u_2(t) \cdot \cos\theta - u_1(t)) = 0 \end{cases} \tag{3}$$

with symbols meaning reported in previous Figure 1.

The use of a displacement amplification system like that described, therefore, allows to overcome the usual limitations in the use of additional dissipation systems usually inserted inside the structural frames, as it is effective even for limited displacements, thanks to the introduction of leverage, displacements are transmitted amplified to the device, increasing the amount of dissipated energy. Another main objective in the development of the described system is to be able to carry out a seismic retrofit of a building, implementing interventions exclusively from the outside, without proceeding to demolition of non-structural elements, finishes and systems. The system of cables, in fact, will be applied primarily on all the building prospects, anchored through clamps to the external nodes of the roof or, if necessary, to intermediate stories. In this way, the clamps reaction is divided between the horizontal (beams) and vertical elements (columns) concurring into the node, stressing them with axial forces. The presence of rigid slabs in the structure also favors transferring seismic action to the frames equipped with the described system. Conversely, there is the possibility of interference between the path of the cables and architectural and functional projections present on the building prospect (balconies, etc. ...). Although variations to the cable path are possible, it is certainly easier to apply it on structures generally without such protrusions, but only windowed walls, such as schools or industrial buildings. In view of the importance that seismic vulnerability of existing school buildings assumes in many areas of the world and in

particular in Italy, where most of the existing school heritage is characterized by seismic performance below the standards required by current regulations, we proceed in the following to the evaluation of the specific characteristics of some of the most common structural types in the school heritage in order to assess in advance and in simplified form the applicability and effectiveness of the proposed system.

2 CASE STUDY BUILDING

The case study is related to the elementary school "Collina Castello" of Bisignano (Italy), built in 1983. The building has three floors plus a pitched roof and is characterized by a rectangular plan with dimensions of about 21.4 m × 15 m. The interstory heights range from about 3.2m to about 3.4m, for a total height of about 9.9m at the roof level. The rooftop has a maximum height of + 11.97 m. The reinforced concrete structure is characterized by a fairly regular frames, consisting of 4 main frames with 5 columns each arranged along the longitudinal direction, along transversal direction longitudinal frames are tied only by slabs and perimetral beams. The columns have dimensions of 50 cm × 40 cm and the longitudinal beams, at all levels, have section 40 cm × 60 cm. The main frames are connected by border beams with dimensions 50 cm × 40 cm arranged in transverse direction. The building was assumed as a benchmark structure for a Research Project financed by the Italian Department of Civil Protection and the authors of present paper take informations about geometrical and structural configuration from study belonging to it [13].

Figure 2 General views of the benchmark building

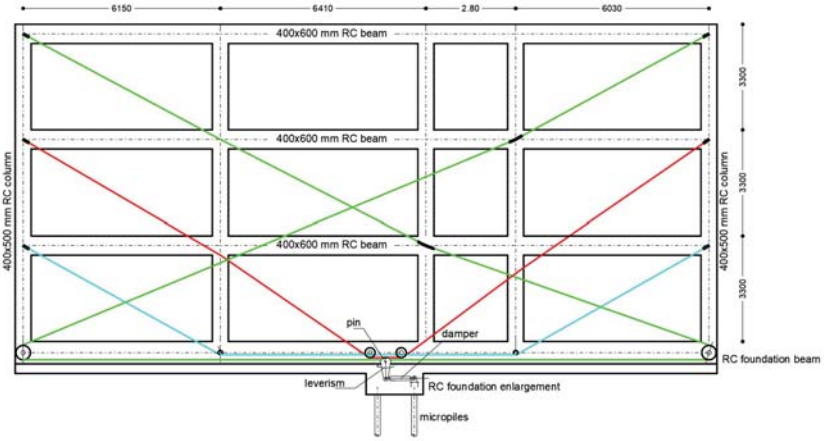
The modal analysis carried out by finite element model of the structure, generated by SAP2000 software [14] showed that the first vibration mode (0.79 s) is purely traslational along transversal direction, which is weakest direction because absence of beams. The second vibration mode is rotational with a period of 0.55 s and third vibration mode is purely translational along stiffer direction with a period of 0.51 s. Because of structural symmetry, the first three vibration modes excite about 85% of the mass in both the directions. The building presents windowed walls regularly arranged along the main facades and no prominent elements like balconies, bow-windows etc…

3 DESCRIPTION OF RETROFIT TECHNIQUE

The objective of the system is to carry out a seismic retrofit mainly intervening from outside, without the need of non-structural elements demolition or interruption to or limitation of the building's activity. Figure 3 shows a possible configuration of the cable system on the benchmark building main prospect. Each cable is connected to a different structure floor and

transfers the displacement of each floor to the lever (pinned at the foundation beam), to which the viscous damper is connected. To do so, may be required a foundation enlargement also with micropiles in order to absorb the forces related to the diversion of the cable, when it does not occur at a foundation beam-column joint, and to do not increase shear forces in the foundation beam. As can be seen, despite the non-uniform spans of the frame beams, the system configuration can be effectively adapted without restricting accessibility in the building. The passage of cables at the windowed walls, although they produce a visual obstacle, does not reduce the functionality of the windows (opening from the inside) nor the light entry in the building. Other building prospects and, if needed, internal frames, will be equipped with similar cables layout.

a)



b)

Figure 3 (a) System layout on the main RC frame of the benchmark building: in green, red and cyan are represented, respectively, steel cables linking the 3th, 2th, and 1th floor to the foundation of the building; (b) Cable system layout depicted on the building prospect: steel cables (red lines), RC frame (dashed green lines);

In the present example only external façade frames are equipped with the system. Each cable is linked by means of a lever to the viscous damper device. Amplification factor α_M is set at 10 for all leverism devices. Characteristics of Linear viscous devices have been chosen so as to find equivalent commercial products; in particular damping coefficient is set at c = 160 kNsec/m and limit force F_L of 20 kN. The value choosen for limit force is related to the maximum cable tension compatible with the strenght of the beam-column joint where cable is clamped.

The leverage, in fact, also produces the amplification of the force generated by the damping device, inside the cable and at the cable clamped end, reaction are so limited to 200 kN ($\alpha_M \cdot F_L$). Higher limit force would require heavy beam-column joint reinforcement.

Each cable consist of a pair of Ø32 steel rods, connected at the deflection point, by a less stiff steel rope. Diversion point are arranged in corrispondence of beam-column joint to limit effects of reaction force on the existing frame elements and made to allow cable/rope sliding. In

the FEM model cable deflection was neglected. As a result of the insertion of the cable and device system, the dynamic properties of the structure undergo a modest variation, less than 2%, with a slight increase in the fundamental first vibration period (0.80 s). Higher modes are even less affected.

4 PERFORMANCE EVALUATION IN ORIGINAL AND RETROFITTED CONDITIONS

The seismic analyses were carried out with a non-linear dynamic approach using the finite element models of the building structure (Figure 4). As way of example of the results obtained, the responses computed before and after retrofit in terms of maximum interstory drift profiles and story displacements, for the main building in its principal direction x and y are compared in Figures 5. Seismic input used consist of a series of natural NTC spectum-compatible unscaled accelerograms [15], taken from a set of accelerograms extracted from the European Strong Motion Database (ESM), [16] through the REXEL software [17] for the Bisignano site, adopting a type B soil category, in the range of periods between 0.15 - 2 s.

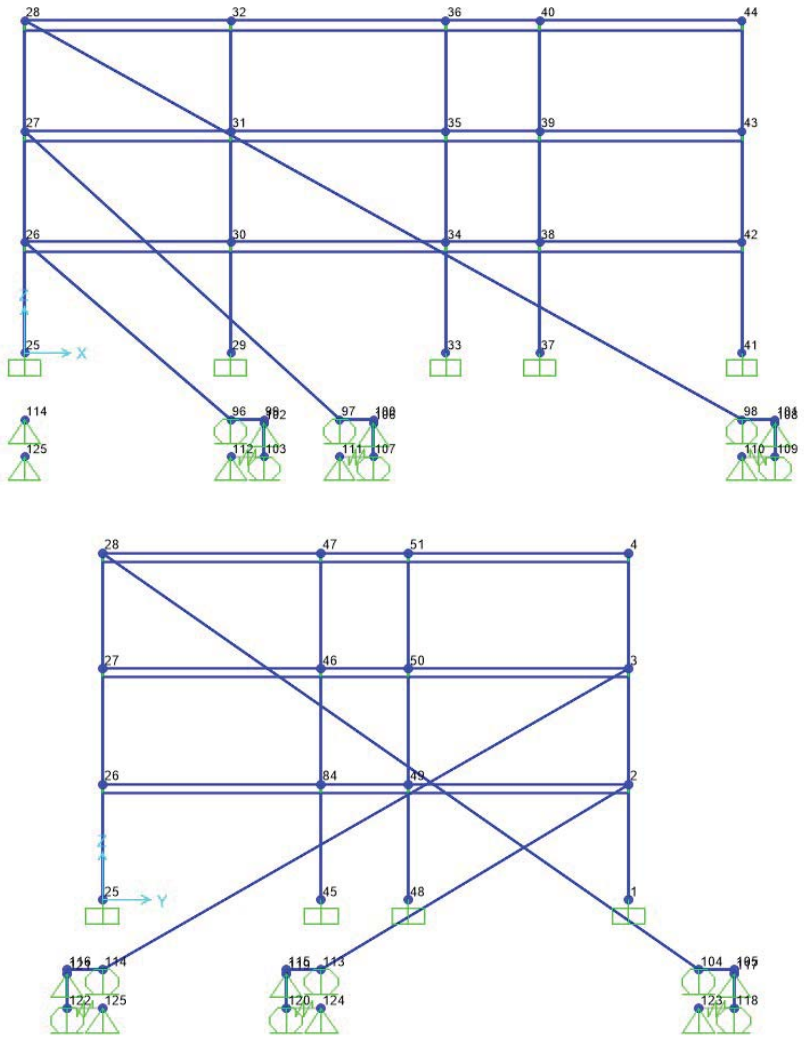


Figure 4 Equivalent SAP 2000 model view of the building longitudinal (X-dir) and trasversal (Y-dir) frames equipped with the damping system.

In the model used, for the sake of simplicity, the X-shaped cable is not modelled with real pattern on the building façade. Alternatively, only a angled strut with equivalent section and lenght of the cable and active in tension and compression was used, which links each edge floor beam-column joint with a leverism through proper node restrains/constrains.

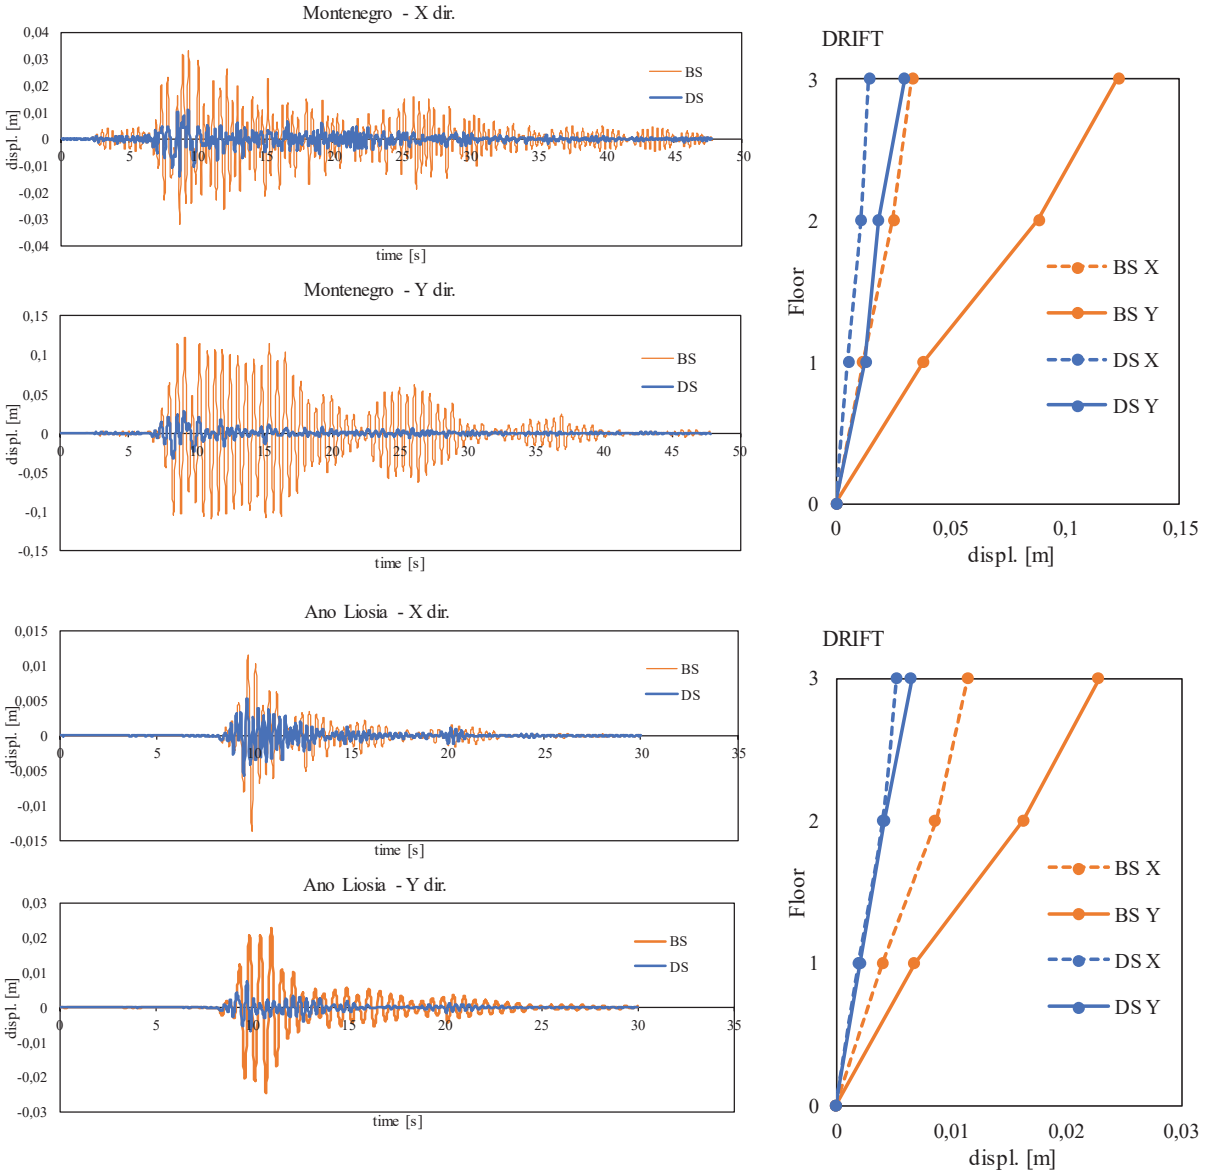

Figure 5 Top displacement and inter-story drift respectively for bare structure (BS – orange lines) and structure equipped with dissipative system (DS – blue lines) for Montenegro and Ano Liosia earthquakes.

Examination of the results shows a significant reduction in the displacements of the structure and story drifts. In particular, introduction of the damping system produces inter story drift reduction between 56% and 102%. It is clearly visible from results that efficiency of the system is higher in the weaker direction of the structure (Y-dir) than in the stiffer one, because cables with the same axial stiffness were used in both directions and therefore a different α_k ratio characterize two structure directions. This, as demonstrated in [12], is a very important feature in defining the response and efficiency of the damped system. Similar results are obtained for base shear as shown in the following Figure 6 for Montenegro earthquake.

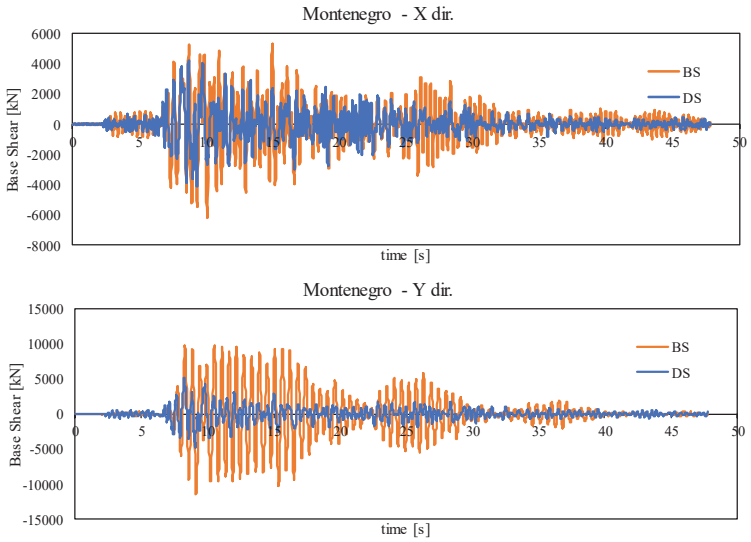

Figure 6 Base Shear respectively for bare structure (BS – orange lines) and structure equipped with dissipative system (DS – blue lines) for Montenegro earthquakes in X and Y direction.

In Figure 7 are presented Base Shear/ roof displacements and Viscous damping force/ device displacements histories. From the examination of the figure results a considerable amount of energy dissipated as result of the displacements amplification produced by the leverage, despite the low values of the force in the dissipation device, whose values it is convenient to keep low to avoid important interventions to strengthen the beam-column joints where cable are connected to the structure and relevant dimensions of the components of the described retrofit system.

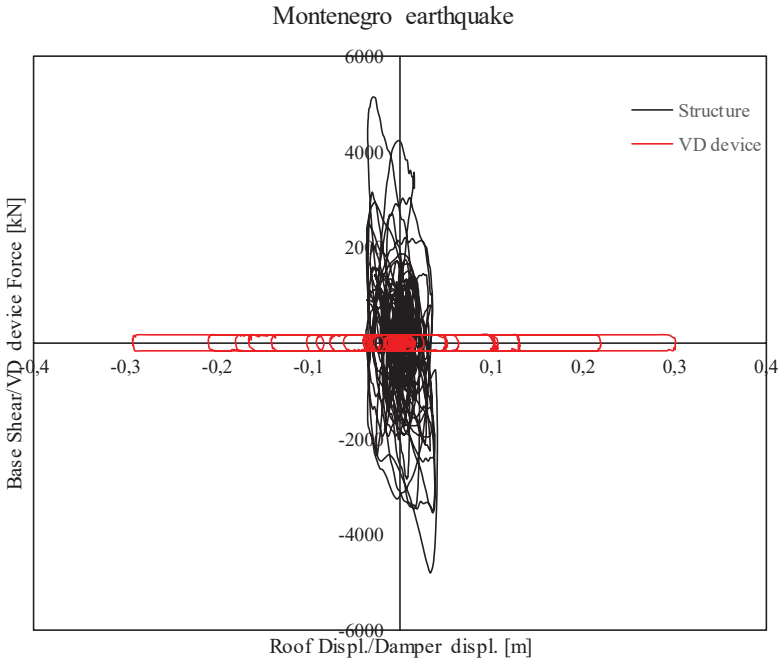

Figure 7 Base Shear/ roof displacements (black line) and Viscou damping (VD) force/ device displacements (red line) for Montenegro earthquake.

5 CONCLUSIONS

Present paper illustrates a seismic retrofit system for existing reinforced concrete structures by using additional viscous dampers connected to the structure by means of a system of cables and lever able to transmit the roof displacements to the base, where displacement amplification is carried out through a lever system and then transmitted to the dissipation device. The paper firstly provides motion equation system for a SDOF system and then describe results of application of the retrofit technique on a RC existing school building. Results show a high efficiency of the system in interstory drift and shear base reduction. The need for little or no demolition of non-structural elements and infills allows the structure to remain functional even during the execution of interventions and limit costs.

It is the aims of the authors to continue the research in order to investigate the effects on the system performances of the use of different dissipative devices (non-linear viscous and friction dampers, etc.) and application to more complex structures.

Keywords: KDamper, Negative Stiffness, Soil-Structure Interaction, Seismic Protection, Earthquake Engineering

Abstract. *Throughout the past decades, seismic isolation of structures has been studied rigorously as an approach to reduce seismic demand and mitigate structural damage. Research in this field has progressed significantly, starting from the use of simple elastomeric bearings for the decoupling of the superstructure from the base, to more complex devices that incorporate the use of an additional oscillating mass and negative stiffness elements. Characteristic examples of these devices are the Tuned Mass Damper (TMD) and the Quasi-Zero oscillators (QZSs). The KDamper is a novel passive vibration absorption concept, based essentially on the optimal combination of appropriate stiffness and mass elements, which include a negative stiffness element. The concept can be implemented using a system of prestressed elements in order to obtain the negative stiffness effects and might prove to achieve a significant advantage for seismic retrofitting.*

In this paper, the extended KDamper system is placed at the ground level and the soil-structure interaction (SSI) between the building foundations and superstructure is utilized as a means to effectively transfer the dynamic forces of the KDamper to the building and to distribute the required displacements between the structural elements and foundation, thus leading to absorption of the vibration energy. The configuration of the KDamper properties and tuning of its stiffness elements are studied herein. The effectiveness of the KDamper is subsequently investigated in view of the performance of a 4-storey building. A series of artificial accelerograms and real earthquake time histories are used as excitation. Results indicate the beneficial role of SSI on the reduction of the spectral acceleration and displacements, hence placing the concept as a compelling alternative to existing seismic protection technologies.

1 INTRODUCTION

During the latest years, seismic codes have significantly been altered with the intention to lead to resilient structures that perform better under seismic loads. To this end, seismic isolation has been one of the main approaches aiming to reduce structural seismic accelerations and, in this way, lead to earthquake-resistant design [1-6]. Therefore, a number of isolation devices from simple elastomeric bearings to more sophisticated roller bearings have been developed and advanced within the years. However, in order to isolate the building from its base, large displacements are required that are not always acceptable, hence rendering this system inadequate for retrofitting.

Seismic protection research focuses lately on devices which include: (a) negative stiffness elements (Negative Stiffness (NS) Devices and "Quazi-Zero Stiffness" (QZS) oscillators) and (b) Tuned Mass Dampers (TMDs). The concept of introducing additional oscillating masses (TMDs) has been employed in a variety of systems including skyscrapers and structure bases aiming to protect the structure from the dynamic effects of environmental loads (e.g. wind, wave and seismic) [7-11]. The main drawback of this method is the need of large additional masses, compared to the mass of the structure itself, as well as the detuning of the TMD parameters that affects the performance of the structure within the years.

A promising class of absorbers is based on increasing the damping by the appropriate introduction of negative stiffness elements. Proposed by Antoniadis et al. [12], the KDamper is a novel passive vibration absorption concept, based essentially on the optimal combination of appropriate stiffness and mass elements, which include a negative stiffness element. This vibration control system has been examined for the protection of bridges [13-17] wind turbines [18, 19] and structural systems [20,21]. In addition, the KDamper is implemented as an Absorption Base (KDAB) in the bases of structures [22-28]. In the recent work of Kapasakalis et al. [28], the KDAB is proven to be a possible supplement to BI, or can be alternatively implemented as a "stiff absorption base".

In this study, the EKD is implemented as a seismic protection measure within the base of a typical residential structure. The effects of the Soil-Structure interaction coupled with the KDamper damping properties are investigated and results indicate the significant benefits of the methodology at the seismic response of the structure.

2 OVERVIEW OF THE VIBRATION ABSORPTION METHODOLOGY

In this section, the extended KDamper concept (EKD) is presented and the fundamental principles of its function are provided in detail. A single degree of freedom (SDoF) oscillator is considered in which the KDamper is implemented between its rigid base and the oscillating mass. Throughout the paper, linear dynamic systems are considered to represent the stiffness elements of the KDamper while the effect of soil-structure interaction (SSI) is represented using non-linear springs.

2.1 The KDamper Vibration Absorber

Figure 1, illustrates the fundamental layout of various vibration isolation and damping concepts described in the literature and presented herein to facilitate the understanding of the KDamper concept. All strategies aim to minimize the response $x(t)$ of a low-damped (or undamped) SDoF comprising a mass m and static stiffness k due to the resulting motion of a base excitation $x_G(t)$. The Negative Stiffness Isolator (Fig. 1A) incorporates a negative stiffness element configured in parallel with the stiffness elements k of the system. To this end, the overall

stiffness of the configuration is reduced to $k_{QZS} = k + k_N \leq k$, hence leading to potential significant decrease of the overall static stiffness and consequently, instability of the system.

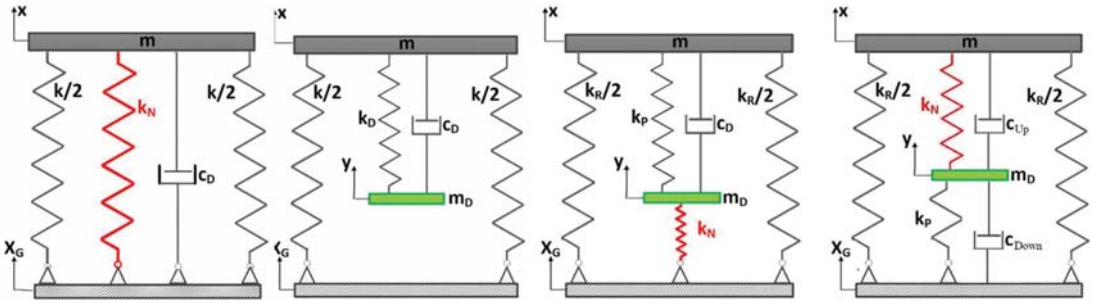

Figure 1. Schematic representation of the vibration absorption concepts considered: (A) Negative Stiffness (NS) isolator (or QZS), (B) Tuned Mass Damper (TMD), (C) KDamper concept and (D) Extended KDamper (EKD).

In a similar way to the Tuned Mass Damper (TMD, Fig. 1B), the KDamper (Fig. 1C) consists of an additional oscillating mass element (m_D) and two positive and negative stiffness elements k_P and k_N respectively. The negative stiffness element (k_N) serves as an indirect approach to increase the inertia of the oscillating mass (m_D) and consequently, increase the damping of the system. In addition, on the contrary to the NS isolator, the basic requirement of the KDamper is that the overall static stiffness of the system is maintained positive and, in this way, the risk of potential instability is eliminated. The total stiffness of the system with the KDamper can be expressed using the following formula:

$$k_R + \frac{k_P k_N}{k_P + k_N} = k_0 = (2\pi f_0)^2 m_{total} \tag{1}$$

Compared to the TMD, the KDamper uses an additional negative stiffness element k_N, which connects the additional mass to the base. Thus, the equation of motion of the KDamper becomes:

$$m\ddot{u}_S + k_R u_S + m_D \ddot{u}_D + k_N u_D = -(m + m_D)a_G \tag{2.a}$$
$$m_D \ddot{u}_D - C_D(\dot{u}_S - \dot{u}_D) - k_P(u_S - u_D) + k_N u_D = -m_D a_G \tag{2.b}$$

A closer examination at the equations above indicates that the additional negative stiffness element is an indirect way to increase the inertia of the KDamper mass m_D and to this end, increase the efficiency of the vibration absorption system without the need to incorporate large masses, contrary to the case of a conventional TMD.

2.2 Extended KDamper Concept (EKD)

The proposed vibration absorption concept is an extension of the KDamper referred to herein as the EKD system and is illustrated in Figure 1D. In a similar way to the KDamper, the EKD incorporates a system of masses, negative stiffness and positive stiffness elements as well as artificial dampers. The main variation would be the change of the system configuration where the positive stiffness spring (k_P) connects the damper mass (m_D) to the base of the system while the negative stiffness element (k_N), is attached between the damper mass (m_D) and the mass of the oscillator (m). Also, an additional artificial damper is adopted and placed in parallel with the negative stiffness element so that we end up having two dampers, namely C_{UP} and C_{DOWN}

Based on the original formulation of the KDamper expressions 2.a and 2.b, the following equations of motion for the EKD are derived:

$$m\ddot{u}_S + k_R u_S + m_D \ddot{u}_D + k_P u_D = -(m + m_D) a_G \tag{3.a}$$

$$m_D \ddot{u}_D - c_{UP}(\dot{u}_S - \dot{u}_D) - k_N (u_S - u_D) + c_{DOWN} \dot{u}_D + k_P u_D = -m_D a_G \tag{3.b}$$

As mentioned in the previous section, the stiffness parameters of the KDamper, and EKD respectively, are selected according to equation (1) in order to maintain the total stiffness of the system. However, an increase of the absolute value of k_N, or reduction of the absolute values of k_P or k_R, may endanger the static stability of the structure. In order to ensure that potential loss of the static stability is prevented, the possible variations of k_N, k_P and k_R should be taken into consideration in the design and optimization of the EKD parameters. The stiffness parameters of the system may present significant fluctuations due to numerous reasons, such as temperature variations, manufacturing tolerances, or non-linear behaviour of structural elements and the unpredictable behaviour of the foundation system (SSI). Consequently, an increase of the absolute value of k_N and/or a decrease of the values of k_P and k_R by a factor ε_N, ε_P and ε_R, respectively, may result in the system being unstable. This situation may happen in the following case:

$$(1 - \varepsilon_R) k_R + \frac{(1 - \varepsilon_P) k_P (1 + \varepsilon_N) k_N}{(1 - \varepsilon_P) k_P + (1 + \varepsilon_N) k_N} = 0 \tag{4}$$

Contrary to the KDamper concept, which foresees variation only in the negative stiffness element k_N, in the proposed extension of the KDamper concept (EKD), a variation in all stiffness elements is taken into consideration. Assuming either the negative stiffness ratio kn=k_N/k_0 or the absolute value of the negative stiffness element (k_N) is known, using the equations (1) and (4), the rest of the stiffness elements result as presented below:

$$kr = \frac{-b - \sqrt{b^2 - 4 * a * c}}{2a} \Rightarrow KR = kr * k_0 \tag{5.a}$$

$$kp = \frac{kn - kr * kn}{kr + kn - 1} \Rightarrow KP = kp * k_0 \tag{5.b}$$

Where parameters a, b and c are defined as:

$$(1 - \varepsilon_R) = R\,;\ (1 + \varepsilon_N) = N\,;\ (1 - \varepsilon_P) = P \tag{6.a, b, c}$$

$$a = R(P - N)\,;\ b = kn * N(P - R) + R(N - P)\,;\ c = -P * N * \mathrm{kn} \tag{6.d, e, f}$$

Finally, assuming that the following parameters are known:

1) the additional mass, m_D, and
2) the variations ε_N, ε_P and ε_R of the stiffness elements

The unknown parameters of the system are:

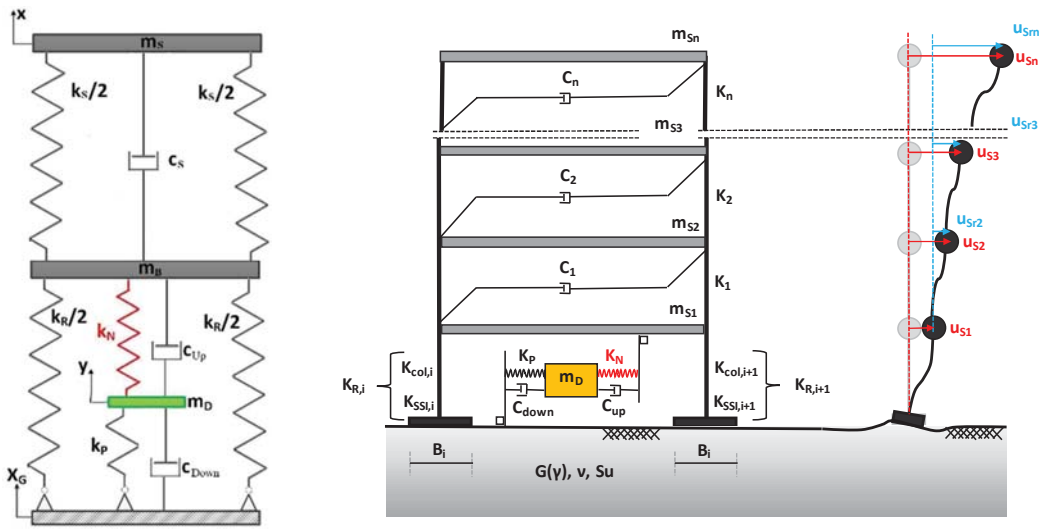
1) the nominal KDamper frequency f_0 (Eq. (1));
2) the negative stiffness ratio kn or the value of the negative stiffness element k_N and
3) the damping coefficients c_{DOWN} and c_{UP}.

3 EXTENSION OF THE EKD TO MULTI-STOREY STRUCTURES INCLUDING SOIL STRUCTURE INTERACTION (SSI) EFFECTS

In this section, the concept of the EKD is extended to multi-degree of freedom systems (MDoF) and applied to multi-storey buildings with aim to control their response to seismic excitations. For this purpose, an extension of the vibration control strategy from a simplified SDoF system (Fig. 1D) to MDoF systems is presented. In addition, Soil-Structure Interaction effects are considered in the analysis of the structural system using non-linear springs derived from numerical analysis of shallow foundation systems.

Based on the methodology presented herein, a numerical application is performed on a 4-storey typical concrete structure in order to assess its behaviour under seismic loading and demonstrate the beneficial role of SSI along with the application of EKD as a vibration absorption method.

3.1 The EKD as a Seismic Base Absorber



(A) (B)

Figure 2. (A) Implementation of the EKD as a seismic base absorber, (B) Multi-storey building with the proposed seismic vibration absorber system, EKD (sketch of the model) together with SSI effects.

The possible implementations of the KDamper and specifically of the Extended KDamper (EKD) might be numerous. In this study, the potential application of the EKD for seismic protection of structures is assessed and the EKD is implemented as a vibration base absorber. To this end, the EKD system is located between the base of the building and the superstructure. The corresponding configuration is illustrated in Fig. 2A and the equations of motion are derived as follows:

$$m_S(\ddot{u}_S+\ddot{u}_B)+c_S\dot{u}_S+k_Su_S=-m_Sa_G \tag{7.a}$$

$$m_B\ddot{u}_B+m_S(\ddot{u}_S+\ddot{u}_B)+c_{UP}(\dot{u}_B-\dot{u}_D)+k_N(u_B-u_D)+k_Ru_B=-(m_S+m_B)a_G \tag{7.b}$$

$$m_D\ddot{u}_D-c_{UP}(\dot{u}_B-\dot{u}_D)-k_N(u_B-u_D)+k_Pu_D+c_{DOWN}\dot{u}_D=-m_Da_G \tag{7.c}$$

where $u_S = x_S - x_B$, $u_B = x_B - x_G$, $u_D = x_D - x_G$. The natural frequencies of the subsystems and the rest of the parameters are defined as:

$$\omega_0 = 2\pi f_0 = \sqrt{k_0 / (m_S + m_B + m_D)}\ ;\ \omega_D = \sqrt{(k_P + k_N) / \mathrm{m}_D} \tag{8.a, b}$$

$$k_0 = k_R + \frac{k_P k_N}{k_P + k_N}\ ;\ m_D = \mu_D (m_S + m_B) \tag{8.c, d}$$

where ω_0 and ω_D refer to the natural frequencies of the total system and the EKD respectively, k_0 is the equivalent static stiffness of the EKD, m_B is the mass of the base, m_S the mass of the superstructure, m_D the mass of the EKD and μ_D the damper's mass ratio. In this study, the EKD parameters are selected according to Section 3.2 and Section 5 and refer to a typical 4-storey structure with total mass of *320 tn*. More details of the case study are presented in the following sections.

3.2 Extension of the EKD to Multi-Storey Structures

A planar *n*-storey building is considered and presented in the sketch of Fig. 2B, in which the proposed base absorber system, EKD is implemented for seismic protection between the base and the first floor of the structure. The following assumptions are made for the modelling of this system:

1. the total structure mass is concentrated at floor levels;
2. the slabs and girders on the floors are rigid when compared to the columns;
3. the columns are considered inextensible and weightless, providing the lateral stiffness of the structure;
4. the effect of soil-structure-interaction (SSI) is taken into consideration with the use of non-linear elastic springs coupled in series with the column stiffnesses of the first floor;
5. the superstructure is considered to remain within the elastic limit during the analysis.

As a result, the superstructure has *n* dynamic DoFs, represented by the relative to the ground displacements of the *n*-story masses m_{Sj} ($j=1, \ldots, n$), as presented in Fig. 2B, which are collected in the array $[u_{Sr}](t)=[u_{Sr1}(t), u_{Sr2}(t), \ldots, u_{Srn}(t)]^T$.

The parameter k_R refers to the coupling of the stiffness of the columns (k_{col}) connecting the foundation of the structure with the first floor together with the stiffness of the foundation system (k_{SSI}) that is derived due to the SSI effects. As a result, the total stiffness of the columns-foundations system is calculated as the k_R of the structure (Eq. 9). More details on the derivation of the k_R and incorporation of the SSI effects are provided in section 3.3 of this paper.

$$k_R = \frac{k_{SSI} k_{col}}{k_{SSI} + k_{col}} \tag{9}$$

The equations of motion Eq. (7) still apply, but now expressed in a matrix form, involving matrices with dimensions $r \times r$ with $r=n+1$:

$$[M][\ddot{u}(t)] + [C][\dot{u}(t)] + [K][u(t)] = -[\tau] a_G(t) \tag{10}$$

where the matrices and vectors entering Eq. (10) are defined as:

$$[K]_{(n+1)\times(n+1)} = \begin{bmatrix} [K_S]_{n\times n} & [0]_{n\times 1} \\ [0]_{1\times n} & [0]_{1\times 1} \end{bmatrix} + \begin{bmatrix} [0]_{(n-1)\times(n-1)} & [0]_{(n-1)\times 1} & [0]_{(n-1)\times 1} \\ [0]_{1\times(n-1)} & k_N + k_R - k_{col} & -k_N \\ [0]_{1\times(n-1)} & -k_N & k_P + k_N \end{bmatrix};$$

$$[C]_{(n+1)\times(n+1)} = \begin{bmatrix} [C_S]_{n\times n} & [0]_{n\times 1} \\ [0]_{1\times n} & [0]_{1\times 1} \end{bmatrix} + \begin{bmatrix} [0]_{(n-1)\times(n-1)} & [0]_{(n-1)\times 1} & [0]_{(n-1)\times 1} \\ [0]_{1\times(n-1)} & c_{UP} & -c_{UP} \\ [0]_{1\times(n-1)} & -c_{UP} & c_{UP} + c_{DOWN} \end{bmatrix}; \quad (11)$$

$$[u(t)]_{(n+1)\times 1} = \begin{bmatrix} [u_{st}]_{n\times 1}(t) \\ u_D(t) \end{bmatrix};$$

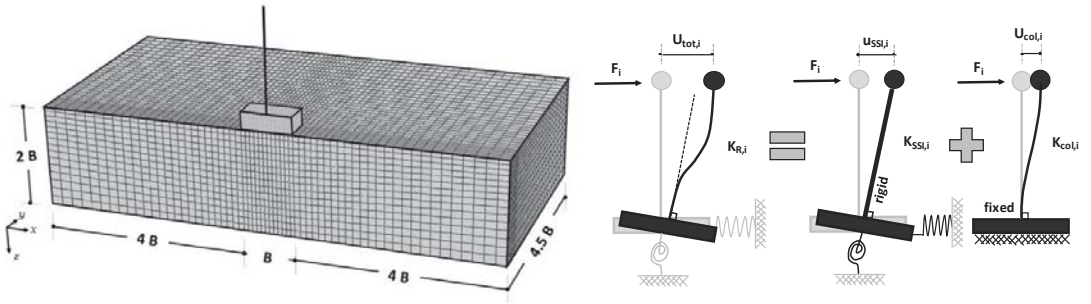
$$[M]_{(n+1)\times(n+1)} = \begin{bmatrix} [M_S]_{n\times n} & [0]_{n\times 1} \\ [0]_{1\times n} & m_D \end{bmatrix}; \; [\tau]_{(n+1)\times 1} = \begin{bmatrix} [M_S][\tau_S] \\ m_D \end{bmatrix}; \; m_{S,tot} = \sum_{i=1}^{n} m_i$$

where $[M_S]$, $[C_S]$ and $[K_S]$ are the n-dimensional matrices of mass, damping and stiffness of the original n-story building and $[\tau_S]$ is the $n\times 1$ influence vector of the superstructure associated with the ground motion $x_G(t)$. The parameter m_S now refers to the total multi-story structure mass and is $m_{S,tot}$ (Eq. (11)). This procedure can also be used in the case the n-story structure is mounted on a conventional or highly damped isolation base by appropriate modification of the matrices in Eq. (10).

3.3 Introduction of Soil-Structure Interaction (SSI) Effects

For the purposes of this study, the EKD is implemented as a vibration absorption technology positioned between the foundations and the first floor of the structure (Ground / 'Pilotis' level). As a consequence, the stiffness k_R (Fig. 2) is the resultant stiffness of both the columns and foundation system and can be expressed as in Eq. (9). The beneficial effect of the Soil-Structure Interaction (SSI) is taken into consideration with the use of non-linear spring stiffnesses (k_{SSI}) coupled in series with the stiffness of the ground floor columns (k_{col}). As a result, the benefits of a softer foundation response can be compared with the conventional approach of a fully fixed model.

The problem is analysed by employing the FE code ABAQUS and a typical foundation and column are modelled in 3D as depicted in Fig. 3A. The soil stratum is considered to be isotropic/homogeneous and modelled using non-linear 8-noded hexahedral continuum elements. The same is applied for the footing which is, however, considered to be elastic (Reinforced Concrete). The column is modelled using linear beam elements and is considered to be fixed on the top of the foundation. The interface between the foundation and the soil is considered to be 'fully bonded' with the foundation elements considered attached to the ground. The boundaries of the model have been strategically selected sufficiently far to avoid spurious boundary-effects on the system response. Static pushover analyses are subsequently undertaken in order to derive the non-linear soil-foundation stiffness relationships (k_{SSI}).



(A) (B)

Figure 3. (A) A view of the ABAQUS 3D FE model for a rigid footing with B=1.5m, (B) A simplified approach to account for the SSI effects (horizontal and rotational stiffness of the soil) for horizontal displacement at the top of each column.

Non-linear soil behaviour and stress-strain relationship is described by a simplified kinematic hardening model that follows a Von Mises failure criterion with associated flow rule. The formulation of this modified Von Mises model is adopted as a subroutine in ABAQUS code and has been parametrised by Gerolymos and Gazetas [29] and Anastasopoulos et al. [30] in order to appropriately simulate the response of clayey materials. Despite its simplicity, this constitutive model has been validated against physical model testing hence ensuring its ability to capture realistically the foundation behaviour and the non-linearity of the soil stiffness.

The foundation system is designed based on the properties and approximate loading of a typical residential 4-storey building as described in Chapter 5 of this paper. To this end, a series of parametric analyses have been conducted by adopting different foundation widths (B) and various material properties (S_u=70, 200 and 300 kPa) resulting in different FoS (Factor of Safety) against vertical loading. On the basis of empirical correlations, the initial, small strain, elastic modulus (E_0) of the soil was considered equal to $1800S_u$ and its non-linear behaviour is simulated realistically by the constitutive relations of the model.

As indicated in Fig. 3B, the equivalent soil-foundation stiffness (k_{SSI}) is calculated assuming a rigid column subjected to horizontal displacement at the top. The height of the column is equal to 3.5m, aligned with the height of the column considered in our case study (Section 5). As a consequence, the calculated stiffness (k_{SSI}), is a result of both the rotational and horizontal displacement of the soil footing and is expressed at the top of the rigid column.

The total stiffness (k_R) of the system can be then calculated as the resultant of the structural column stiffness (k_{col}) and the equivalent stiffness at the top of the beam due to the rotational and horizontal displacement of the footing (k_{SSI}). Results for a few foundation widths (B) and soil profiles that have been considered relevant for the study are presented in Fig. 4 below. The horizontal displacement at the top of the column is plotted against the reaction force (RF) and soil-foundation stiffness (k_{SSI}) respectively. All foundations considered below have a total FoS against vertical loading between 3.5 and 4 thus ensuring the stability of the structure under static loading. For the purposes of the study, the footing geometry selected represents a relatively soft foundation that allows deformation of the soil-foundation system during earthquake excitation as a means to reduce the forces transmitted to the structural members. This design is based on the idea of "rocking" foundations which has been investigated using numerical and physical models by several researchers [31-34].

4 OPTIMIZATION OF THE EKD PARAMETERS

After the equations of motion of the EKD and structural system are derived, the aim is to determine efficient parameters for the proposed configuration in order to achieve an optimized vibration control strategy. As stated in the previous sections, the parameters f_0, k_N, c_{DOWN} and c_{UP} are the free design variables taken into consideration in the optimization problem, while parameters such as the additional damper mass m_D and the stability factors ε_N, ε_P, and ε_R are considered known. For the optimization process, a novel metaheuristic algorithm, harmony search algorithm (HS), is adopted. In this study, the optimization problem is formed according to the seismic design codes. The constraints and objective function are selected from the time-domain responses. The optimisation procedure is described in greater detail in the following sections.

4.1 Selection of Seismic Excitations Compatible to the Seismic Design Codes for the Analysis and Optimization of the EKD

The calculation of structural displacements, velocity and acceleration due to seismic excitation is usually undertaken according to seismic design codes (e.g. EC8) and the design response spectrum. As a consequence, the seismic intensity measures are within specified limits for a system with given properties (fundamental structural period and damping ratio). The parameters that mainly control these limits are the ground conditions, the expected seismic intensity, the damping ratio of the system as well as the fundamental period of the structure.

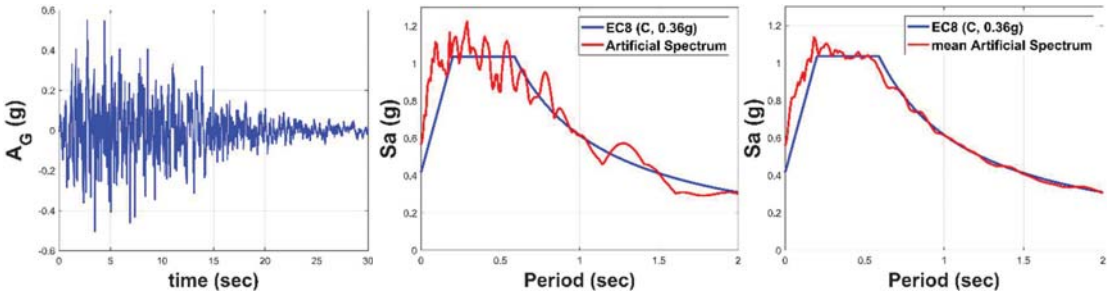
However, the application of such approach and the use of the code's Design Response Spectra for the selection of the extended KDamper parameters, is not considered adequate, since the application of the KDamper leads to MDoF systems with multiple eigenfrequencies. Therefore, analysis in the time-domain is required for the optimal design of the proposed base absorber. Strong earthquake records can be generated from various types of accelerograms such as synthetic records obtained from seismological models, real earthquake excitations and artificial accelerograms, compatible with a specific design response spectrum.

4.2 Generation of Artificial Accelerograms

In this section, a presentation of the details of the generation of artificial accelerograms based on the design response spectra is undertaken. This is a task that has been widely studied by researchers, overviews of which can be found among others in Giaralis and Spanos [35] and Cacciola and D'Amico [36]. For the purposes of this study, the approach followed is based on

generating a sample of artificial accelerograms with acceleration response spectra in accordance with the EC8 design response spectra. Artificial, spectrum-compatible accelerograms are generated using the SeismoArtif Software [37]. In this paper, the Artificial Accelerograms are designed to match the EC8 response spectra incorporating the following seismic properties: ground type C, spectral acceleration 0.36 g, spectrum type I and importance class II.

An artificial accelerogram is illustrated in Fig. 5A, along with its acceleration response spectrum (S_a) (Fig. 4B). A sample of 15 artificial accelerograms is generated and plotted in Fig. 5C along with the EC8 response spectrum for comparison with the design guidelines. An accurate match is observed with the EC8 acceleration response spectrum with characteristics: spectral acceleration 0.36 g, ground type C, spectrum type I and importance class II. More specifically, the percentage deviation is below *10%* in the range of periods from *0.2* to *2* sec, which are considered relevant for the structural performance.



(A) (B) (C)

Figure 5. (A) Artificial Accelerogram, (B) Acceleration response spectrum of Artificial Accelerogram and (C) Mean Artificial acceleration response spectrum of the 15 generated Artificial Accelerograms compared to the EC8 acceleration response spectrum.

4.3 Evaluation of Optimization Constraints and Limitations

The design of the proposed control strategy must be efficient and realistic at the same time. For this reason, proper constraints that refer to the structural dynamic responses and therefore the EKD components must be applied. The structure's first floor drift is set as the objective function (mean of 15 maximum responses). The system is subjected to 15 Artificial Accelerograms generated according to section 4.1, with a mean PGA of *0.519g*.

Furthermore, the given parameters of the system with the EKD, i.e. the additional mass m_D and the stability factors ε_N, ε_P, and ε_R, as well as the limits of the free design variables sought in the optimization problem, f_0, k_N, c_{DOWN} and c_{UP}, must be within reasonable technological capabilities in order for design to be realistic. In particular:

i. In the previous work of KDamper, the stability factor ε_N that relates to the variation of the negative stiffness element k_N, is taken as *5%*. In this study, a variation in all stiffness elements is considered, making the design of the proposed vibration absorption concept rather conservative. The stability factors ε_P and ε_N are selected equal to *10%*, and the stability factor that relates to the stiffness element k_R is selected equal to 25%. The potential 25% stiffness reduction was selected based on an initial linear analysis with the EKD implemented in the structure assuming rigid footing. In this way, the anticipated displacement of the column top was calculated and the expected reduction of the k_{SSI} stiffness due to this deformation was estimated (approximately 25%, refer to Fig. 4B).

ii. The purpose of this design is to implement the proposed control strategy for seismic protection of building structures. Since KDamper can be implemented between the floors of structures, there are no strict limitations regarding the additional mass. According to the previous work of KDamper implemented as an Absorption Base (KDAB) of multi-story building structures with the same characteristics, [28], a *5%* additional mass is efficient and realistic.

iii. The negative stiffness element k_N, in the proposed configuration of EKD, is realized with pre-compressed springs. Based on previous indicative designs of KDamper with pre-compressed springs by Antoniadis et al. [12] and Kapasakalis et al. [27], for a total superstructure mass of *300 tn*, a realistic value of k_N is *-34171 kN/m*. In this work, the negative stiffness element absolute upper value is *|30000| kN/m*.

iv. The damping coefficients maximum value is set equal to *600 kNs/m* for the whole configuration (multiple KDamper devices can be implemented), therefore, common linear damping devices can be used.

v. The negative stiffness element stroke ($X_{S\text{-}D}$) is set as a constraint, with an upper limit value of *15 cm* which, based on previous work of Kapasakalis et al. [25], proves to be a realistic value for the design of the negative stiffness element with pre-compressed springs.

Finally, the limits of the free design variables are: 1) the nominal KDamper frequency f_0 (*Hz*) [*0.15 1.5*], 2) the negative stiffness element k_N (*kN/m*) [*-30000 -1*] and 3, 4) the damping coefficients c_{DOWN} and c_{UP} (*kNs/m*) [*1 600*].

5 NUMERICAL CASE STUDY ON A TYPICAL 4-STOREY STRUCTURE

A numerical case study has been conducted considering a 4-storey typical residential building. The structural system has 4 dynamic DoFs represented by the relative displacements of the 4 storeys with respect to the ground. The elastic modulus of reinforced concrete (assuming long-term cracked conditions) is equal to E=26 GPa. The mass of the building is considered to be concentrated at the floor levels, with m_i=80000 kg denoting the mass of the 4 storeys (i=1,…,4), while the columns are assumed to be weightless.
The superstructure's damping coefficients are mass and stiffness proportional (Rayleigh damping), with ζ_{Si}=0.02 (i=1,…,4).

The geometry of the model is presented in Fig. 6 below. A 15x15m floor in plan-view has been considered with 0.3x0.3m square columns. Analysis for different foundation widths (B) and soil material properties has been undertaken and results for a single case are presented herein. Therefore, the material under investigation has an undrained shear strength equal to S_u=70 kPa and a G_0=53 MPa. The footing width (B) is considered as 1.50m and a total FoS against vertical loading equal to 3.8 is calculated, hence ensuring the static stability of the system. For more details regarding the selection of the material properties refer to Section 3.3.

The soil-structure interaction is regarded in the excitation analysis as explicitly detailed in section 3 of this paper and the parameters of the EKD are optimized based on the methodology described in section 4. A Matlab-based code is incorporated to model the structure and extended KDamper system as a series of masses and springs; linear and non-linear representing the structural elements and soil-foundations respectively. A number of artificial and real seismic excitations are subsequently applied and the response of the structure is investigated. Results of the analysis are presented in Fig. 6 and Table 1 below.

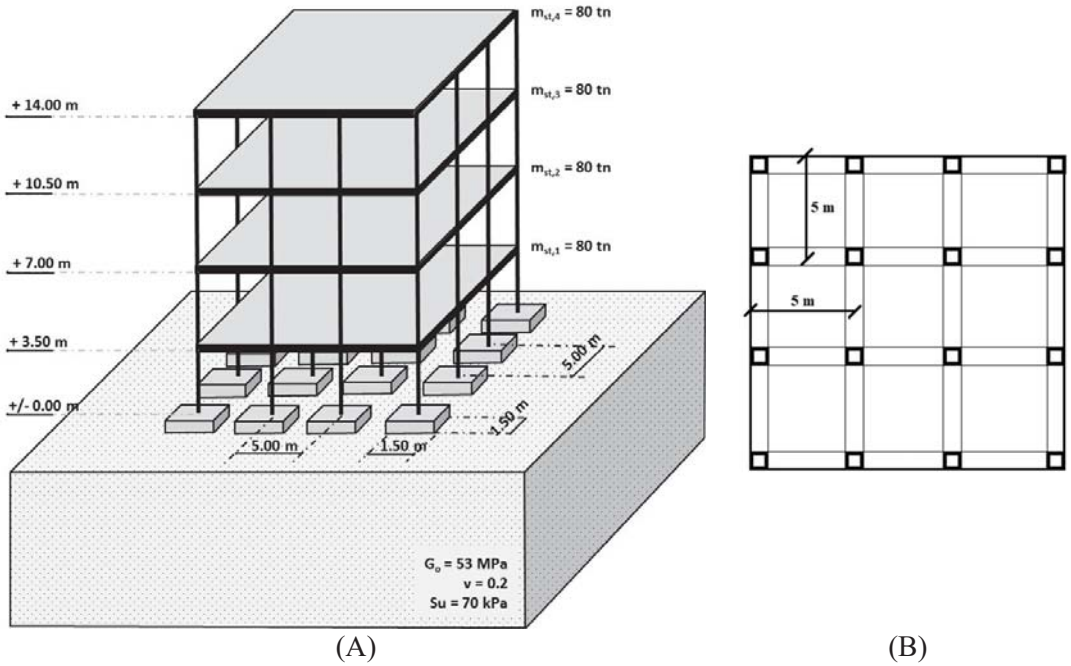


Figure 6 (A) Typical 4-storey residential building investigated as a case study, (B) Plan view of a typical floor of the building considered in this case study.

Structural System	Ensemble of 15 artificial accelerograms, PGA = 0.24 g					L'Aquila (2009), PGA = 0.40 g				
	$a_{s,4}$ (*g*)	$u_{s,1}$ (*cm*)	$u_{col,1}$ (*cm*)	$u_{SSI,1}$ (*cm*)	V_b (*kN*)	$a_{s,4}$ (*g*)	$u_{s,1}$ (*cm*)	$u_{col,1}$ (*cm*)	$u_{SSI,1}$ (*cm*)	V_b (*kN*)
Building with fixed footings	1.18	3.91	3.91	-	2,540	1.13	2.35	2.35	-	1,527
Building with SSI footings	1.08	6.67	2.02	4.65	1,310	0.89	5.72	1.85	3.88	1,204
Building with KDamper & fixed footings	0.35	3.32	3.32	-	640	0.29	3.60	3.60	-	745
Building with KDamper & SSI footings	0.29	3.29	1.36	1.93	518	0.29	4.50	1.61	2.90	400

Table 1: Dynamic response of the four examined residential building systems (with fixed footings, with SSI footings, with KDamper and fixed footings, with KDamper and SSI footings) for an ensemble of 15 artificial accelerograms (mean of 15 max values), and a real near fault earthquake record (L'Aquila, 2009, Mw = 6.3).

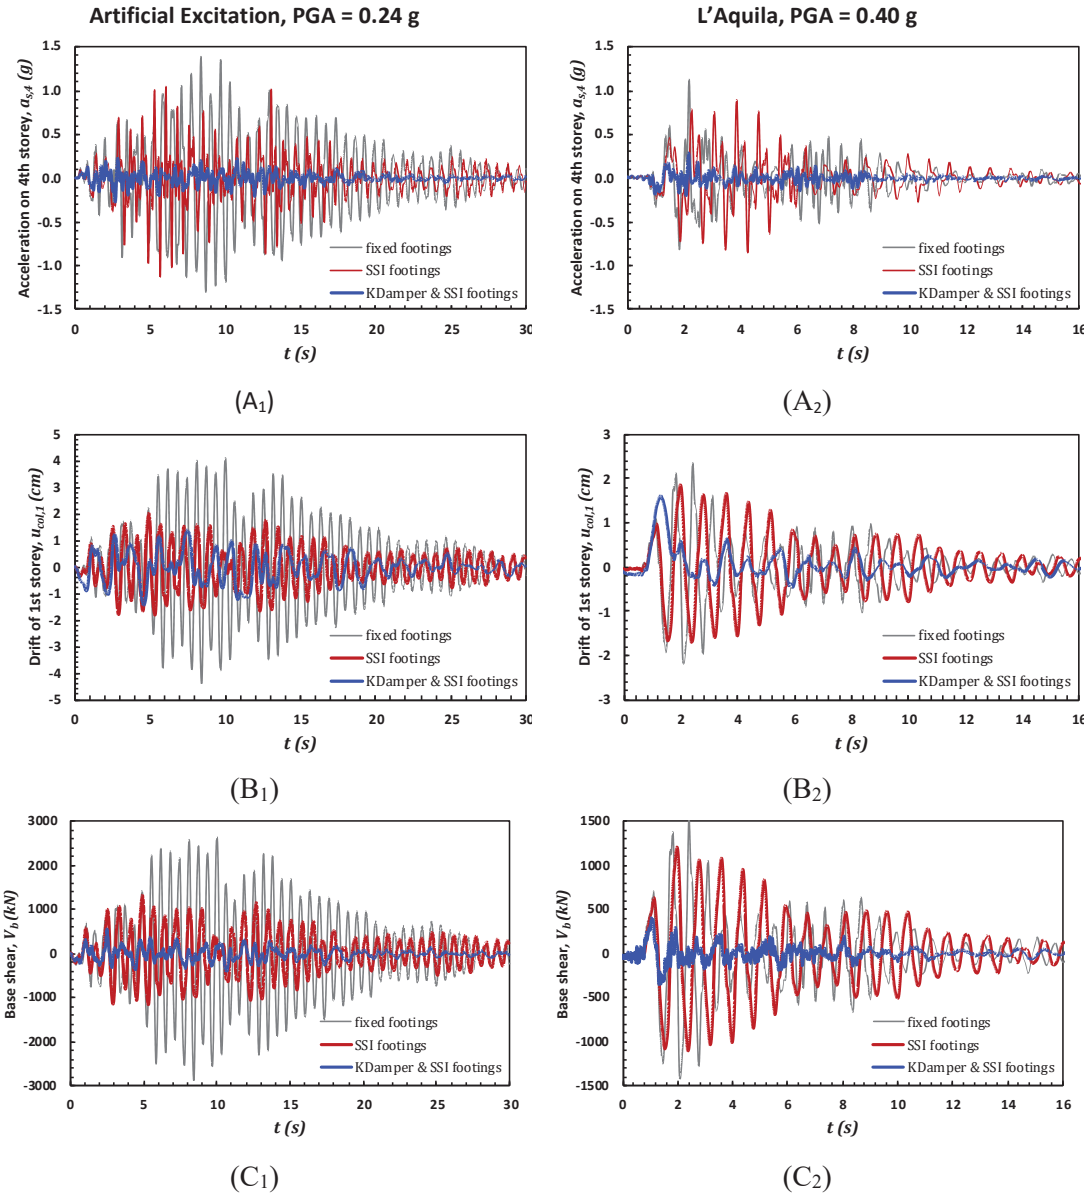

Figure 6. Comparative results in terms of (A) Absolute acceleration of the top storey of the structure (B) Horizontal displacement (drift) of the 1st floor and (C) Base shear-force of the structure for one artificial accelerogram (A_1, B_1, C_1) and the L'Aquila earthquake record (A_2, B_2, C_2) respectively.

A comparison between the response of the structural model considering a) fixed foundations, b) SSI effects by incorporating the non-linear stiffness of the soil and c) the extended KDamper coupled with SSI effects is undertaken for one of the artificial accelerograms (matching the EC8 design spectrum) and a real earthquake excitation. It can be observed that, the application of the extended KDamper along with the SSI effects lead to the main following results:

1. The EKD together with the SSI effects appear to improve the structural response under a dynamic seismic excitation, indicating that the non-linearity of the overall system stiffness parameters does not lead to detuning of the damper;
2. A 40-70% reduction of the absolute acceleration values of the building storeys is achieved, hence remaining within the structural limits;
3. The base shear values appear to be significantly reduced in accordance with the absolute acceleration values;
4. The total horizontal displacement of the first floor is slightly reduced compared to the fixed footings. However, as indicated in Fig. 7 below, due to the rotational and horizontal movement of the foundation the total displacement is distributed between the column and the footing (SSI) and consequently structural flexural displacements are reduced and remain within an acceptable region.

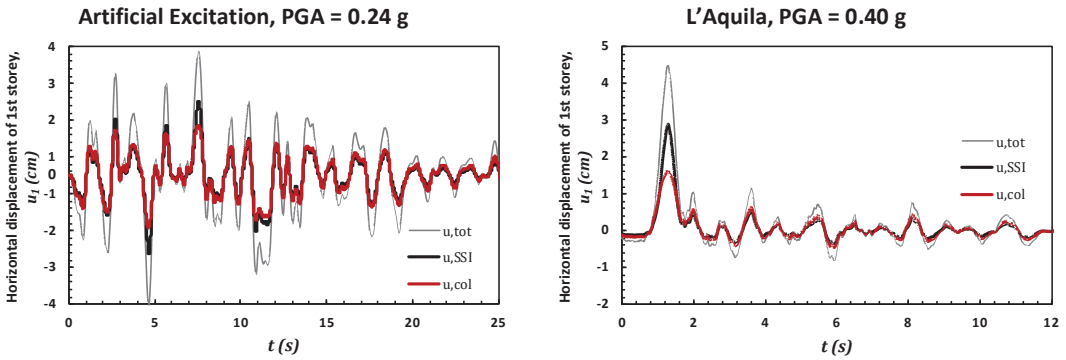

Figure 7. Distribution of the first storey total horizontal displacement due to the flexural deformation of the column (drift) and deformation due to SSI effects (horizontal and rotational movement of the footing), for the case of an artificial accelerogram (A), and the L'Aquila record (B)

As it can be observed in Fig. 7, although the displacement of the first storey for the case of an artificial accelerogram (u_{tot}) reached 3.36 cm, it was distributed both in the column, in the form of flexural deformation (u_{col}), and in the footing, in the form of predominantly rotational, and also translational displacement, due to the SSI effects (u_{SSI}). The maximum flexural deformation was a mere 1.37 cm, which is almost three times lower than the flexural deformation that was demanded in the case of the building with no seismic protection. The 1st-storey displacement is primarily undertaken by the SSI mechanism, meaning that during the shaking, the equivalent soil-foundation stiffness of a single footing 1.50 m x 1.50 m has dropped below the structural column stiffness of a single column, equal to 4,000 kN/m. In general, the distribution of the stiffness in the column-footing-soil system governs the distribution of the deformation in these components. It should be highlighted that for the case of either wider surface footings, or for footings whose rotational and horizontal displacement have been kinematically constrained, as in the case of footings connected with strap beams, the equivalent soil-foundation stiffness of the system increases dramatically, and hence the displacement is not distributed among the column and the foundation. Thus, the total displacement is undertaken by the columns leading to additional loading of the structural elements.

6 CONCLUSIONS

In this paper, the extended KDamper (EKD) is implemented as a seismic protection vibration control system located at the base of a typical building structure. The beneficial effects of soil-structure interaction (SSI) of a relatively soft foundation system along with the EKD as excitation absorber are investigated. An analytical approach for the selection of the EKD parameters aiming to optimize acceleration response, under base excitation, is considered and the initial structural system is introduced along with the vibration absorber concepts. A sample of Artificial Accelerograms with acceleration response spectra compatible to EC8 is generated, and a few real earthquake shaking records are considered. The concept is applied between the foundation system and the first floor of a 4-storey building that is examined as a case study herein. Results show significant reduction of the structural accelerations, drifts and base shear forces, hence placing the concept of a coupled EKD-SSI system as a compelling methodology for seismic protection of structures.

Abstract. *Throughout the last decades, seismic isolation of structures has attracted the attention of civil engineers and scientists. Research around this field has progressed tremendously, starting from the use of simple elastomeric bearings for the decoupling of the superstructure from the foundation and moving towards the invention of more complex devices (characteristic examples being the Tuned Mass Dampers – TMDs or the Quasi-Zero Stiffness oscillators – QZSs) aiming to enhance structural dynamic behavior.*

In this paper, an extension of the KDamper (EKD) concept is proposed, for implementation as a seismic base absorber. The complexity of the EKD renders the conventional minmax (H∞) approach ineffective. For this reason, a constrained optimization problem is proposed for the selection of the optimal system parameters. The EKD is designed according to seismic design codes and the constraints and limitations of the EKD components are evaluated based on engineering criteria. A database of artificial accelerograms, compatible with the EC8 response spectra is generated. Sensitivity analysis is performed, and the effect of detuning is observed.

Based on a comparison with a conventional base isolated system, the EKD manages to retain the structure absolute acceleration at acceptable levels, while the structure relative displacement is drastically reduced, in the order of a few centimeters, rendering the implementation of the extended KDamper feasible using conventional structural elements, without the need for special types of bearing. Thus, EKD can be considered a possible retrofitting option for seismic protection.

1 INTRODUCTION

Seismic design codes for building structures, bridges and industrial facilities have changed with the intention of leading towards better seismic performance. Seismic isolation is perhaps the most popular approach to earthquake-resistant design. Contemporary seismic isolation systems provide horizontal isolation from the effects of earthquake shaking and an energy dissipation mechanism to reduce the large required base displacements, with the latter being the most important drawback of base isolation, as it prohibits retrofitting. Increasing the damping of the base isolation system, to reduce the large displacements, cannot be considered as a mainstream alternative due to the technological requirements and the increase of the inter-story drifts and floor accelerations. Numerous isolation devices have been developed, including elastomeric, frictional/sliding and roller bearings as well as fluid viscous and viscoelastic dampers. In the past few years, however, research focuses on the next generation of seismic protection devices that include: (a) the introduction of negative stiffness elements (Negative Stiffness Devices and "Quazi Zero Stiffness" oscillators) and (b) the implementation of additional masses (Tuned Mass Dampers).

The central concept of negative stiffness isolators is to significantly reduce the natural frequency of the system, lower than the predominant energy-containing frequencies of earthquake ground motions. Quazi Zero Stiffness (QZS) oscillators find numerous applications in seismic isolation [1–10]. The use of additional masses as a passive control strategy (TMDs) has been employed in a variety of systems, with skyscrapers [11–13] and implementations in the bases of structures [14–18], being the most interesting ones. TMDs are effective and reliable, but their usage presents significant drawbacks such as (a) detuning, which deteriorates the system performance, and (b) the need for large additional masses, that render the construction and placement of such configurations difficult.

In order to combine the advantages mentioned previously, without their respective drawbacks, a stiff and stable linear oscillator that incorporates a negative stiffness (NS) element, has been proposed in Antoniadis et al. [19]. The KDamper, first introduced in Antoniadis at al. [20], is essentially an extension of the conventional TMD concept, by the introduction of an appropriate NS element to the additional mass of the TMD. The KDamper is examined for the protection of bridge structure [21–25], Wind Turbines [26,27] and structural systems [28,29]. In addition, the KDamper is implemented as an Absorption Base (KDAB) in the bases of structures [30–36]. In the recent work of Kapasakalis et al. [35], the KDAB is proven to be a possible supplement to BI, or can be alternatively implemented as a "stiff absorption base".

This paper proposes an extension of the KDamper concept (EKD). The optimization problem is formed from which the optimal system parameters are selected. The constraints that refer to the dynamic responses and the limits of the free design variables, i.e. the EKD components, are evaluated base on engineering criteria. For the optimization process, the harmony search algorithm (HS) [37], a novel metaheuristic algorithm, is adopted. The EKD is designed according to seismic design codes. For this reason, artificial seismic excitations are generated, with compatible acceleration response spectra to EC8, using SeismoArtif [38] software. Finally, the system is compared to a conventional base isolated system, designed to have a natural frequency of *0.4 Hz*, in order to prove the efficiency of the EKD. The novel aspects of the innovative passive vibration control strategy developed here are summarized as follows:

i. Extended KDamper (EKD) presents similar/marginally superior results as compared to the previously optimal KDamper concept [35]. However, the proposed EKD foresees variation in all stiffness elements, while in the KDamper concept only the negative stiffness element is examined. Furthermore, the negative stiffness element stroke, which is critical for the whole configuration design, is dramatically reduced.

ii. The evaluation of the optimization constraints is based on engineering criteria. The realization of the additional mass, the damping coefficients and the stiffness elements are within reasonable technological capabilities and render the implementation of the EKD feasible.
iii. The EKD is designed according to seismic design codes. For this reason, the acceleration filter, used in the optimization procedure, is defined by a database of 30 Artificial Accelerograms, design to match the EC8 acceleration response spectra.
iv. The effects of detuning are observed via sensitivity analysis.

In conclusion, the essential features of the EKD design implemented in a SDoF system, as compared to a conventional base isolated system, are summarized as follows:

i. The EKD implemented in a SDoF system manages to retain the structure absolute acceleration in acceptable levels (base on the selected design Acceleration Filter) while at the same time the structure relative displacement is significantly low, as compared to conventional and highly damped base isolation systems.
ii. The small base displacement of the EKD with high Acceleration Filters, render its implementation feasible using conventional structural elements, without the need of special type of bearings. As a consequence, retrofitting is possible.

2 PROPOSED NEGATIVE STIFFNESS ABSORBER

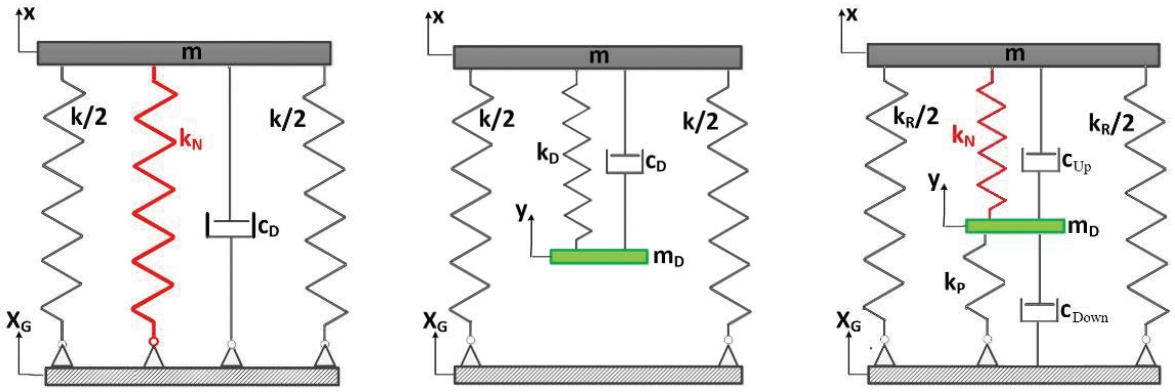

Figure 1: Schematic representation of the vibration absorption concepts considered: (A) Negative Stiffness (NS) isolator, (B) Tuned Mass Damper (TMD) and (C) Proposed Negative Stiffness Absorber (Extended KDamper).

The fundamental concept of the vibration control strategies presented in Figure 1 is to improve the dynamic behavior of an undamped (or low damped) SDoF system of mass m and static stiffness k to a base excitation of $x_G(t)$. The concept of the NS isolator is to add a negative stiffness element k_N in parallel to the original stiffness k of the system so that the overall stiffness of the system becomes $k_{QZS} = k + k_N \leq k$. However, this limits the static loading capacity of the structure. The proposed passive vibration absorption concept, presented in Figure 1.C is an extension of the KDamper (EKD) concept. Similarly to the KDamper, it incorporates a negative stiffness element. Contrary to the NS isolator, the first basic requirement of the EKD is that the overall static stiffness of the system is maintained:

$$k_R + \frac{k_P k_N}{k_P + k_N} = k = (2\pi f_0)^2 m_{total} \tag{1}$$

This way, the EKD overcomes the fundamental disadvantage of the NS isolator. Compared to the TMD (Figure 1.B), the EKD uses an additional negative stiffness element k_N, which

connects the additional mass to the structure, and a positive stiffness element which connect the additional mass to the base. Thus, the equation of motion of the EKD becomes:

$$\begin{gathered} m\ddot{u}_S + k_R u_S + m_D \ddot{u}_D + k_P u_D = -(m+m_D)a_G \\ m_D \ddot{u}_D - c_{UP}(\dot{u}_S - \dot{u}_D) - k_N(u_S - u_D) + c_{DOWN}\dot{u}_D + k_P u_D = -m_D a_G \end{gathered} \tag{2}$$

However, increasing the absolute value of k_N, or decreasing the absolute values of k_P or k_R, may endanger the static stability of the structure. Although theoretically the values of k_N, k_P, and k_R are selected according to Equation (1) to ensure the static stability, due to various reasons, such as temperature variations, manufacturing tolerances, or non-linear behavior, k_N, k_P and k_R may present significant variations in practice, since almost all negative stiffness designs result from unstable non-linear systems. Consequently, an increase of the absolute value of k_N and/or a decrease of the values of k_P *and* k_R by a factor ε_N, ε_P and ε_R, respectively, may result in the system being unstable:

$$(1-\varepsilon_R)k_R + \frac{(1-\varepsilon_P)k_P(1+\varepsilon_N)k_N}{(1-\varepsilon_P)k_P + (1+\varepsilon_N)k_N} = 0 \tag{3}$$

Contrary to the KDamper concept, which foresees variation only in the negative stiffness element k_N, in the proposed extension of the KDamper concept, a variation in all stiffness elements are taken into account. Assuming the negative stiffness ratio $kn=k_N/k_0$ or the absolute value of the negative stiffness element k_N is known, using Equations (1 and 3), the rest of the stiffness elements result:

$$kr = \frac{-b-\sqrt{b^2-4*a*c}}{2a} \Rightarrow KR = kr*k_0 \,;\; kp = \frac{kn-kr*kn}{kr+kn-1} \Rightarrow KP = kp*k_0 \tag{4}$$

Where parameters a, b and c are defined as:

$$\begin{gathered} (1-\varepsilon_R) = R \,;\; (1+\varepsilon_N) = N \,;\; (1-\varepsilon_P) = P \\ a = R(P-N) \,;\; b = kn*N(P-R) + R(N-P) \,;\; c = -P*N*\mathrm{kn} \end{gathered} \tag{5}$$

Finally, assuming that the following parameters are known: A) the additional mass, m_D, and B) the variations ε_N, ε_P and ε_R of the stiffness elements, the unknown parameters of the system are: i) the nominal EKD frequency f_0 (Equation (1)), ii) the negative stiffness ratio kn or the value of the negative stiffness element k_N and iii, iv) the damping coefficients c_{DOWN} and c_{UP}.

3 STATEMENT OF THE OPTIMIZATION PROBLEM

Once the equations of motion of the controlled system with the proposed configuration are stated, the goal now is to determine the "optimal" parameters such that the attained vibration control strategy turns out to be the best possible. As mentioned previously, the parameters f_0, k_N, c_{DOWN} and c_{UP} are the free design variables sought in the optimization problem, while other parameters such as the additional mass m_D and the stability factors ε_N, ε_P, and ε_R are supposed known. For the optimization process, the harmony search algorithm (HS), a novel metaheuristic algorithm, is adopted. In this paper, the optimization problem is formed according to the seismic design codes. The constraints and objective function are selected from the time-domain responses. The procedure from which the earthquake ground motions are selected for the optimization problem is described in section 3.1.

3.1 Selection of earthquake ground motion according to seismic design codes

Seismic design codes indicate that the structure's relative displacement and absolute acceleration, are within specified limits for a system with given characteristics (fundamental structure period and damping ratio). The parameters that mainly control these limits are the ground conditions, the expected seismic intensity, the damping ratio of the system as well as the fundamental period of the structure. A typical form of the so-called "Design Response Spectra" is depicted in Figure 2.

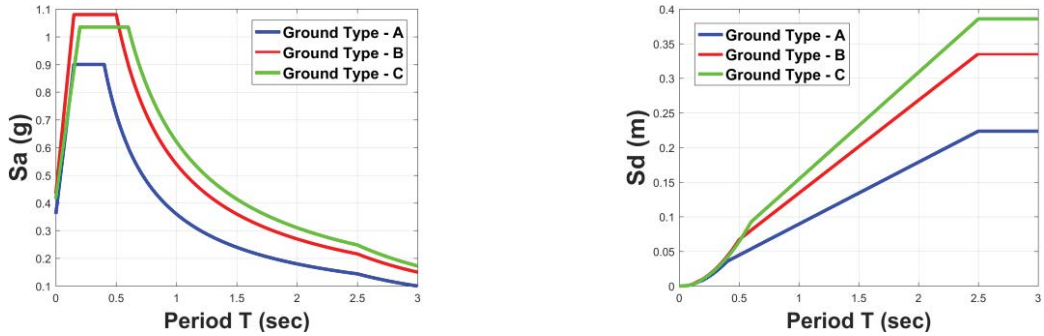

Figure 2. EC8 Design response spectra. (A) Spectral acceleration and (B) Spectral displacement.

However, the application of such approaches for the selection of the EKD parameters, isn't possible, since the application of the EKD leads to MDoF systems with multiple frequencies. Therefore, analysis in the time-domain is required for the optimal design of the proposed base absorber. Strong earthquake records can be generated from various types of accelerograms, the fundamental of which being: synthetic records, real earthquakes excitations, and artificial accelerograms, compatible with a specific design response spectrum, with the latter being the most suitable. For this reason, the approach followed in this paper is based on generating a database of artificial accelerograms, with response spectra closely compatible with the EC8 design response spectra using SeismoArtif Software [38]. In this paper, the Artificial Accelerograms are designed to match the EC8 response spectra with characteristics: ground type C, spectral acceleration 0.36 g and spectrum type I.

In Figure 3.A-B, an Artificial Accelerogram is presented, using the calculation method Artificial Accelerogram Generation and Adjustment, along with its acceleration response spectrum. In Figure 3.C, a comparison of the mean acceleration response spectrum of 30 Artificial Accelerograms with the EC8 design response spectrum is presented. An accurate match is observed. More specifically, the percentage deviation is under *10%* in the range of periods from *0.2* to *2* sec, which is of actual concern.

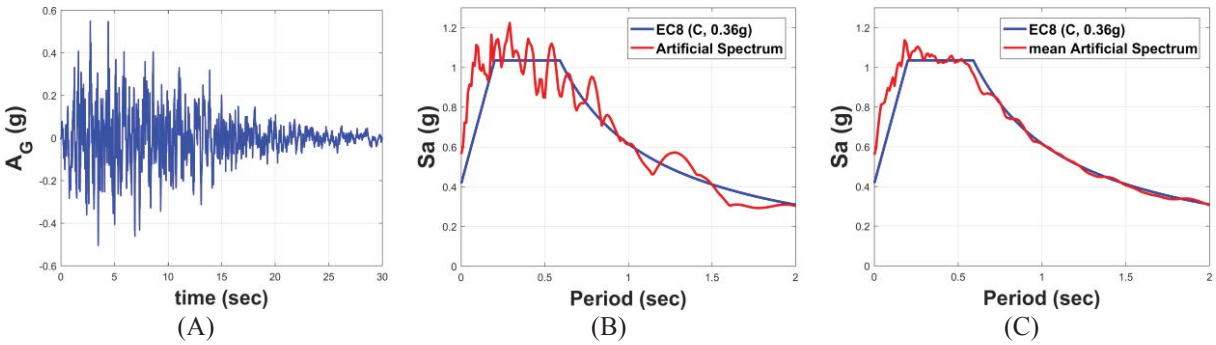

Figure 3. (A) Artificial Accelerogram, (B) response spectrum of Artificial Accelerogram and (C) mean Artificial acceleration response spectrum of 30 Artificial Accelerograms compared to the EC8 response spectrum.

3.2 Evaluation of optimization constraints and limitations

The design of the proposed control strategy must be efficient and realistic at the same time. For this reason, proper constraints that refer to the structural dynamic responses must be applied. More specifically, the system is subjected to 30 Artificial Accelerograms generated according to section 3.1. The relative structure displacement is set as the objective function (mean of 30 maximum responses). In order to better observe the efficiency of the proposed configuration, an acceleration filter is placed. Therefore, each set of optimized parameters of the extended KDamper refers to the maximum structure acceleration, expressed as a percentage of mean PGA. The mean PGA of the 30 Artificial Accelerograms of the database is *0.519g*. Furthermore, the given parameters of the system with the EKD, i.e. the additional mass m_D and the stability factors ε_N, ε_P, and ε_R, as well as the limits of the free design variables sought in the optimization problem, f_0, k_N, c_{DOWN} and c_{UP}, must be within reasonable technological capabilities in order for design to be realistic. In particular:

i. In the previous work of KDamper [17–22], the stability factor ε_N that relates to the variation of the negative stiffness element k_N, is taken as *5%*. In this paper, a variation in all stiffness elements is taken into account, making the design of the proposed vibration absorption concept pretty conservative, since all the stability factors ε_N, ε_P and ε_R are selected as *10%*.
ii. The purpose of this design is to implement the proposed control strategy for seismic protection of structures. Since KDamper can be implemented in the bases of structures, there are no strict limitations regarding the additional mass. According to the previous work of KDamper implemented as an Absorption Base (KDAB) in [30–33,35], a *5%* additional mass is efficient and realistic.
iii. The stiffness elements must be within reasonable technological capabilities. The negative stiffness element k_N, in the proposed configuration of EKD, is realized with pre-compressed springs. Based on previous indicative designs of KDamper with pre-compressed springs by Antoniadis et al. [20] and Kapasakalis et al. [34] (in Greek), for a total superstructure mass of *300 tn*, a realistic value of k_N is *-34171 kN/m*. In this paper, the negative stiffness element is set at least *50%* lower. The same reduction applies to the rest of the stiffness elements, k_R, and k_P.
iv. The damping coefficients maximum value is set *600 kNs/m* for the whole configuration, therefore common linear damping devices can be used.
v. The negative stiffness element stroke ($X_{S\text{-}D}$) is set as a constraint, with an upper limit that of *12 cm*, which based on previous work of Kapasakalis et al. [34] proves to be a realistic value for the design of the negative stiffness element with pre-compressed springs.

Finally, the limits of the free design variables are: 1) the nominal KDamper frequency f_0 (*Hz*) [*0.15 1.5*], 2) the negative stiffness element k_N (*kN/m*) [*-15000 0*] and 3, 4) the damping coefficients c_{DOWN} and c_{UP} (*kNs/m*) [*1 600*].

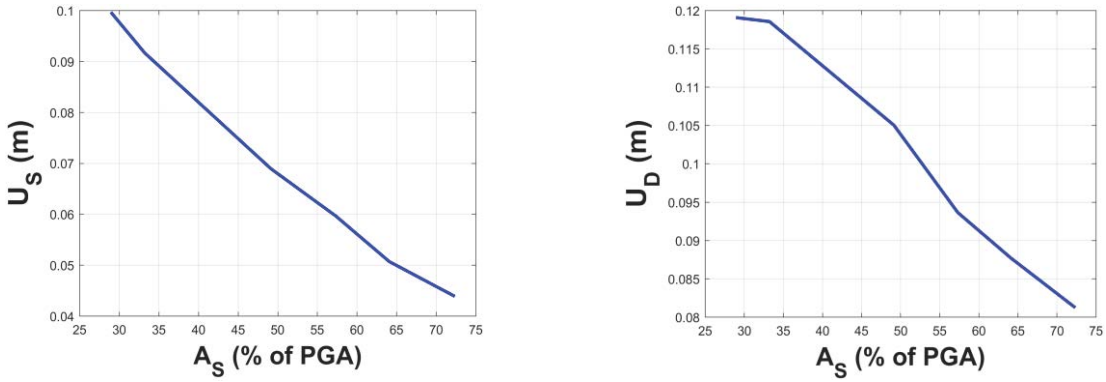
4 DYNAMIC PERFORMANCE

4.1 Optimization curves

Based on the previous, the set of optimized parameters, for a reference structure mass of *300 tn* is presented in Table 1. Each set of optimized parameters refers to the maximum structure acceleration. The extended KDamper (EKD) with Acceleration Filter as a percentage of PGA will be referred hereafter as EKD-*AF (%)*. The system dynamic responses (mean of 30 max values) of the proposed vibration absorption system (EKD) are presented in Figure 4.

Acceleration Filter, *AF*	f_0 (*Hz*)	k_N (*kN/m*)	k_P (*kN/m*)	k_R (*kN/m*)	C_{UP} (*kNs/m*)	C_{DOWN} (*kNs/m*)
30	0.3965	-5815.3	34587	8946	581.3	473.8
40	0.377	-4145.4	16601	7292	590.8	224.4
50	0.664	-9246.7	26575	19664	541.3	91.1
60	0.7287	-8909.3	21968	21591	571.9	262.6
70	0.9857	-14857	34747	38038	517.8	115.6
80	1.02	-12440	25887	36844	577.8	21.5

Table 1: Set of optimized parameters following the procedure described in section 3.2.



(A) (B)

Figure 4: (A) Structure relative displacement and (B) negative stiffness element stroke displacement maximum values over the structure absolute acceleration expressed as a percentage of the mean PGA (Acceleration Filter).

Furthermore, the EKD is compared with the previous optimal design of KDamper, as presented in Kapasakalis et al. [35]. For this reason, two sets of parameters of each concept, that present similar results, in terms of the structure's main dynamic responses, are selected and compared in Table 2.

Set #	System	A_S (*m/sec2*)	% (reduction)	U_S (*m*)	$U_{N.S.}$ (*m*) NS Stroke	ε_i (%)
Set #1	EKD	1.725	66.76	0.092	0.118	$\varepsilon_{N,P,R}=10$
	KDamper in [35]	2.085	59.83	0.093	0.363	$\varepsilon_N=5$
Set #2	EKD	3.755	27.65	0.0439	0.0812	$\varepsilon_{N,P,R}=10$
	KDamper in [35]	3.692	28.86	0.0379	0.163	$\varepsilon_N=5$

Table 2: Comparison of the SDOF system implemented with KDamper, designed in Kapasakalis et al. [35] and EKD proposed in this paper.

4.2 Time histories

In order to observe the efficiency of the EKD, it is compared with a conventional base isolated (BI) system with a damping ratio of *5%*. The BI system is designed to have a natural frequency of *0.4 Hz*. Comparative results between the conventional base isolated system (BI) and the EKD-*30* and EKD-*70*, are presented in Figure 5. The presented time histories relate to an Artificial seismic excitation.

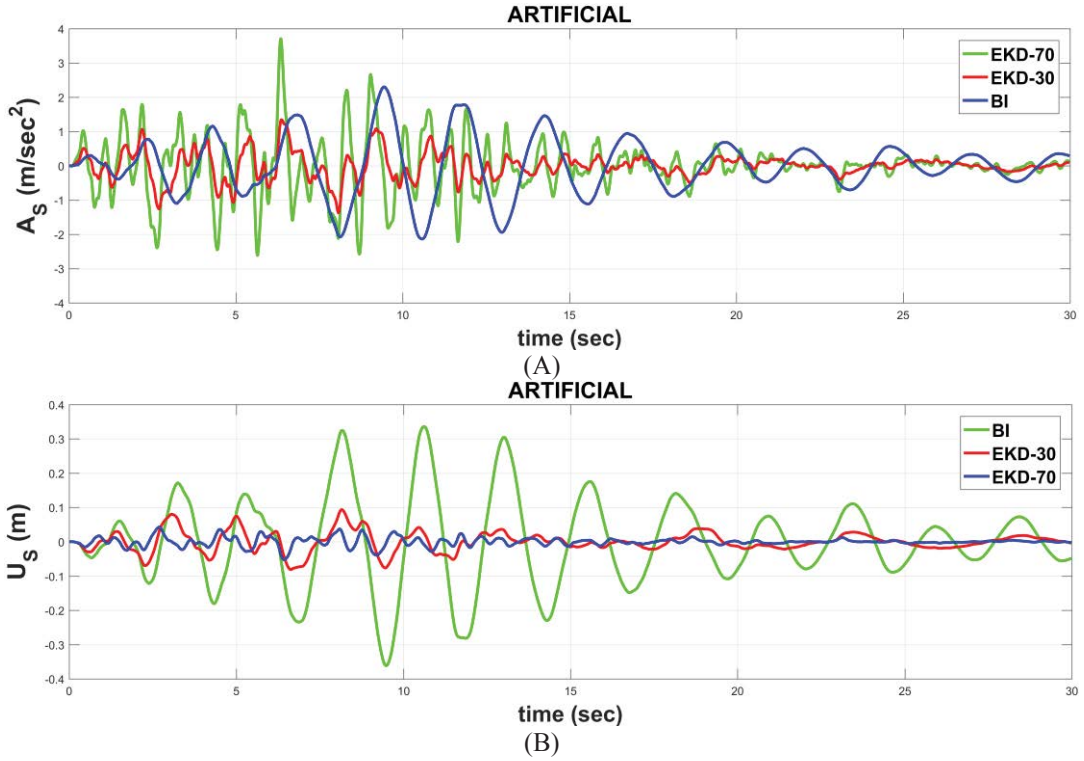


Figure 5: Comparative results, in terms of (A) structure's absolute acceleration (m/sec^2) and (B) structure relative displacement, between the BI, EKD-30, and EKD-70 systems, for an Artificial Accelerogram.

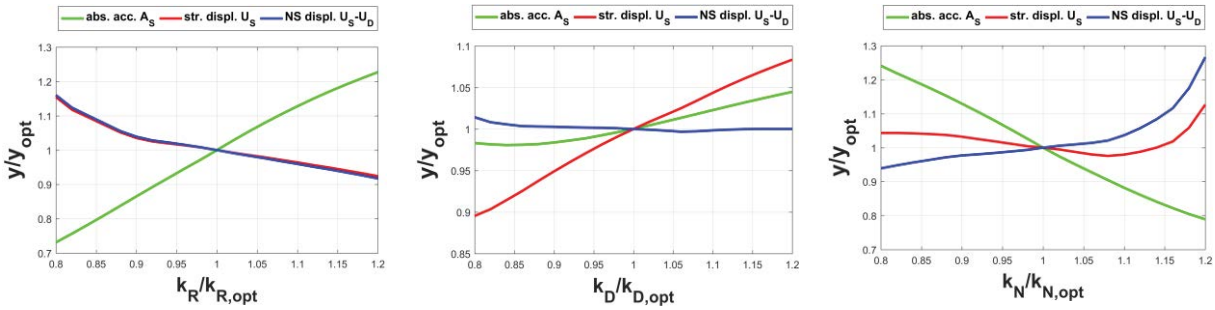
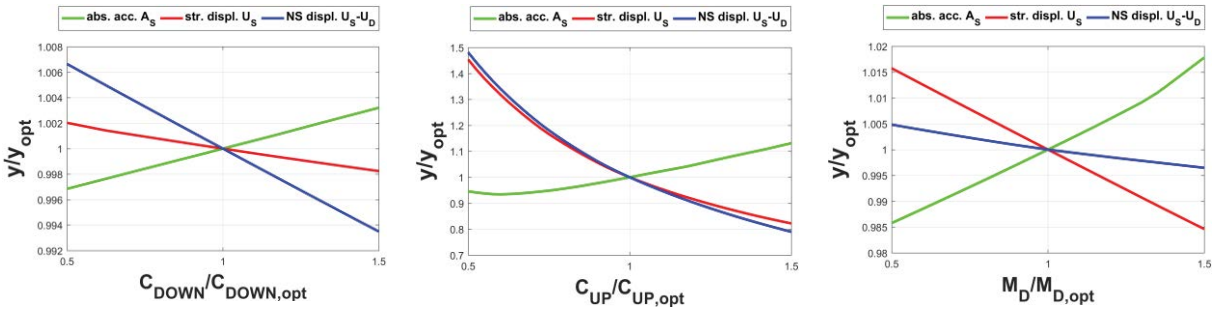
5 EFFECT OF DETUNING

It is important to analyze how the main system responses vary by shifting the optimal EKD parameters from their respective values (effect of detuning). We expect that as the system parameters depart from their optimal values (Table 1), the effectiveness of the proposed passive vibration control strategy decreases. In Figure 6, we observe the effect of detuning of the EKD-*50* set of optimized parameters. The stiffness elements of the EKD are designed to have a *10%* variation as described in section 3 of the paper. In Figures 6.A-C, the system main responses are depicted in a range of *20%* variation of the optimal stiffness elements. Sensitivity analysis reveals that the variation of the stiffness elements k_N and k_R have a greater influence on the system responses, up to *30%*, compared to k_D (up to *10%*). In Figures 6.D-E, we observe that the variation of the damping coefficient that is parallel to the negative stiffness element, k_N, presents an increased influence as compared with the camping coefficient parallel with k_D. Finally, the effect of the variation of the additional mass has no significant influence on the system responses.





(D) (E) (F)

Figure 6: Sensitivity analysis. Main system responses (mean of 30 max values) by varying the system parameters. (A-C) 20% variation of the stiffness elements and (D-F) 50% variation of the damping coefficients and additional mass.

7 CONCLUSIONS

In this paper, an extension of the KDamper (EKD) concept is proposed, for implementation as a seismic base absorber. The optimization problem is stated, from which the optimal system parameters are selected. The evaluation of the optimization constraints is based on engineering criteria, from previous indicative designs of the KDamper implemented as an absorption base. In order to better observe the efficiency of the proposed configuration, an acceleration filter is placed as a constraint. Therefore, each set of optimized parameters of the EKD refers to the maximum structure acceleration, expresses as a percentage of PGA. The EKD is designed according to seismic design codes, therefore a database of artificial accelerograms, compatible with the EC8 response spectra is generated, to define the acceleration filter (AF). Sensitivity analysis is performed, and the effect of detuning is discussed accordingly. A comparison with a conventional base isolated system is then made in order to prove the efficiency of the proposed seismic base absorber (EKD). Finally, the following conclusive comments can be made:

- EKD presents similar/marginally superior results as compared to the previously optimal KDamper concept [35], while it foresees variation in all stiffness elements (ε_N, ε_P, ε_R=*10%*), while in the KDamper concept only the negative stiffness element (ε_N=*5%*) is examined. Furthermore, the negative stiffness element stroke is reduced by *50-67%*, which is critical for the whole configuration design.
- The evaluation of the optimization constraints is based on engineering criteria and render the implementation of the EKD feasible. As compared with previous indicative designs of KDamper, all the stiffness elements are at least *50%* lower. Thus, the realization of the additional mass, the damping coefficients, and the stiffness elements are within reasonable technological capabilities.

- Based on the performed sensitivity analysis, the EKD is not vulnerable to detuning.
- The EKD implemented in a SDoF system manages to retain the structure absolute acceleration at acceptable levels (base on the selected design Acceleration Filter) while at the same time the structure relative displacement is significantly low, as compared to conventional and highly damped base isolation systems (*50%-80%* lower).

Keywords: Piezoelectric Active mount, Isolation System, Transmissibility

Abstract. *This paper presents the simulation of dynamic analysis and performance of a 2-Degree-of-Freedom active vibration isolation system. Vibration isolation is studied on both feedforward and feedback schemes, exploiting their transmissibility reduction capabilities and different effects to the system dynamics. The 2-DoF system is mounted on the isolated structure of interest, while the disturbance is induced through the secondary structure. The two structures are connected with an active mount, where a passive spring-damper element and a piezoelectric actuator are parallelly placed. In feedforward approach, the optimal controller input is calculated a-priori and offline, while in the feedback scheme, LQR and Proportional-Derivative control algorithms are tested and compared. The results demonstrate great vibration suppression capabilities to the structure of interest, as both force transmissibility and displacement are considerably degraded.*

1 INTRODUCTION

Engine induced vibration in means of transportation influences not only the lifetime and reliability of the structure, but also the user comfort and satisfaction. In order to suppress the unwanted vibrations transmitted from the engine to the cabin structure through the connecting mounts, various methods have been developed, which increase the mount isolating capabilities. Conventional passive mounts have been widely used in the past, however their frequency compensation limitations and considerable addition of mass [1] has led to the development of active mounts. Active mounts introduce new requirements to the existing isolation system, such as sensors and external energy in order to induce the appropriate actuating input, however their ability to suppress vibration transmissions at all frequencies have made them very appealing. Among the various types of actuators used in antivibration mounts, such as electromagnetic [2] and hydraulic actuators [3], piezoelectric actuators have gathered most of the scientific interest due to their high force generation, reliability, quick response and minimum energy consumption [4].

For the active vibration isolation to be efficient, the vibration control researcher must choose between various control techniques, including adaptive feedforward control[5], such as LMS, RLS and FxLMS [6], feedback control, such as the Delayed Resonator [7], PID control [8], [9], and LQR [10], and their combinations [11]. Although both feedforward and feedback control schemes have been widely investigated and tested, little literature has been dedicated to exploiting their different interference with the systems dynamics. Moreover, the theoretical approach of vibration transmissibility of 2-DoF vibrating systems has been covered by [12], however no control scheme was taken under consideration. For these reasons, this paper deals with the simple 2-DoF isolation system and explores how the different control approaches affect the system dynamics and transmissibility. For the feedforward scheme, the optimal controller input is calculated a priori and offline, while for the demonstration of feedback control, LQR and Proportional-Derivative control algorithms are taken under consideration. The 2-DoF model is presented in Section 2, while in Section 3, the feedforward and feedback control designs are presented. The different effects of the control algorithms to the system dynamics and disturbance rejection capabilities are illustrated and discussed in Section 4. Section 5 summarizes the main concluding remarks of this work.

2 DYNAMIC 2-DOF MODEL

The 2-DoF model is illustrated in Figure 1a and is simulating a fuselage-engine system, where the isolation system is mounted between the main mass m_1 (fuselage/structure of interest) and the secondary mass m_2 (engine), while the disturbance is induced through the secondary mass m_2 (engine). The active mount connecting the two masses is a system that consists of a passive component of a spring-damper capable to operate solely, and the active part using a linear piezoelectric actuator. The active part operates synergistically with the passive one and is installed parallel to the passive components. The actuator is assumed to have zero damping and contributes only to the stiffness of the mount, introducing an actuating force to the system through the converse piezoelectric effect: $F_{act} = \bar{e}\Delta\varphi$, where $\bar{e}$ is the piezoelectric stress coefficient of the actuator and $\Delta\varphi$ the electric potential applied to the actuator [13], as shown in Figure 1b.

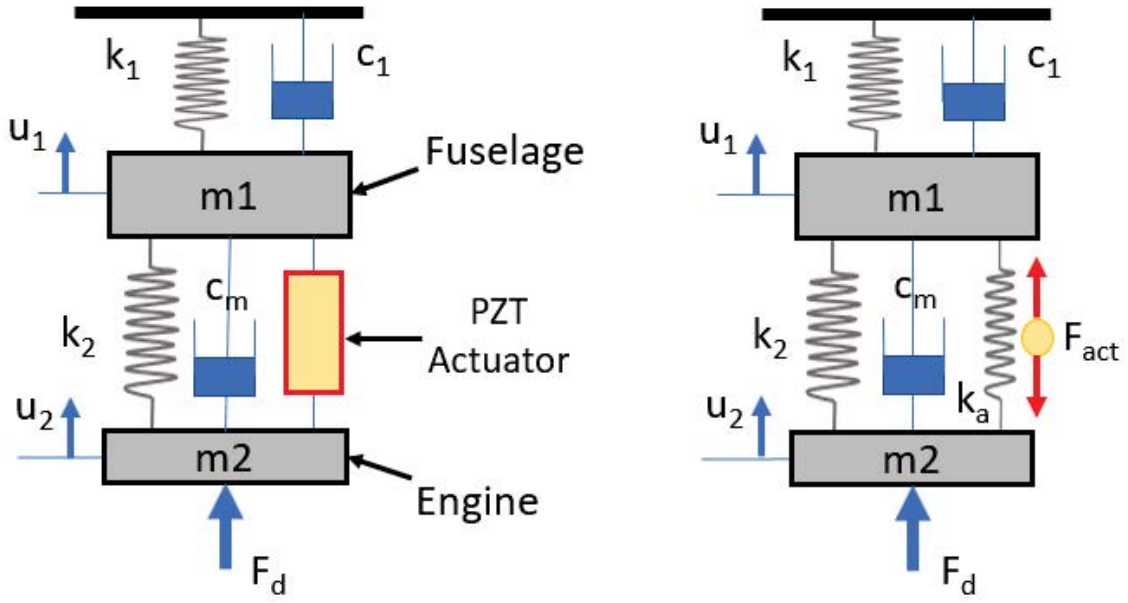

Figure 1: 2-DoF isolation model

Applying equations of motion to each degree of freedom, the dynamic equation that describes the 2-DoF system is presented as follows:

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix}\begin{Bmatrix} \ddot{u}_1 \\ \ddot{u}_2 \end{Bmatrix}+\begin{bmatrix} c_1+c_m & -c_m \\ -c_m & c_m \end{bmatrix}\begin{Bmatrix} \dot{u}_1 \\ \dot{u}_2 \end{Bmatrix}+\begin{bmatrix} k_1+k_m & -k_m \\ -k_m & k_m \end{bmatrix}\begin{Bmatrix} u_1 \\ u_2 \end{Bmatrix}=\begin{Bmatrix} \bar{e}\Delta\varphi \\ F_d-\bar{e}\Delta\varphi \end{Bmatrix} \quad (1)$$

where m_1, m_2 are the main and secondary mass, respectively, $u_1, u_2, \dot{u}_1 \dot{u}_2 \ddot{u}_1 \ddot{u}_2$ are the displacements, velocities, and accelerations of m_1, m_2 respectively, k_1, c_1 are the stiffness and viscous damping of m_1, $k_m = k_2 + k_a$ is the equivalent mount stiffness with k_2 representing the stiffness of the passive mount and k_a the stiffness of the actuator, c_m is the passive mount viscous damping and F_d is the disturbance force. In our case the disturbance is introduced from the engine operation.

Transforming (1) to the frequency domain, we derive:

$$\begin{bmatrix} k_1+k_m+(c_1+c_m)j\omega-m_1\omega^2 & -k_m-c_m j\omega \\ -k_m-c_m j\omega & k_m+c_m j\omega-m_2\omega^2 \end{bmatrix}\begin{Bmatrix} U_1 \\ U_2 \end{Bmatrix}=\begin{Bmatrix} \bar{e}\Delta\varphi \\ F_d-\bar{e}\Delta\varphi \end{Bmatrix} \quad (2)$$

where ω is the angular frequency, U_1, U_2 are the amplitudes of the m_1, m_2 displacements at the corresponding ω and $j = \sqrt{-1}$ is the imaginary number.

The force transmissibility is defined as:

$$T_F(\omega)=\frac{F_1(\omega)}{F_d(\omega)} \quad (3)$$

where $F_1(\omega)$ is the transmitted force to the isolated mass of interest for the frequency ω and is equal to:

$$F_1(\omega)=k_m[u_2(\omega)-u_1(\omega)]+c_m[\dot{u}_2(\omega)-\dot{u}_1(\omega)]-k_1u_1(\omega)-c_1\dot{u}_1(\omega) \quad (4)$$

when no control is applied and

$$F_1(\omega) = k_m[u_{2,contr}(\omega) - u_{1,contr}(\omega)] + c_m[\dot{u}_{2,contr}(\omega) - \dot{u}_{1,contr}(\omega)] \\ -k_1 u_{1,contr}(\omega) - c_1 \dot{u}_{1,contr}(\omega) + F_{act}(\omega) \quad (5)$$

when control is applied. All the X_{contr} terms refer to the controlled values which differ from the baseline results for each angular frequency, due to the existence of $F_{act}(\omega)$.

The model parameters used, are presented in Table 1:

Parameter	Term	Value
Mass [kg]	m_1	30
	m_2	7
Damping [N*s/m]	c_1	143
	c_2	18
Stiffness [n/m]	k_1	$150*10^4$
	k_2	$5.2*10^4$
	k_a	$8.2*10^4$
Disturbance [N]	F_d	5
Piezoelectric Stress Coefficient [N/V]	$\bar{e}$	1

Table 1: System Parameters

3 DESIGN OF CONTROLLER

The control is implemented in State Space. The State Space representation of the isolating system (Plant) is:

$$\dot{x} = Ax + Bu \\ y = Cx \quad (6)$$

where $x = [u_1 \ u_2 \ \dot{u}_1 \ \dot{u}_2]'$: the state vector,
$\dot{x}$: time derivative of x,
u: system input F_{act},
y: system output

$$A = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\frac{k_1 + k_m}{m_1} & \frac{k_m}{m_1} & -\frac{c_1 + c_m}{m_1} & \frac{c_m}{m_1} \\ \frac{k_m}{m_2} & -\frac{k_m}{m_2} & \frac{c_m}{m_2} & -\frac{c_m}{m_2} \end{bmatrix}$$: the state matrix, $$B = \begin{bmatrix} 0 \\ 0 \\ \frac{1}{m_1} \\ -\frac{1}{m_2} \end{bmatrix}$$: the input matrix

C : the output matrix that depends on the control scheme.

3.1 Feedforward Control

The Feedforward Control scheme is presented in Figure 2, where $G_d = {}^1/_{m_2}$.

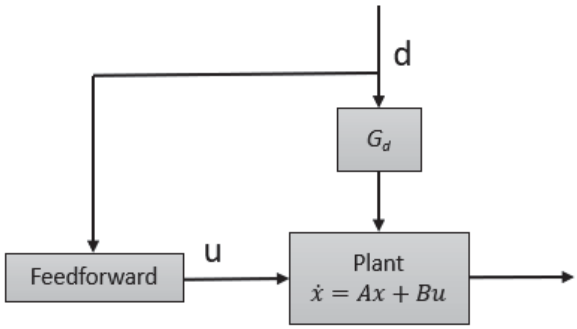

Figure 2: Feedforward Control

In case of a known disturbance d and considering that the control system operates in steady state conditions (i.e. an aircraft or yacht traveling with cruise speed), it is reasonable to compute, offline, a feedforward isolating signal in advance and apply it at an appropriate time [14]. Assuming that, due to the operation of the active force, the remaining disturbance on the main mass is negligible ($U_1 = 0$), the optimal $F_{act} = \bar{e}\Delta\varphi$ and corresponding U_2 can be found for each given combination of ω and F_d by (7).

$$\begin{bmatrix} k_m + c_m j\omega & 1 \\ k_m + c_m j\omega - m_2\omega^2 & 1 \end{bmatrix} \begin{Bmatrix} U_2 \\ \bar{e}\Delta\varphi \end{Bmatrix} = \begin{Bmatrix} 0 \\ F_d \end{Bmatrix} \tag{7}$$

We are performing a forced response of the system (Figure 1), solving the system of Equation (7) for each frequency step in the range of 15-50Hz for a periodic disturbance $F_d = 5sin\omega t$. It can be easily understood that the terms of mass, stiffness and viscous damping corresponding to the main structure do not affect the controller input. Variation of the required actuation Force F_{act} as a function of disturbance frequency is presented in Figure 3, where $f_{n1} = 20.6Hz$ and $f_{n2} = 37.9Hz$ are the 2-DoF system eigenfrequencies. The main observation is that the required actuation force is not related to the system modal characteristics.

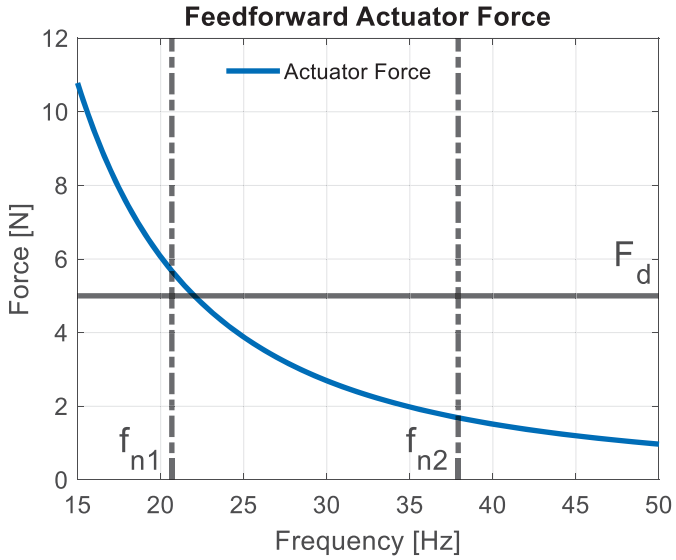

Figure 3: Optimal feedforward input

3.2 Feedback Control

3.2.1 LQR Controller

The Linear Quadratic Regulator Control scheme is presented in Figure 4:

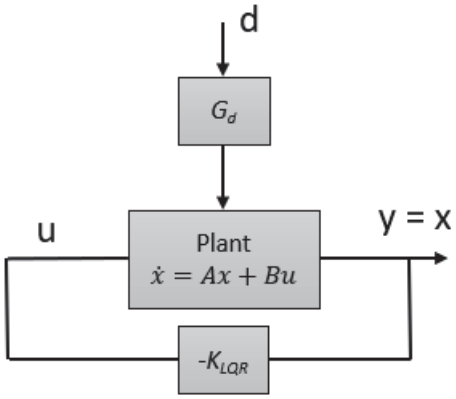

Figure 4: LQR Control

The presented isolation system is controllable: *rank(Ć)=4*, where $\acute{C}$ is the controllability matrix, so if all State Space variables are measured: $C = [1\ 1\ 1\ 1]$, an optimal controller K_{LQR} can be found, utilizing the LQR theory. The term "optimal" here, refers to the minimization of the cost function:

$$J = \int_{t_0}^{t_1} (x^T Q x + u^T R u) dt \tag{8}$$

where *Q* and *R* are positive-definite matrices which represent the weight that penalizes the state vector *x* and the energy cost for input *u*, respectively. The optimal controller K_{LQR} is given by:

$$K_{LQR} = R^{-1} B^T P \tag{9}$$

where the matrix P is found by solving Riccati's equation:

$$A^T P + PA - PBR^{-1} B^T P + Q = 0 \tag{10}$$

The control law that minimizes the cost function *J* is: $u = -K_{LQR} x$, so the State Space expression of the system with the external disturbance will be:

$$\dot{x} = Ax + Bu + G_d d = A(x - BK_{LQR})x + G_d d \tag{11}$$

Moreover, it is assumed that the energy cost of the electric potential is subordinate, so 2 Cases with small weights were taken under consideration: *Case 1: R = 0.001, Case 2: R = 0.0001*.

The vibration reduction of the main mass is more important from the one of the secondary mass, so the state variable weights for *Cases 1 and 2* are chosen as:

$$Q = \begin{bmatrix} 10 & 0 & 0 & 0 \\ 0 & 10 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

3.2.2 PD Controller

Proportional-Derivative control is implemented as shown in Figure 5:

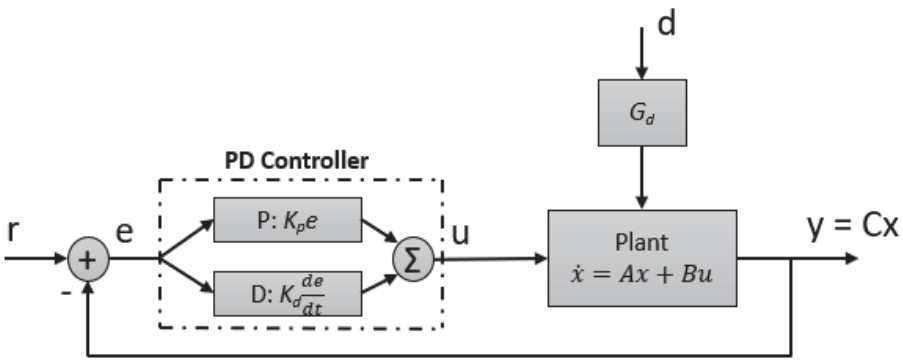

Figure 5: PD Controller

The measured variable here is the displacement of m_1: $u_1 = x_1$, so the output matrix is $C = [1\ 0\ 0\ 0]$. The Integral term from the Proportional-Integral-Derivative PID scheme is neglected, because this term would affect the integral of u_1, which is a parameter with no physical meaning.

The measured output is compared to the reference value r (here $r = 0$) and the error e is calculated and used as input to the PD controller. The output of the controller serves as the isolating input force and is defined as:

$$\begin{aligned} u &= K_p e + K_d \frac{d(e)}{dt} = K_p (r - y) + K_d \frac{d(r - y)}{dt} \\ &= -K_p y - K_d \frac{d(y)}{dt} = -K_p Cx - K_d C\dot{x} \end{aligned} \tag{12}$$

where K_p and K_D denote the proportional and derivative gain, respectively, so the State Space expression of the system with the external disturbance will become:

$$\begin{aligned} \dot{x} &= Ax + Bu + G_d d \\ \dot{x} &= Ax - BK_p Cx - BK_d \dot{x} + G_d d \\ \dot{x}(I + BK_d C) &= (A - BK_p C)x + G_d d \\ \dot{x} &= A'x + B'd \end{aligned} \tag{13}$$

where:

$$\begin{aligned} A' &= (I + BK_d C)^{-1}(A - BK_p C) \\ B' &= (I + BK_d C)^{-1} G_d \end{aligned} \tag{14}$$

are the new state and input matrices, respectively. The selected gains are: $K_p = 2 * 10^6$ and $K_d = -100$.

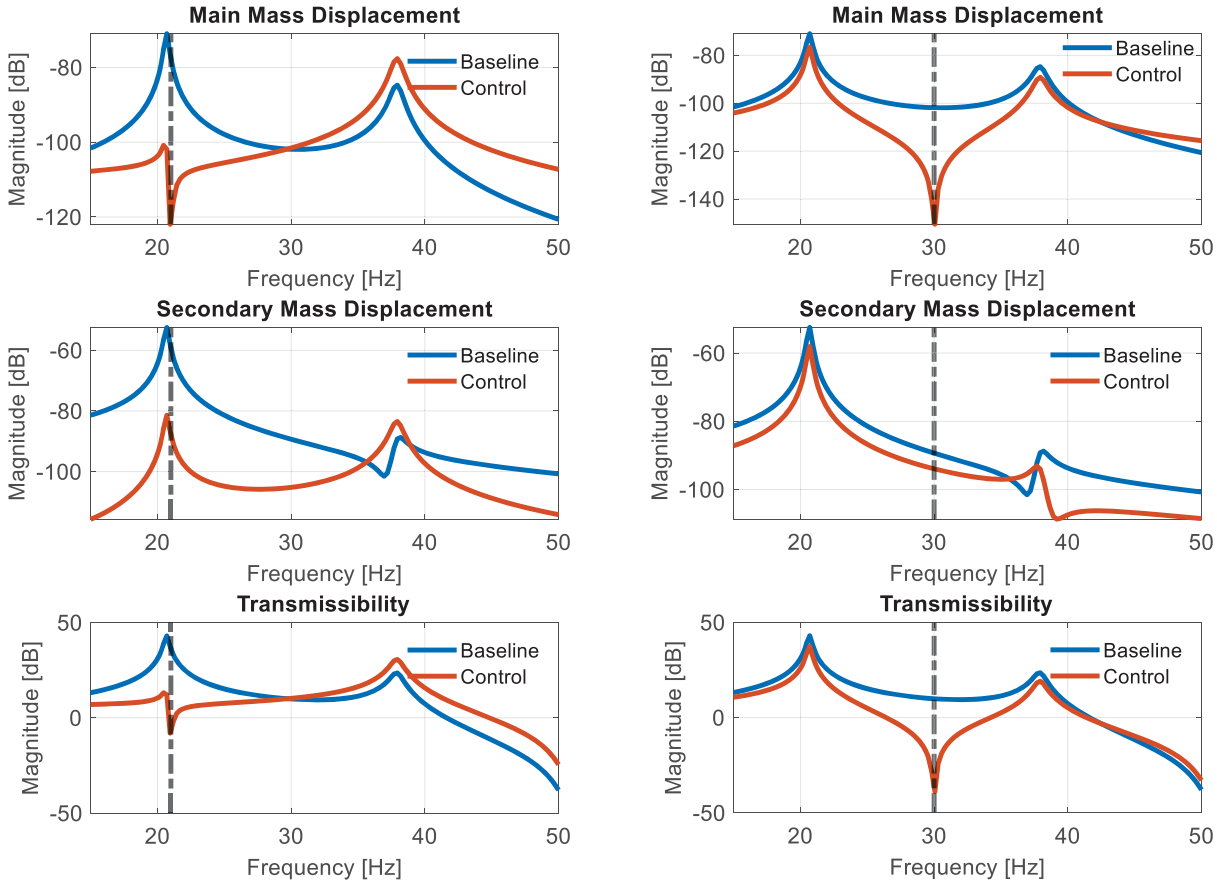
4 ACTIVE ISOLATION SIMULATION AND RESULTS

The simulation was carried out in the frequency domain. The results reveal the vibration reduction capabilities if the applied disturbance is a harmonic excitation at a specific frequency. In order to compare the change in the system dynamics and vibration reduction capabilities of each control mechanism, the displacements of the two masses and the transmissibility

to the main mass are presented with and without control (baseline). Moreover, in order to extract meaningful deductions both near and away from resonance, the analysis focused on 2 frequencies: (1) near resonance: $f_1 = 21Hz$ and (2) away from resonance: $f_2 = 30Hz$.

4.1 Feedforward Results

The vibration isolation is evident for both targeted frequencies, as shown in Figure 6. Drastic reductions are calculated locally at the frequencies of interest. Near resonance (Figure 6a), both main and secondary mass displacements are heavily reduced, resulting to extreme reduction of transmissibility, as well. The targeted frequency away from resonance (Figure 6b) also demonstrates great vibration isolation capabilities, as both main mass displacement and transmissibility show great reductions. Moreover, the displacement of the secondary mass inducing the vibration, is also degraded. Another important remark is the fact that, each calculated actuation force reduces the transmitted vibration not only exactly on the targeted frequency, but in a bandwidth of at least 10Hz. This is a useful result in case of multi-DoF problems, where the system uncertainty is higher, and the system parameters are not fully known. It is easily understood that the feedforward control, as discussed in Section 3.1, heavily interferes with existing system dynamics, dramatically changing the displacement amplitude, as well as the force transmissibility. The dB reductions of transmissibility for each targeted frequency are shown in table Table 2.



a. Focus on 21Hz

b. Focus on 30Hz

Figure 6: Feedforward Control Results

4.2 Feedback Results

The selected parameters of LQR and PD control influence the existing isolation system dynamics in the way that is illustrated in Figure 7. As shown in Figure 7, both LQR Cases do not seem to satisfactory isolate the structure of interest in the whole frequency bandwidth, except for the resonance. This implies that LQR control slightly changes the system dynamics, mainly adding damping to the resonance, so it may not be appropriate for dynamic isolation applications. Furthermore, to implement LQR control, all state variables must be measured, which is not realistic and might be an impossible task for multi-DOF systems.

From the results of Figure 7, it can also be seen that by choosing appropriate controller gains K_p and K_D, the isolation capabilities of PD control can be satisfactory, especially near resonance. K_p and K_D terms change the stiffness and damping system matrices, respectively, shifting the resonance away from its baseline values. As a result, the displacements of both targeted frequencies are reduced in both masses, using the same gains. The transmissibility is affected analogously, meaning that it appears decreased compared to the baseline. However, reduced performance is recorded compared to the feedforward control. Achieved reductions are summarized in Table 2. The bandwidth of the vibration reduction using the existing values of K_p and K_D is over 25Hz.

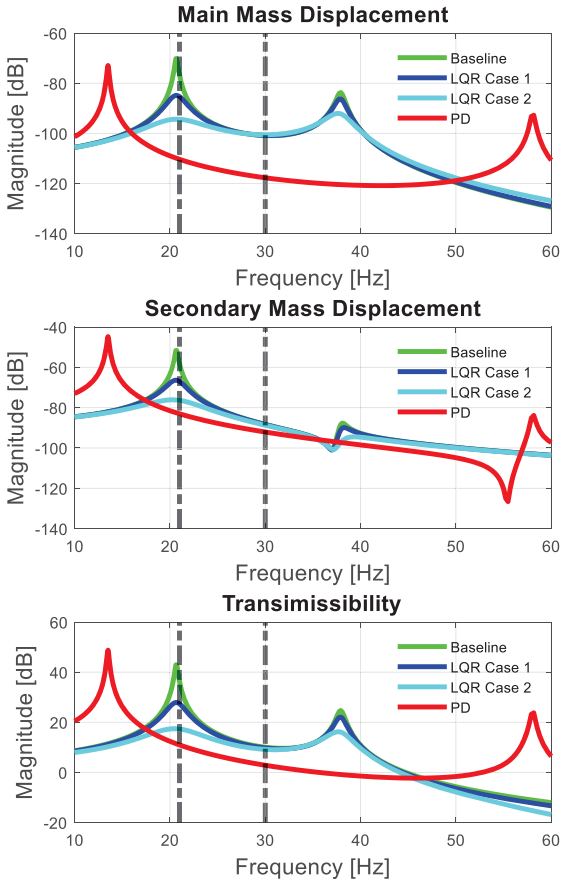


Figure 7: Feedback Control Results

	Control scheme			
	Feedforward		PD Feedback	
Frequency [Hz]	21	30	21	30
dB Reduction	**45**	**47**	**28**	**7**

Table 2: Transmissibility dB Reduction

5 CONCLUDING REMARKS

Current paper investigates with a simple paradigm of a 2-DoF system the concept of eliminating the force transmitted from an operating engine to the fuselage. The proposed antivibration system is based on the development of an active engine mount using piezoelectric device to reduce/ eliminate the transmitted force from the engine to the fuselage. This simple system was selected in order to investigate the dynamic interference and isolating capabilities of two different control algorithms, the feedforward and feedback control. The main contribution of this paper is the demonstration that the proposed feedforward control achieves significant reduction to the transmitted forces at specific frequencies of interest having minimum interference to the studied system modal characteristics. On the other hand, the feedback control interferes with the dynamic characteristics of the system, such as the stiffness and damping matrices, by shifting or damping the existing resonance. The results of displacement and force transmissibility reduction demonstrated better results for the proposed feedforward control. However, this is applicable only in the case that the exact characteristics of the disturbance are a priori known. Going a step forward, combining the two methodologies so that feedforward control simultaneous with feedback input, online calculates the potential change in frequency or amplitude of the disturbance, could lead to a more robust concept of engine vibration isolation.

Keywords: masonry multi-leaf walls, voxel based mesh, limit analysis, homogenization

Abstract. *A recurring construction technique in many European countries (Italy included) is based on the erection of multi-leaf walls. Their seismic vulnerability is usually high, due to the fact that the wythes are poorly or by no means connected one each other. Hence, masonry buildings with multi-leaf walls regularly display an insufficient strength against out-of-plane actions (such as those caused by earthquakes and those causing the highest vulnerability), which leads to partial or total collapse. This paper proposes a novel approach devoted to the out-of-plane analysis of masonry multi-leaf walls at collapse, with special attention given to the case of non-periodic masonry – in which the units display different geometries and are randomly arranged in the walls. This approach is based on the so-called "voxel strategy", in which the 3D finite element mesh of a multi-leaf wall is created directly from the rasterized images of its external wythes. Every pixel of the rasterized images is transformed into its 3D counterpart (the "voxel", indeed), which is then converted into a solid finite element. The "voxel strategy" for generating the finite element mesh is translated into a MATLAB function, which is itself part of a broader limit analysis approach based on the upper bound theorem, that aims at deriving homogenized out-of-plane failure surfaces. These represent macroscopic out-of-plane strength criteria for the selected non-periodic multi-leaf masonry walls; they are expressed in terms of flexural and torsional moments around the horizontal and vertical axes of the considered wall. The approach also enables the extraction of the deformed shapes at collapse for single out-of-plane load conditions. The homogenized out-of-plane failure surfaces are the results of an upper bound limit analysis problem coupled with homogenization, aptly formulated as a standard-form linear programming problem. The solid finite elements of the created mesh are rigid, and the velocity jumps at the interfaces between adjacent finite elements obey a Mohr-Coulomb failure criterion with separate tension and compression cut-offs and associated flow rule. A case study is investigated to benchmark the procedure, namely a rubble masonry three-leaf wall with absente interconnection between leaves.*

1 INTRODUCTION

Multi-leaf walls are quite common in the architectural heritage of several European countries. They are usually structured as follows: two external wythes (called also layers) of masonry are erected, leaving a thinner in-between void that is later filled with loose material (e.g. stone chips) or low-quality mortar. Multi-leaf walls are often characterized by a rate of transversal interconnection among the wythes that is either very poor or wholly absent most of the times. This entails an insufficient resistance against out-of-plane actions: the outer wythe is often ejected, weakening the construction up to the point where its partial or even total collapse is a very likely occurrence. Unfortunately, in historical masonry buildings the presence of multi-leaf walls is only revealed after the local or global failure of the structure. On the left, it is possible to observe the ejection of the external wythe caused by the seismic action, although in this case the building is still standing. On the right, it is possible to observe that the inner wythe of the multi-leaf wall is basically absent, suggesting a total lack of transversal interconnection between the outer wythes. At present, very few papers are available with the study of multi-leaf masonry walls (they are equally subdivided between experimental [1]-[4] and numerical approaches [5]-[8]), due to the complexity that is typical of this kind of walls, therefore it is very difficult to employ micro- or macro-modelling approaches. In general, these walls are characterized by peculiar geometries and units' arrangements that make each of them a unique instance; an extremely refined analytical model at the microscale is then required, which would make any numerical analysis very cumbersome and computationally unfeasible. On the other hand, it is also very difficult to properly investigate the mechanical properties of the masonry constituents in these walls, not to mention the impossibility to run extensive and effective experimental tests, thus ruling out any possibility of defining a reliable macroscale model for such kind of masonry. Eventually, assessing the actual rate of transversal interconnection between adjacent layers represents another delicate issue to be addressed for these walls.

The pairing of homogenization and limit analysis seems to offer once more an acceptable solution to all the aforementioned issues; this is especially true when considering the fact that in many cases it is paramount to only assess the out-of-plane behavior at collapse of these walls in a swift and straightforward way, and limit analysis with a homogenized approach is potentially a very powerful tool in this sense.

Therefore, this paper presents a homogenized limit analysis model aiming at investigating the out-of-plane collapse behavior of non-periodic multi-leaf masonry walls, which is a novelty due to the substantial lack of dedicated models in this regard. Specifically, the out-of-plane collapse behavior is addressed by extracting out-of-plane homogenized failure surfaces for the multi-leaf walls, which actually represent out-of-plane macroscopic strength criteria for the considered wall. The out-of-plane kinematics of the multi-leaf wall is governed by a Kirchhoff-Love plate model; each wythe of the wall is provided with its own average strain rate tensor components, whereas a single average curvature rate tensor is introduced for the wall. The out-of-plane homogenized failure surfaces are derived from the solution of a mixed limit analysis-homogenization problem, written into a MATLAB script as a standard-form linear programming problem; a custom-built post-processing phase enables also the extraction of the deformed configurations at collapse ("failure modes") for the considered multi-leaf wall.

The representative element of volume, irregular both in plane and along the thickness, is meshed by means of a very refined voxel-based discretization where dissipation is allowed at the interfaces between voxels. Interfaces, where all plastic dissipations occur, behave following a cohesive-frictional failure criterion with limited tensile strength and cap in compression. Such homogenization approach has been first applied to random one-leaf masonry in [9][10] with a

2D pixel discretization, then extended with simple on-thickness integration to multi-leaf masonries in [11]-[12], finally changed in a more complex voxel procedure applied first to periodic masonry in- and out-of-plane loaded in [13] and to rubble masonry in [14]-[17]. In these last attempts, it is stressed how the representative element of volume was discretized by means of voxels. Conversely, here it is worth mentioning that the novelty of the numerical procedure here discussed stands in the generalization of the voxel approach to three-leaf masonry with external leafs constituted by the irregular assemblage of stones/blocks. The possibility of a partial interlocking among leafs is in principle accounted for and any configuration of the blocks both externally and along the thickness can be easily taken into account by means of the discretization into small voxels.
This paper is structured as follows: Section 2 offers a short presentation of the upper bound limit analysis problem with homogenization as formulated for the present application, including a short overview of the kinematic model here used as well as the several constraints required in the linear programming problem. Section 3 presents a preliminary numerical application of this model, consisting of a three-leaf rubble masonry wall. The effects on the out-of-plane collapse behavior coming from the possible presence of separate but similar masonry bonds in the outer wythes is finally investigated.

2 HOMOGENIZATION PROBLEM FORMULATION IN CASE OF MULTI-LEAF WALLS

This section presents very concisely the bases of the mathematical formulation of the homogenized limit analysis problem, used to derive out-of-plane homogenized failure surfaces for multi-leaf masonry walls Such formulation requires the definition of a kinematic model that accounts for the presence of different layers.

Analogous to the single leaf-case [10][13][14], a representative element of volume REV large enough to account for the irregular disposition of the stones in the leaf is a-priori selected, in the same way done for irregular textures made by only one leaf. Then, each leaf is meshed into rigid-infinitely resistant voxel finite elements with dissipation at the interfaces between contiguous voxels, behaving as Mohr-Coulomb interfaces. One of the main advantages is to deal exclusively with interfaces parallel to the material axes frame of reference. A standard linear programming problem is then written and solved to estimate homogenized failure surfaces. Full details of the numerical implementation for single leaf irregular textures –not reported here for the sake of conciseness- can be found in [10][13][14], where the reader is referred for further details.

The main difference with respect to the single-leaf formulation lies in the definition of separate average strain rate tensors for each wythe; conversely, the average curvature rate tensor is still unique for all the wythes. This modification is enforced to reproduce separate in-plane behaviors for each wythe, as is usually the case in multi-leaf walls where the wythes are not so well connected; the use of a single average curvature rate tensor for all the wythes instead represents a simplification of the out-of-plane behavior, for which the multiple wythes cannot bend differently with respect to each other, therefore removing the possibility of disconnection between the wythes along the out-of-plane direction (in this case, axis Z). Even though multi-leaf walls in general do not behave as sandwich structures, it is also well known that their inner core usually consists of either loose materials such as stone chips or materials that display poor mechanical properties. Therefore, it is totally reasonable to suppose that there is no actual contact between the outer wythes and the inner core, which justifies the simplifications adopted in the present formulation.

The difference between the single- and multi-leaf formulation is displayed in Figure 1, where the macroscopic quantities involved in each case are highlighted.

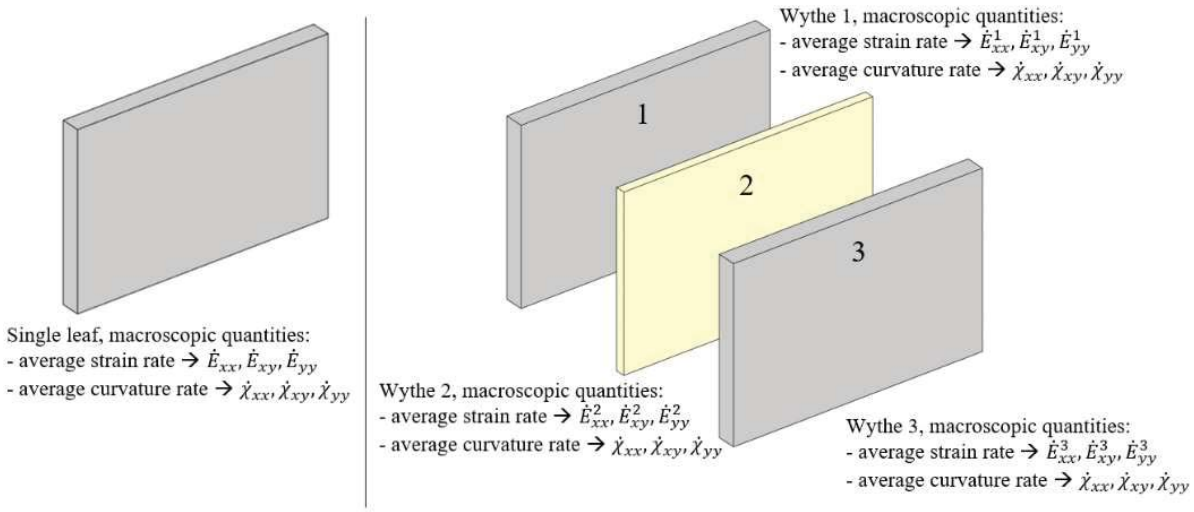

Figure 1: Difference in terms of macroscopic quantities between the single-leaf (left) and multi-leaf case (right).

Since each voxel of the multi-leaf wall is rigid and bereft of rotation rate, its kinematics is fully determined by the displacement rate field of its centroid $\{\dot{u}_x, \dot{u}_y, \dot{u}_z\}$, where axis Z represents the transversal direction. The use of a Kirchhoff-Love plate model leads to the following expressions for the three components of the displacement rate field, written for each wythe in the general case of a three-leaf masonry wall:

$$\dot{u}_x = \dot{u}_{x,per} + \dot{E}^1_{xx} x_G + \dot{E}^1_{xy} y_G + \dot{\chi}_{xx} z_G x_G + 0.5 \dot{\chi}_{xy} z_G y_G \tag{1}$$

$$\dot{u}_y = \dot{u}_{y,per} + \dot{E}^1_{xy} x_G + \dot{E}^1_{yy} y_G + \dot{\chi}_{yy} z_G y_G + 0.5 \dot{\chi}_{xy} z_G x_G \tag{2}$$

$$\dot{u}_z = \dot{u}_{z,per} - 0.5 \dot{\chi}_{xx} {x_G}^2 - 0.5 \dot{\chi}_{yy} {y_G}^2 - 0.5 \dot{\chi}_{xy} x_G y_G \tag{3}$$

$$\dot{u}_x = \dot{u}_{x,per} + \dot{E}^2_{xx} x_G + \dot{E}^2_{xy} y_G + \dot{\chi}_{xx} z_G x_G + 0.5 \dot{\chi}_{xy} z_G y_G \tag{4}$$

$$\dot{u}_y = \dot{u}_{y,per} + \dot{E}^2_{xy} x_G + \dot{E}^2_{yy} y_G + \dot{\chi}_{yy} z_G y_G + 0.5 \dot{\chi}_{xy} z_G x_G \tag{5}$$

$$\dot{u}_z = \dot{u}_{z,per} - 0.5 \dot{\chi}_{xx} {x_G}^2 - 0.5 \dot{\chi}_{yy} {y_G}^2 - 0.5 \dot{\chi}_{xy} x_G y_G \tag{6}$$

$$\dot{u}_x = \dot{u}_{x,per} + \dot{E}^3_{xx} x_G + \dot{E}^3_{xy} y_G + \dot{\chi}_{xx} z_G x_G + 0.5 \dot{\chi}_{xy} z_G y_G \tag{7}$$

$$\dot{u}_y = \dot{u}_{y,per} + \dot{E}^3_{xy} x_G + \dot{E}^3_{yy} y_G + \dot{\chi}_{yy} z_G y_G + 0.5 \dot{\chi}_{xy} z_G x_G \tag{8}$$

$$\dot{u}_z = \dot{u}_{z,per} - 0.5 \dot{\chi}_{xx} {x_G}^2 - 0.5 \dot{\chi}_{yy} {y_G}^2 - 0.5 \dot{\chi}_{xy} x_G y_G \tag{9}$$

Where (1)-(3) refers to wythe 1, (4)-(6) to wythe 2, (7)-(9) to wythe 3, $\{\dot{u}_{x,per}, \dot{u}_{y,per}, \dot{u}_{z,per}\}$ is the periodic velocities of the element, $\{\dot{E}^t_{xx}, \dot{E}^t_{xy}, \dot{E}^t_{yy}\}$ are the components of the average in-plane strain rate tensor of each t-th wythe of the multi-leaf wall and $\{\dot{\chi}_{xx}, \dot{\chi}_{xy}, \dot{\chi}_{yy}\}$ are the components of the average curvature rate tensor (with $\dot{\chi}_{yx}$ equal to $\dot{\chi}_{xy}$ for symmetry). In com-

pliance with the hypothesis of a Kirchhoff-Love plate model, such kinematics satisfies the requirements of $\dot{\chi}_{xx} = -\frac{\partial^2 \dot{u}_z}{\partial x^2}$, $\dot{\chi}_{yy} = -\frac{\partial^2 \dot{u}_z}{\partial y^2}$, and $\dot{\chi}_{xy} = -2\frac{\partial^2 \dot{u}_z}{\partial x \partial y}$.. When compared with a classic homogenization problem, the novelty is that a different in-plane average strain rate tensor is enforced in the different leaves (3 in this case), so the total number of macroscopic unknowns is here equal to 12, namely 9 in-plane macroscopic strain rates $\{\dot{E}^1_{xx}, \dot{E}^1_{xy}, \dot{E}^1_{yy}, \dot{E}^2_{xx}, \dot{E}^2_{xy}, \dot{E}^2_{yy}, \dot{E}^3_{xx}, \dot{E}^3_{xy}, \dot{E}^3_{yy}\}$ and 3 curvature rates $\{\dot{\chi}_{xx}, \dot{\chi}_{xy}, \dot{\chi}_{yy}\}$, instead of the classic 6 components originally included in the single-leaf formulation.

A master-slave formulation is also adopted to reduce the computational effort, which consists in considering the stones/blocks infinitely resistant, i.e. assuming only 6 kinematic unknowns for all the voxels belonging to the same stone. The relations that link the kinematic field of a single finite element and that of the masonry unit to which it belongs, are the following:

$$\dot{u}^S_x = \dot{u}^M_x + \dot{\theta}^M_{yy}(z^S_G - z^M_G) \tag{10}$$

$$\dot{u}^S_y = \dot{u}^M_y - \dot{\theta}^M_{xx}(z^S_G - z^M_G) \tag{11}$$

$$\dot{u}^S_z = \dot{u}^M_z + \dot{\theta}^M_{xx}(y^S_G - y^M_G) - \dot{\theta}^M_{yy}(x^S_G - x^M_G) \tag{12}$$

Where $\dot{u}^M_x$, $\dot{u}^M_y$, and $\dot{u}^M_z$ are the components of the displacement rate field of a generic masonry unit (the "master element", superscript M) expressed according to Eqs. (1)-(9), x^M_G, y^M_G, and z^M_G are the coordinates of the centroid of the stone/block, $\dot{u}^S_x$, $\dot{u}^S_y$, and $\dot{u}^S_z$ are the components of the displacement rate field of a generic finite element belonging to the considered masonry unit (the "slave element", superscript S), expressed according to Eqs. (1)-(9) as well. $\dot{\theta}^M_{xx}$ and $\dot{\theta}^M_{yy}$ are the rotations of the master element about the X and Y axes, respectively; in fact, the kinematics of any master element is here enriched to enable the occurrence of macroscopic rotations, which are displayed in the deformed shape of the multi-leaf wall associated to an out-of-plane load condition.

No modifications with respect to the single leaf case are needed by the constraints related to the periodicity of the velocity field at the boundaries. Conversely, the equation that expresses the normalization of the dissipated external power - needs to be modified as follows:

$$\begin{aligned} P^{ext} &= \Sigma_{xx}\dot{E}^1_{xx} + \Sigma_{yy}\dot{E}^1_{yy} + \Sigma_{xy}\dot{E}^1_{xy} + (\dots) + \Sigma_{xx}\dot{E}^n_{xx} + \Sigma_{yy}\dot{E}^n_{yy} + \Sigma_{xy}\dot{E}^n_{xy} + \\ &\quad + M_{xx}\dot{\chi}_{xx} + M_{yy}\dot{\chi}_{yy} + M_{xy}\dot{\chi}_{xy} = 1 \\ P^{ext} &= \Sigma_{xx}\sum_{t=1}^{n}\dot{E}^t_{xx} + \Sigma_{yy}\sum_{t=1}^{n}\dot{E}^t_{yy} + \Sigma_{xy}\sum_{t=1}^{n}\dot{E}^t_{xy} + \\ &\quad + M_{xx}\dot{\chi}_{xx} + M_{yy}\dot{\chi}_{yy} + M_{xy}\dot{\chi}_{xy} = 1 \end{aligned} \tag{13}$$

Eventually, the homogenized limit analysis problem is once more formulated as a linear programming problem. The objective function that ought to be minimized is still the dissipated

internal power, and the equality constraints are still given by periodicity conditions and constraints for plastic flow in continuum, provided that they include the modifications introduced in the previous equations. In the usual standard form, the components of the average strain tensors are split with a decomposition assuring that optimization variables are all non-negative:

$$\dot{E}_{ij}^{t} = \dot{E}_{ij}^{t,+} - \dot{E}_{ij}^{t,-} \qquad i,j = x,y \tag{14}$$

The standard form for this linear programming problem can therefore be written as follows:

$$\text{Minimize} \quad \boldsymbol{C^T X} \tag{15}$$

$$\text{Subject to} \quad \boldsymbol{AX = B} \tag{16}$$

$$\boldsymbol{X \geq 0} \tag{17}$$

Where $\boldsymbol{C^T X}$ is the dissipated internal power, $\boldsymbol{X}$ collects all non-negative optimization variables, according to Eq. (14), which include macroscopic strain and curvature rates, master elements velocities, periodic velocities and plastic multipliers and $\boldsymbol{AX=B}$ collects all the equality constraints, which include among the others Eqs. (10)-(13).

An efficient linear programming solver as CPLEX is utilized to deal with several variables and the need to recursively solve Eqs. (15)-(17) to find an approximation of the homogenized strength domain, also changing the REV considered (an operation needed when the external leaves are constituted by irregular stones disposed randomly and the identification of a suitable test window is required [10]).

3 CASE STUDY

A multi-leaf case study is investigated in terms of out-of-plane homogenized failure surfaces. The case study deals with a three-leaf wall whose outer wythes consist of rubble masonry. Two separate sets of mechanical parameters (cohesion, friction angle, tensile strength, and compressive strength) are employed: one set is dedicated to simulate the properties of the outer wythes, the other set is dedicated to simulate the properties of the inner wythe, which is supposed to consist of low quality mortar. Both sets are listed in Table 1.

Type of interface	Cohesion [MPa]	Friction angle [°]	Tensile strength [MPa]	Compressive strength [MPa]
Outer wythes	0.15	30	0.1	1.5
Mortar inner wythe	0.05	35	0.02	0.5

Table 1: Mechanical properties for the material employed.

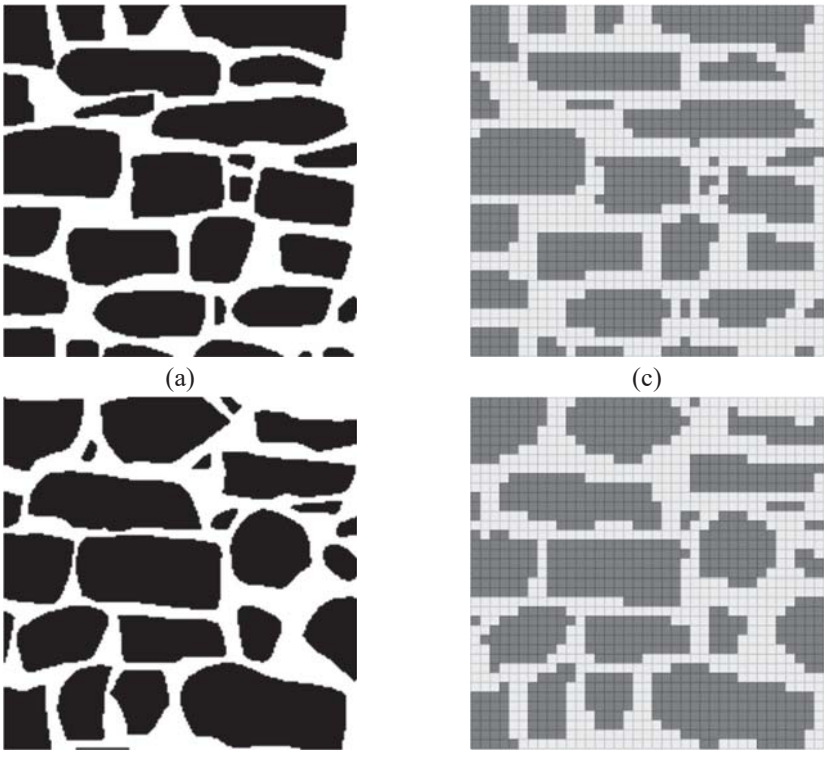

Figure 2: (a) Test-window C of case study 1; (b) test-window B of case study 1; (c) in-plane configuration of both the outer wythes for Instance 1, and of one wythe of Instance 2; (d) in-plane configuration of the other outer wythe of Instance 2.

3.1 Three-Leaf Rubble Masonry Wall

The case study under consideration consists of a three-leaf wall whose outer wythes are rubble masonry walls. Two instances of such wall are created aiming at investigating how the possible presence of different rubble masonry bonds influences the out-of-plane response of a three-leaf wall: specifically, one is named “Instance 1” and considers test-window C of case study 1 illustrated in [10][18], as the masonry bond for both outer wythes (Figure 2a), whereas the other is named “Instance 2” and employs the previous masonry bond for a single wythe, considering instead test-window B of the same case study as the masonry bond for the opposite wythe (Figure 2b). In both instances, a 5×5 coarsing strategy is employed to reduce the number of finite elements in the analytical models (Figure 2c and Figure 2d), see also [10][18] for a better insight into the coarsing strategy adopted to speed up computations; the outer wythes are supposed to be 40 cm thick and the mortar inner one 15 cm thick. The 3D finite element meshes of the two instances are shown in Figure 3 along with their exploded view: the outer wythes employ 16 finite elements over the thickness, while the mortar inner one employs 6 finite elements over the thickness.

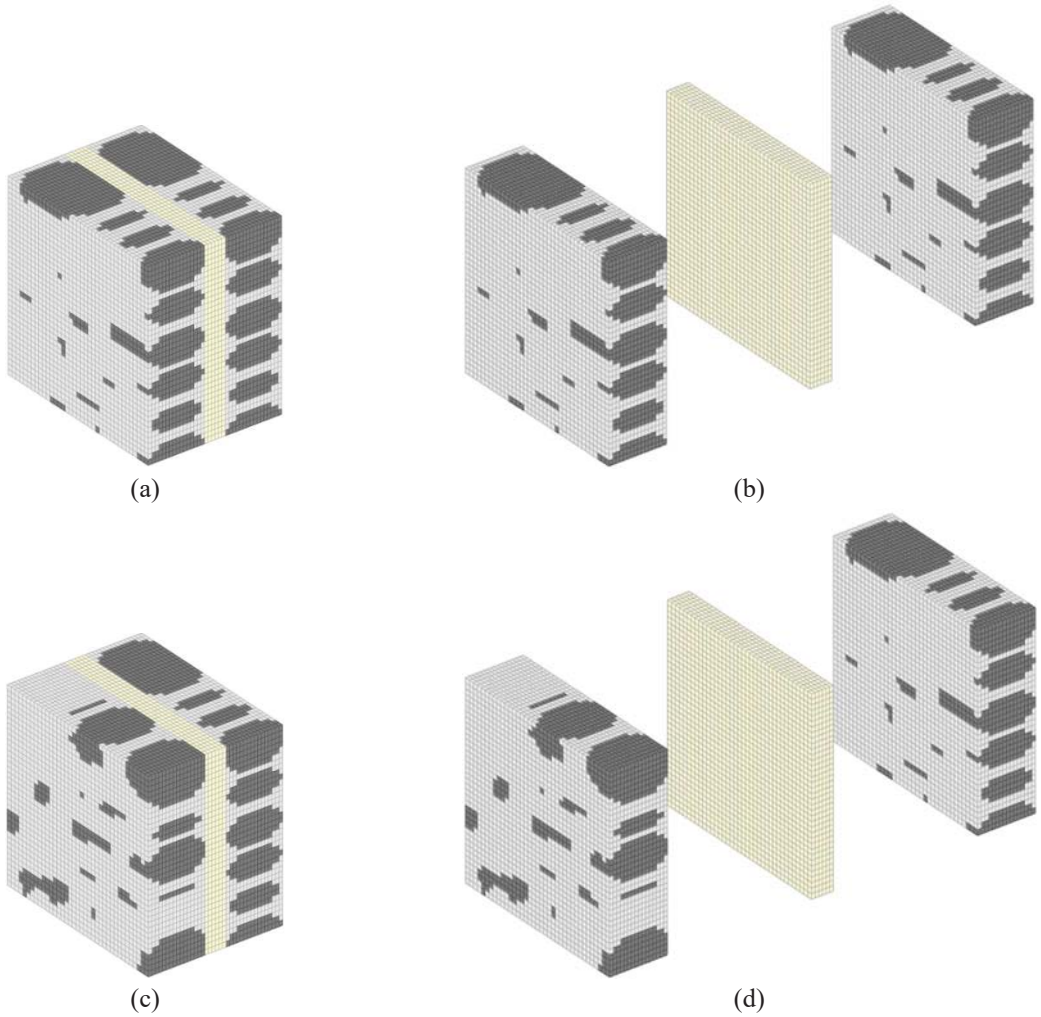

Figure 3: Case study considered to benchmark the procedure: (a) 3D finite element mesh for Instance 1; (b) exploded view of the 3D finite element mesh for Instance 1; (c) 3D finite element mesh for Instance 2; (d) exploded view of the 3D finite element mesh for Instance 2.

Figure 4 shows the comparison between the two instances in terms of flexural and torsional out-of-plane homogenized failure surfaces. It is possible to observe that Instance 2 (the one with different rubble masonry bonds in the outer wythes) displays larger failure surfaces in both the flexural and torsional cases: this means that, when it comes to rubble masonry three-leaf walls, the presence of different bonds in the outer wythes somehow increases the out-of-plane resistance of the wall, probably due to the combined effect of the two different types of irregularity at the extremities.

The deformed shapes at collapse ("failure modes") of the two instances of this case study are shown in Figure 5, which come from the single application of M_{xx}, M_{yy}, and M_{xy}. The outcomes of both the out-of-plane homogenized failure surfaces are corroborated: in fact, it is possible to observe how Instance 2 shows less widespread crack patterns for all the applied moments, suggesting a more compact (and, in the end, stiffer) out-of-plane response with respect to Instance 1.

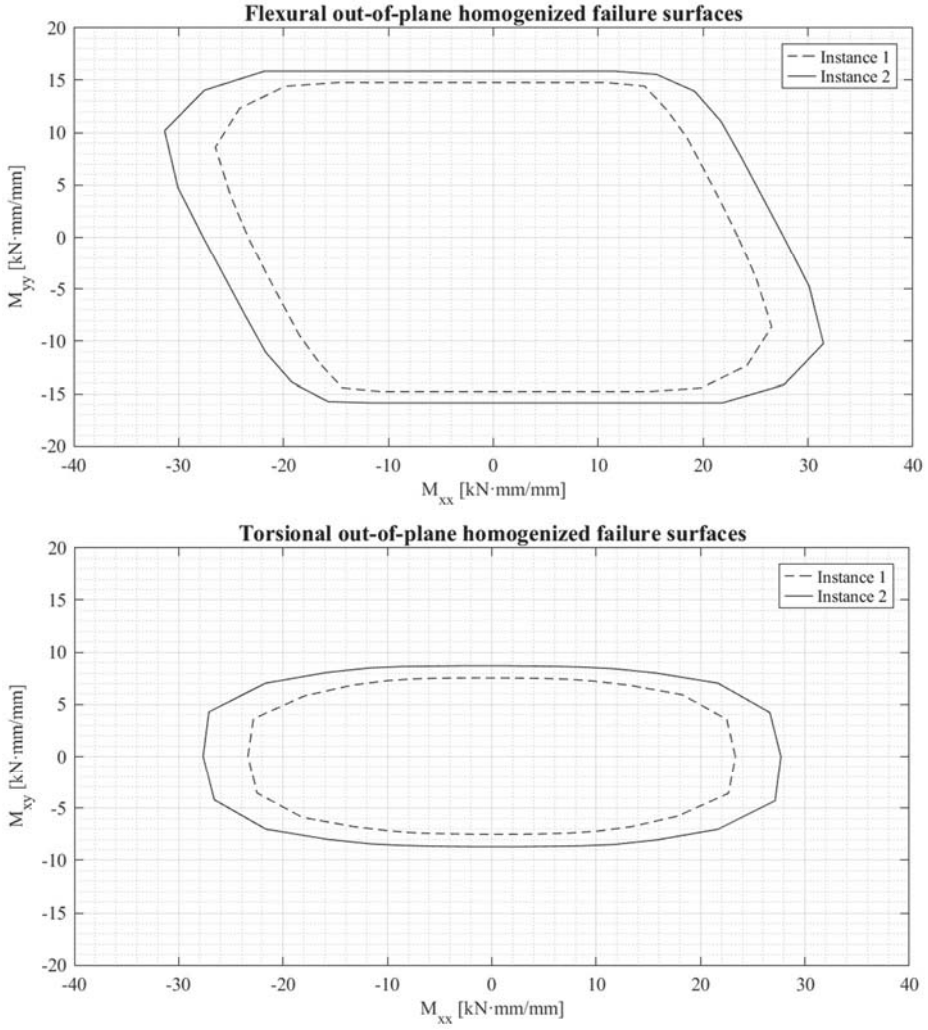

Figure 4: Flexural and torsional out-of-plane homogenized failure surfaces for the two instances of the first case study.

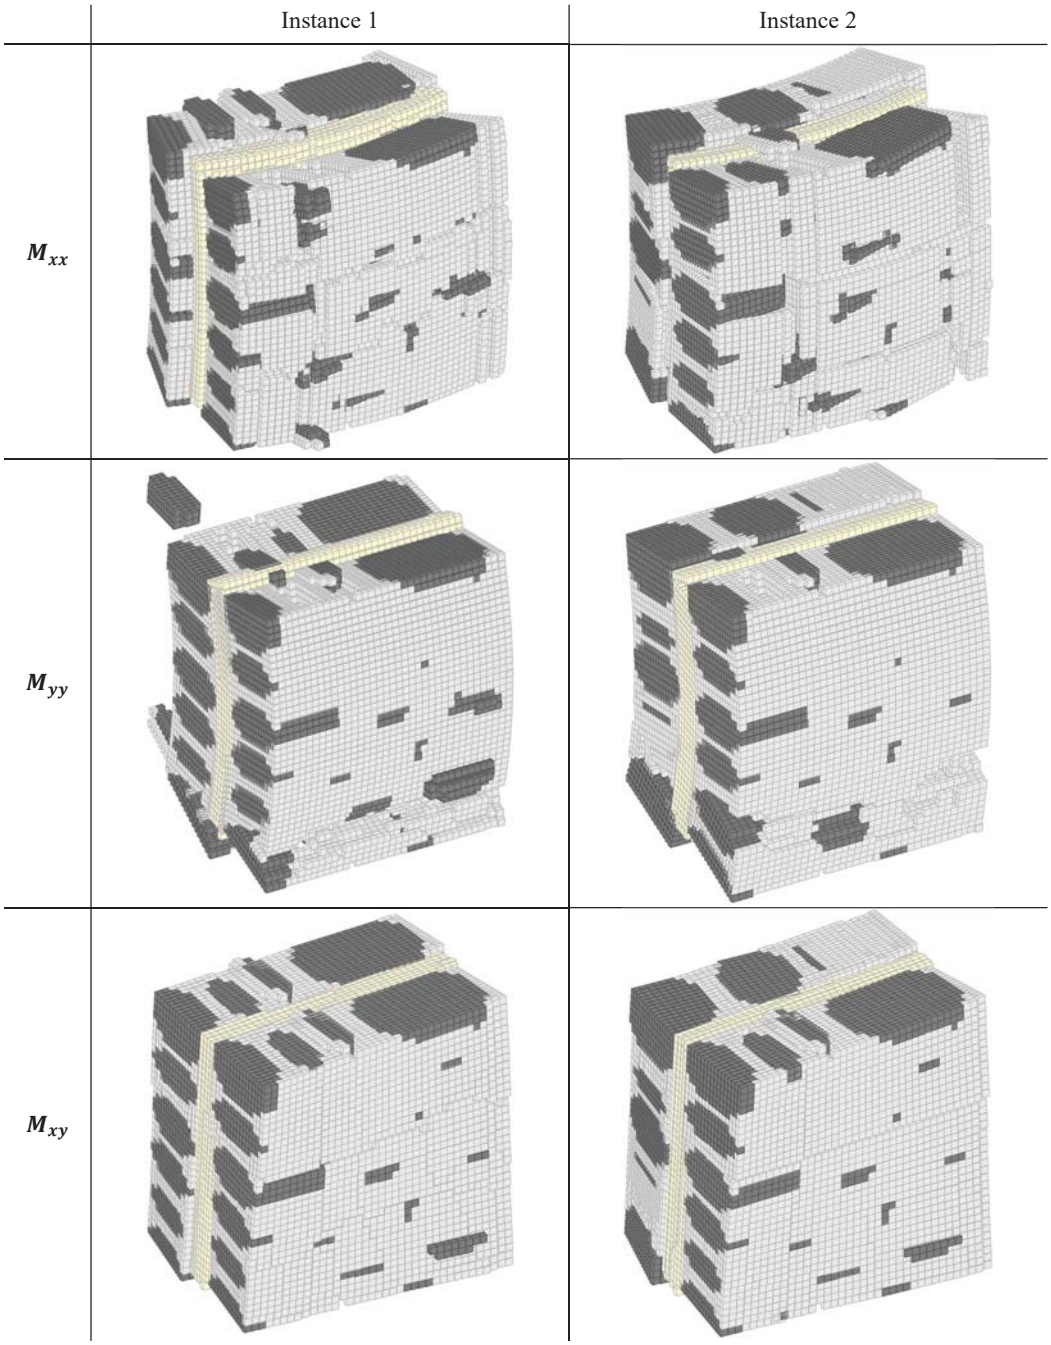

Figure 5: Failure modes under M_{xx}, M_{yy}, and M_{xy} for the two instances of the first case study.

4 CONCLUSIONS

The paper presented the first results obtained with a simple homogenized limit analysis model able to predict the ultimate out-of-plane behavior of non-periodic multi-leaf walls. The approach proposed enabled the derivation of out-of-plane homogenized failure surfaces for the multi-leaf wall, which can be useful for a quick assessment of the out-of-plane ultimate behavior of entire façades. The out-of-plane homogenized failure surfaces were obtained from the iterated solution of a standard linear programming problem with coupled kinematic limit analysis and homogenization hypotheses. The multi-leaf wall was discretized into infinitely resistant small voxels and the homogenization problem was solved in the rigid-plastic case

following a Kirchhoff-Love plate formulation. A preliminary numerical application was discussed, relying into a three-leaf non-periodic masonry wall, where external leaves consisted of rubble masonry. The effect due to the possible presence of separate but similar masonry bonds in the outer wythes were also investigated, showing that the presence of two different wythes increases the out-of-plane response of the wall both under flexural and torsional actions. The effects induced by (i) the presence of quasi periodic masonry for the external leaves and (ii) a good transversal interconnection between the outer wythes are two future issues to be investigated. A final implementation of the homogenization procedure at a structural level for the determination of the seismic vulnerability of entire multi-leaf masonry façades will be the last step of the research.

5 ACKNOWLEDGMENTS

The analyses were partially developed within the activities of ReLUIS (Rete dei Laboratori Universitari di Ingegneria Sismica – Network of the Italian University Laboratories of Seismic Engineering), for the research program funded by the Department of Civil Protection, Executive Project 2019, gratefully acknowledged by the authors.

Keywords: seismic assessment & strengthening, historic masonry structures, full-scale testing, numerical analysis

Abstract. *Induced seismicity due to gas extraction in the province of Groningen in the Netherlands has a noticeable impact on building structures. Historic masonry structures in the area, which are non-engineered and lacking empirical design features often present in traditionally seismic regions, are especially vulnerable to dynamic loading. Compounding the problem, gas extraction additionally generates soil settlement, which can induce damage to masonry buildings and thus reduce their capacity to bear seismic loads.*

The objective of this paper is the evaluation of the performance of a widely used structural intervention method applied in masonry structures in the Groningen region of the Netherlands. This method, initially developed against soil subsidence damage, consists in the embedment of stainless steel helical bars in repointed bed joints. Additionally, diagonal anchors are placed in drilled holes across existing cracks in the masonry. The increase in induced seismicity in Groningen raises the question whether this intervention technique can additionally enhance the behaviour of masonry structures during seismic loading.

A masonry wall was experimentally tested in two configurations: a) a pre-damaged state, with simulated damage typical of imposed soil settlement, and b) a post-damaged and post-intervention state, this being the wall from the previous configuration after being tested to its maximum base shear and subsequently strengthened. Differences between the two configurations in terms of stiffness, peak force and prevalent damage patterns are discussed.

Accompanying the experimental campaign, results of finite element simulations of the strengthened wall are presented. The strengthened wall is simulated using non-linear macro-modelling techniques. The model accounts for the experimentally simulated damage as well as for the damage arising after the testing in the first configuration. The analysis results clarify and quantify the experimental observations on the strengthened wall, particularly as regards stress development and bond-slip in the reinforcement bars.

Based on the experimental and numerical results, the effectiveness of the intervention in restoring the strength of the wall and in preventing the re-emergence of major diagonal cracking is confirmed.

1 INTRODUCTION

1.1 State of the art and motivation

Induced seismicity is the term used for describing low-magnitude ground shaking caused by human activity. It is characterised by high frequency of incidence, potentially exceeding hundreds of events every year in a single location. Among the main human activities linked to the generation of induced seismicity events is gas extraction [1]. While these low-magnitude earthquakes typically do not pose a threat to the structural safety of buildings and infrastructure, they can gradually reduce the durability and aesthetic integrity of structures through the formation and accumulation of light damage.

Soil-subsidence and uplift are responsible for the formation of damage in structures. The difference in stiffness between the superstructure/foundation and the soil causes the induction of bending and shear strain in buildings, an effect known as soil-structure interaction [2]. Gas extraction, in addition to inducing seismicity, leads to soil subsidence over wide geographic areas. Masonry structures are particularly vulnerable to soil-structure interaction effects due to their high stiffness and low tensile strength.

Due to the presence of soft clay, sand and peat top-soils, the Dutch region of Groningen has continuously experienced soil subsidence. Over the preceding decades, repair measures have been employed against the effects of soil movement in historic and traditional masonry buildings. One such widely employed measure consists in the placement of stainless steel helical bars in bed joints repointed using a high strength mortar. Additional bars are placed across cracks formed in masonry through drilled pilot holes. In more recent times, gas extraction operations in the region have not only exacerbated soil subsidence, but have been the cause of induced seismicity. This combined action poses substantial risk to the durability of the masonry building stock in the region, including both vernacular and monumental structures [3]. The role of the embedded reinforcement bars in enhancing the seismic capacity of masonry buildings, a role for which it was not originally intended, has not been sufficiently studied.

The role of embedded steel or CFRP reinforcement in masonry has received some attention in the literature, in both experimental and numerical studies [4, 5, 6]. However, the role of bed joint reinforced repointing as the main means of strengthening has not been sufficiently investigated, particularly in full-scale structures.

1.2 Objectives

The main objective of the paper is the evaluation of the overall role of bed joint reinforced repointing for masonry walls on structural behaviour under in-plane earthquake loading. The conditions in Groningen require that the walls be tested in a combination of subsidence- and earthquake-induced loads. Further, the nature of induced seismicity requires that structural behaviour be evaluated for both low- and high-magnitude loading.

The strengthening technique is evaluated in terms of contribution to capacity and ductility. Additionally, the shift in failure mode during low- and high-magnitude loading is an important parameter to consider.

1.3 Methodology

The effectiveness of the strengthening was evaluated through preliminary experimental testing of masonry walls with dimensions and layout commonly encountered in Groningen. Two walls with a window opening and simulated damage were tested up to light damage. Subse-

quently, one of the walls was strengthened and re-subjected to the light damage loading protocol. Finally, both the unstrengthened and strengthened walls were tested up to failure.

Following the experimental testing, a numerical campaign was executed. The primary objective of the campaign was the simulation of the strengthened wall test. Different modelling techniques were employed in order to establish the influence of the modelling approach on the results.

This paper focuses on the numerical simulation of the in-plane testing of the strengthened wall. The experimental results of both the unstrengthened and strengthened walls are detailed in a separate work [7]

2 EXPERIMENTAL CAMPAIGN

2.1 Testing of constituent materials

The units were solid clay bricks measuring $210 \times 50 \times 100\ mm^3$ in length $\times$ height $\times$ width. The width of the walls is equal to the width of the units. These units are very typical in traditional clay-brick masonry construction in the Netherlands, including in Groningen, and feature a high compressive strength [8].

The construction mortar was an O-type lime cement mortar, with an expected compressive strength of $2.4\ N/mm^2$ at 28 days. While this mortar type is not typically recommended for load-bearing members in new construction, it offers a reasonable approximation of traditional mortars while simultaneously not requiring excessive curing time before developing a compressive strength sufficient for low-rise construction. The thickness of all mortar joints was $10\ mm$.

The properties of the units and mortar as determined experimentally are shown in Table 1.

Parameter	Symbol	Units	Average	Coefficient of variation
Unit compressive strength	$f_{c,u}$	N/mm^2	28.31	0.10
Mortar compressive strength	$f_{c,m}$	N/mm^2	3.59	0.09

Table 1: Results of masonry constituent material tests.

2.2 Testing of masonry composite

Masonry wallets were subjected to different mechanical tests for the determination of the properties of the masonry composite. Further, the mechanical properties of the unit-mortar interface were determined experimentally.

Compressive tests on the masonry composite were executed according to EN 1052-1 [9], both normal and perpendicular to the bed joints (vertical and horizontal directions).

The shear strength of the unit-mortar interface was characterised through triplet testing according to EN 1052-3 [10]. The tensile strength of the interface was determined through manually-operated bond-wrench testing according to EN 1052-5 [11].

The results of the masonry composite tests are summarised in Table 2.

2.3 Layout of masonry walls

The masonry wall samples measured $3070 \times 2690 \times 100\ mm^3$ in length $\times$ height $\times$ width, with an eccentric window opening measuring $780 \times 1510\ mm^2$ in length $\times$ height. The masonry was constructed in single-wythe running bond, with a concrete lintel constructed over the open-

Parameter	Symbol	Units	Average	Coeff. of variation

Table 2: Material properties of masonry composite.

ing. The walls were constructed in a single day by an experienced mason. The samples were were constructed directly atop a steel HEB 300 beam and capped with a HEB 600 beam.

For the simulation of damage caused by soil settlement, thin plastic sheets were introduced at targeted locations between the units and the mortar, thus preventing the formation of the unit-mortar interface bond, but allowing the mortar to develop its compressive strength. This damage is designated as 'pre-damage' in this paper. It consists in diagonal cracks near the edges of the window, as would be formed from a sagging deformation towards the right of the wall.

The layout of the walls, along with the disposition of the pre- and post-damage, can be seen in Figure 1a.

2.4 Strengthening method and intervention materials

The strengthening method consists in two interventions: a) the embedment of horizontal helical bars in repointed bed joints and b) the insertion of diagonal helical bars in pilot holes across formed cracks, without grout or other anchoring measures.

The repair mortar used in this application is a strong cementitious intervention material that can be injected in mortar joints. Its expected compressive strength at 28 days is 45 N/mm^2. For the repointing of the bed joints, a 40 *mm* portion of the joint was removed from one face of the wall. Subsequently, helical bars were placed in the groove singly or in pairs and the groove was completely filled with the repair mortar. This intervention method introduces some eccentricity to the wall, since the bars are not placed centrally along the thickness of the wall and since the repair mortar, applied on a single face, is much stiffer than the construction mortar.

The helical bars are stainless steel grade ASTM 304, with a diameter of 6 *mm*. The steel has a yield strength of 215 N/mm^2 and a tensile strength of 505 N/mm^2. The bond-slip behaviour of the bars was investigated in two setups: a) in bars embedded in repair mortar for testing the behaviour of the bed joint reinforcement and b) in bars inserted vertically in masonry prisms for testing the behaviour of the diagonal reinforcement [12]. The test results were fitted to the piecewise Model Code 2010 bond-slip model [13]:

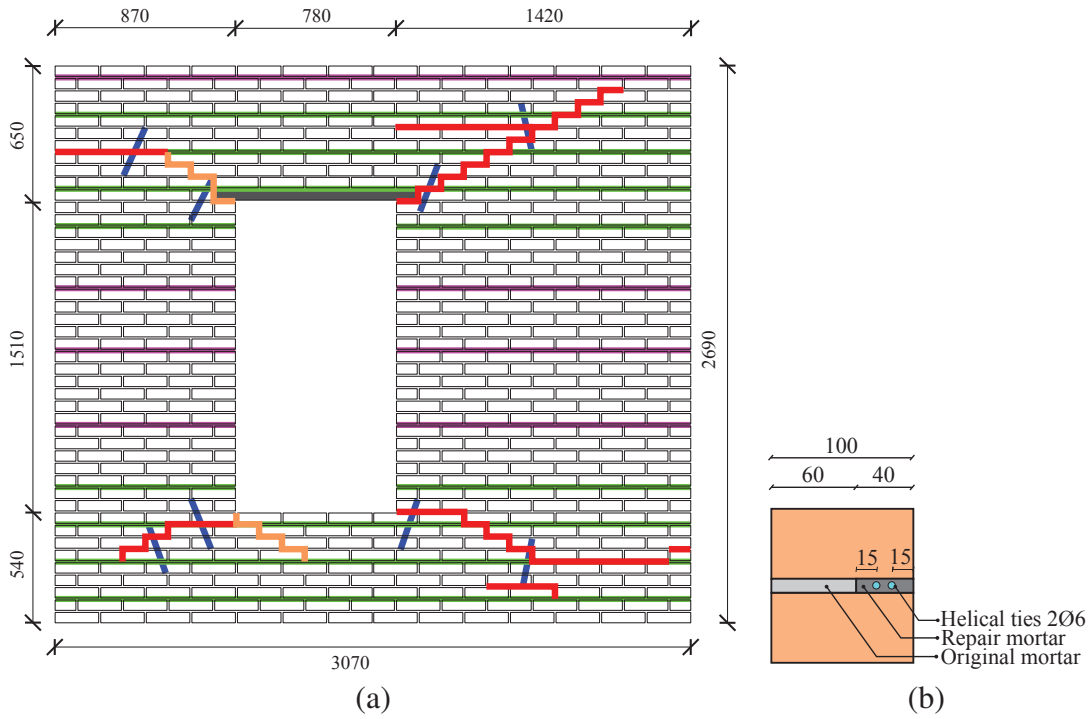

Figure 1: a) Layout of strengthened masonry wall. Pre-damage in orange, post-damage in red. Single bed joint bars in purple, double bed joint bars in green, diagonal anchors in blue. b) Cross-section of repointed joint. All dimensions in *mm*.

$$\tau_0(s) = \begin{cases} \tau_{max}\,(s/s_1)^a & \text{for} \quad 0 \le s \le s_1 \\ \tau_{max} & \text{for} \quad s_1 \le s \le s_2 \\ \tau_{max} - \left(\tau_{max} - \tau_f\right)(s - s_2)\,/\,(s_3 - s_2) & \text{for} \quad s_2 \le s \le s_3 \\ \tau_f & \text{for} \quad s_3 \le s \end{cases} \tag{1}$$

where a is a numerical parameter controlling the shape of the initial branch, τ_{max} is the peak bond stress, τ_f is the residual bond stress and s_1, s_2 and s_3 are slip values determining the inflection points of the bond-slip curve. The value of s_1 is here considered as the elastic limit for the bond-slip. The experimentally determined bond-slip properties according to Eq. 1 are summarised in Table 3.

	s_1	s_2	s_3	τ_{max}	τ_f	a
	mm	mm	mm	N/mm^2	N/mm^2	-
Bed joint	5.0	110.0	120.0	2.0	0.05	0.7
Diagonal	20.0	45.0	50.0	1.3	0.05	0.7

Table 3: Numerical parameters for Model Code 2010 bond-slip model.

The properties of the repair materials are summarised in Table 4. The repair mortar was tested at 28 days and the properties of the bars are determined according to the properties of ASTM 304 stainless steel.

Material	Parameter	Symbol	Units	Average	Coeff. of variation
Repair mortar	Compressive strength	$f_{c,M}$	N/mm^2	46.42	0.09
	Flexural strength	$f_{b,M}$	N/mm^2	7.68	0.24
Helical bar	Young's modulus	E_s	N/mm^2	193000	-
	Yield strength	$f_{y,s}$	N/mm^2	215	-
	Tensile strength	$f_{t,s}$	N/mm^2	505	-

Table 4: Mechanical properties of repair materials.

2.5 Testing procedure for masonry walls

A vertical compressive load of $0.12\,N/mm^2$ was applied on the top beam. The testing setup allowed rotation of the top (cantilever configuration). The horizontal in-plane load was applied in displacement control through a horizontal actuator to the top steel beam. Digital image correlation and an arrangement of sensors were employed for monitoring the deformation and crack pattern of the walls.

Both walls were initially tested in their un-strengthened, pre-damaged state up to light damage. The damage due to this test, similar in pattern for both walls, was documented and designated as 'post-damage' and was concentrated at the mortar joints. These cracks propagate from the corners of the window, both as extensions of the pre-damage and in new locations, and propagated primarily in a diagonal direction. One wall was subsequently strengthened using the repair mortar and helical bars and diagonal ties. Finally, both walls were tested up to failure. The geometric layout of the bars is illustrated in Figure 1a, while a cross-section of a repointed bed joint can be seen in Figure 1b.

The loading protocol for in-plane shear-compression was designed in order to simulate the loading that may arise in regions were both soil settlement and induced seismicity are encountered [7]. Thus, the loading protocol for both tests was composed of three phases. In phase 1, low-magnitude repeated in-plane displacement was applied. In phase 2, low magnitude cyclic loading was applied. In phase 3 the target displacement per cycle was increased in magnitude up to failure of the wall. The loading protocol is detailed in Table 5. The net displacement refers to the displacement of the top beam with respect to an external reference point, excluding rotations of the setup and horizontal displacement of the bottom beam with respect to the external reference.

2.6 Experimental results

The results of the in-plane tests are illustrated in terms of force displacement graphs obtained in phase 3 in Figure 2. The eccentric placement of the window results in noticeable difference in the capacity and stiffness of the unstrengthened wall in the negative and positive direction. The unstrengthened wall presents substantial residual drift accumulation for negative displacement, whereas the residual drift is reduced in magnitude and oscillates according to the loading direction in the strengthened case.

Despite the wall having sustained substantial damage in the initial test, the strengthening technique not only restores the strength and stiffness of the wall, but modestly enhances these parameters. Similarly enhanced is the ductility of the wall, with limited reduction in the shear force after attaining its peak value. Further, the strengthening reduces the difference between the response in the negative and positive directions.

The crack patterns registered through digital image correlation for both the unstrengthened

Phase	Cycle	Runs	Net horizontal displacement	
				mm
1	C1	30	0.73	-
	C2	30	0.92	-
	C3	30	1.09	-

	C20	2	80.76	-63.31

Table 5: Loading protocol for the in-plane shear-compression test.

and strengthened walls are illustrated in Figure 2. In the unstrengthened wall the diagonal cracking around the window is prevalent. The presence of the bars in the strengthened wall produces a shift in the arrangement of the crack pattern. The bed joint reinforcement prevents for the most part the diagonal cracks from propagating, resulting in the formation of more pronounced horizontal cracks. These cracks are well-defined at the top of the two piers, but are more distributed at the base of the piers. Damage in the spandrel is significantly limited compared to the unstrengthened case. Both piers in both tests are generally undamaged due to the predominance of rocking in their response. Toe crushing was not extensive due to the low vertical load.

3 NUMERICAL SIMULATION OF STRENGTHENED WALL

3.1 Modelling approach

The modelling campaign presented here focuses on the strengthened wall. Analyses of the unstrengthened wall, with the absence of pre-damage, have been presented in a previous work [14].

For the simulation of the in-plane experiment, a finite element macro-modelling approach is adopted in this paper. In this approach, the masonry composite is modelled as a plane stress orthotropic continuum, with no distinction between units and mortar in the analysis domain. The mean edge length of the finite element mesh was 30 *mm*. Each cycle of the loading protocol was executed once. A regular Newton-Raphson scheme was employed for the iterations and an energy norm of 0.1% was used as a convergence criterion at each load step.

The finite element model was constructed and analysed using the DIANA finite element

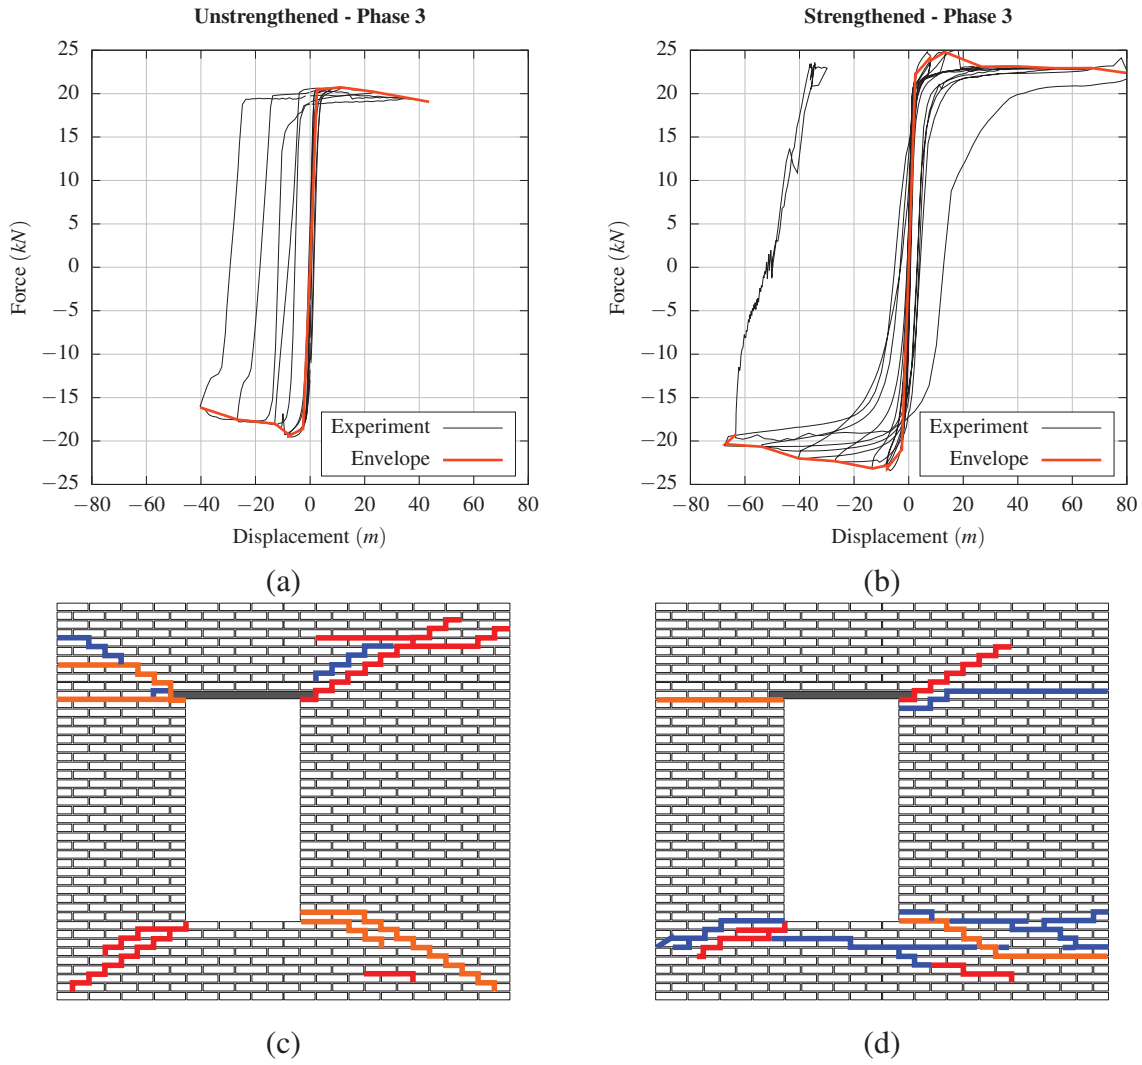

Figure 2: Force-displacement graphs for phase 3: a) unstrengthened wall and b) strengthened wall. Experimentally obtained damage patterns for: c) unstrengthened wall and d) strengthened wall. Damage arising in phase 1 (orange), in phase 2 (red) and in phase 3 (blue).

program. Material non-linearity was modelled using the Engineering Masonry Model, jointly developed by TU Delft and DIANA FEA [15]. Within an anisotropic total strain context, the model accounts for the compressive, shear and tensile failure of the masonry composite.

The tensile strength of the masonry composite in two orthogonal in-plane directions is calculated as a function of the masonry bond, unit-mortar bond strength, friction angle and shear strength.

In the direction normal to the continuous bed joints (vertical), the tensile strength of masonry is determined at the load of first cracking during the bond strength test, empirically equal to:

$$f_{t,y} = \frac{2}{3} f_w \tag{2}$$

In the direction parallel to the bed joints (horizontal), the tensile strength of masonry is equal to:

$$f_{t,x} = \tau_{max} / \tan(\alpha) \tag{3}$$

where α is the angle between the staircase crack and the bed joint (here equal to 0.50 rad) and τ_{max} is equal to:

$$\tau_{max} = \max\left[0, f_{v0} - \sigma_y \mu\right] \tag{4}$$

where σ_y is the vertical stress, compression being negative. Diagonal staircase cracking, defined as the opening of a crack at an angle of α from the horizontal, is evaluated against the diagonal tensile strength, calculated as:

$$f_{t,a} = \frac{f_{t,x} f_{t,y}}{f_{t,x}^2 \sin^2\left(\frac{\pi}{2} - \alpha\right) + f_{t,y}^2 \cos^2\left(\frac{\pi}{2} - \alpha\right)} \tag{5}$$

The reinforcement bars were modelled as truss elements embedded in the plane stress elements. Their bond-slip behaviour is modelled by considering a uniaxial constitutive relation between slip and bond stress according to Eq. 1. Yielding of the bars is also considered with a uniaxial constitutive relation between axial strain and stress according to the properties of ASTM 304 stainless steel. The material properties as summarised in Table 2 and Table 3 were used as input for the model without further calibration.

To model the pre- and post-damage, reduced strength and stiffness were assigned to the damaged areas of the masonry. The compressive strength was left unchanged due to the damage having been caused by opening of the unit-mortar interface. The tensile and shear strength, as well as the tensile and shear fracture energy, were reduced to zero in order to account for the artificial absence of bond in the pre-damage and the loss of interface cohesion in the post-damage due to crack opening. The Young's modulus was reduced by 50% in all damaged locations.

The top steel beam was modelled as an elastic beam element in perfect bond with the masonry wall. The model was clamped at the base and unrestrained at the top. Out-of-plane effects that may arise due to the eccentricity of the reinforcement were not considered in the model.

4 NUMERICAL ANALYSIS RESULTS

The numerical force-displacement curve for phases 1 and 2, in comparison with the experimentally derived curve, is presented in Figure 3. The stiffness of the structure is approximated well. The peak force is overestimated by 20% in the positive direction, but predicted with good accuracy in the negative direction. The hysteresis loops are also better approximated in the negative direction.

The numerically obtained crack patterns are shown in Figure 4 at the instances of peak negative and positive applied displacement. The cracking pattern matches the experimentally obtained damage to a significant extent, with the exception of the re-opening of the diagonal crack at the upper left corner of the window for positive displacement instead of the formation of a new horizontal crack propagating towards the edge of the wall. The difference in the crack pattern for positive displacement is possibly linked to the overestimation of the peak force in that loading direction. It is interesting to note that this horizontal crack was formed in the unstrengthened wall during phase 1 but was not formed in the wall that was eventually strengthened.

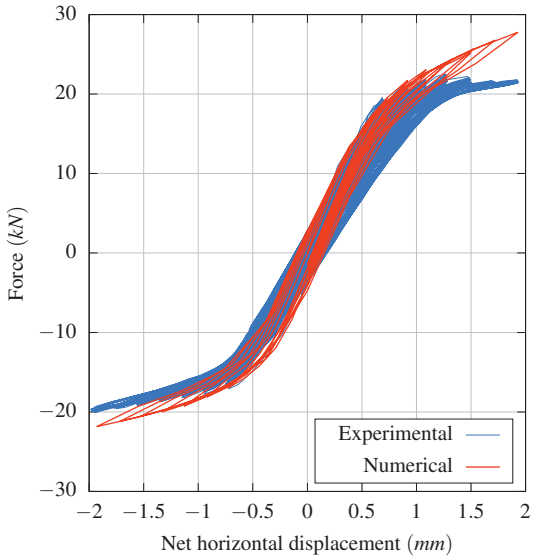

Figure 3: Comparison of experimental with numerically-derived force-displacement curve for phase 2.

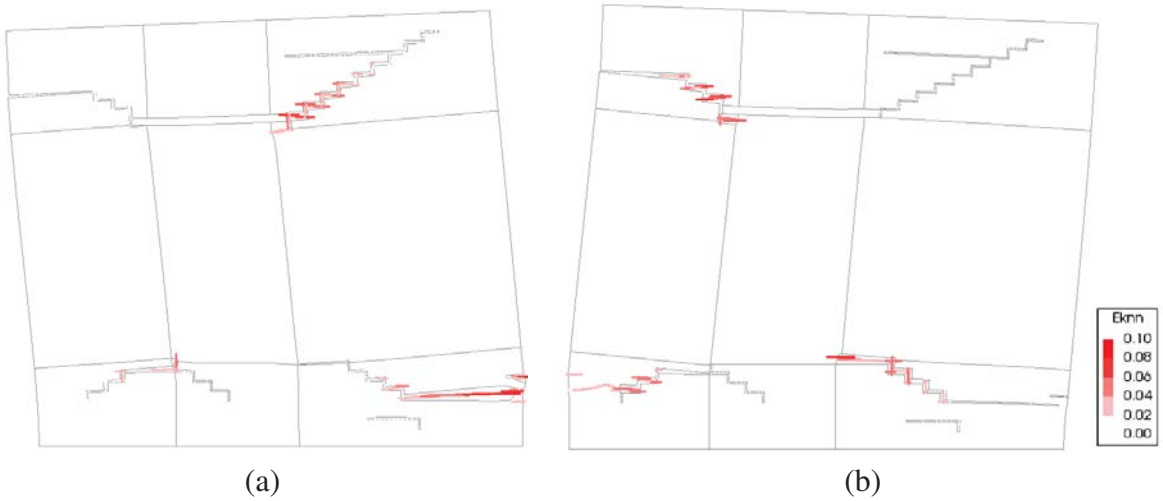

Figure 4: Numerically obtained crack patterns, as crack strain vectors parallel to the crack in red, for phase 2 at: a) peak negative displacement ($-1.98\ mm$) and b) peak positive displacement ($1.93\ mm$).

The bed joint reinforcement, being oriented in parallel with the main direction of cracking, did not register any substantial slipping. The maximum axial stress borne by the bed joint bars was $53.2\ N/mm^2$ well below the yield strength ($215\ N/mm^2$). The maximum slip of the diagonal anchors was roughly $0.26\ mm$, while the maximum axial stress was limited to $1.5\ N/mm^2$.

The numerical force-displacement curve for phase 3, in comparison with the experimentally derived curve, is presented in Figure 5. The stiffness of the structure is well approximated, as is the capacity in the negative direction. As in the simulation of the previous phase, an overestimation of the capacity in the positive direction was obtained, but this overestimation is much reduced in this phase. The hysteresis cycles are well approximated up to a displacement of $20\ mm$ and $40\ mm$ in the positive and negative directions respectively. The residual resistance of the wall in the positive direction is very well approximated and is slightly overestimated in

the negative direction.

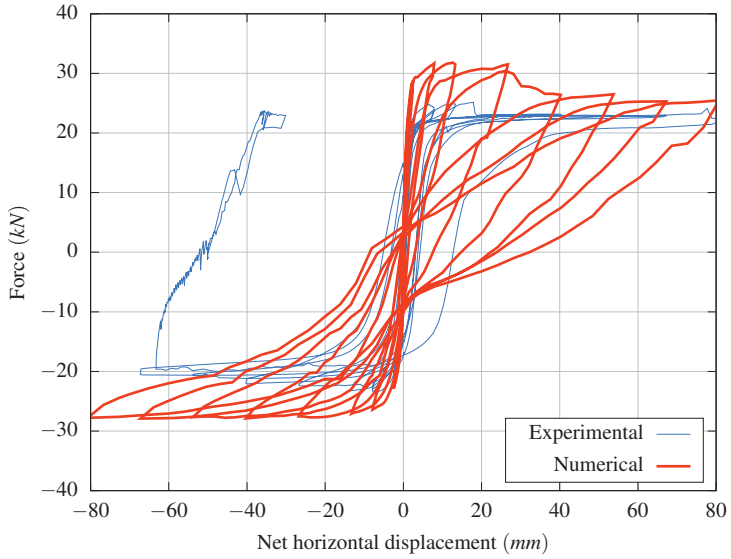

Figure 5: Comparison of experimental with numerically-derived force-displacement curves for phase 3.

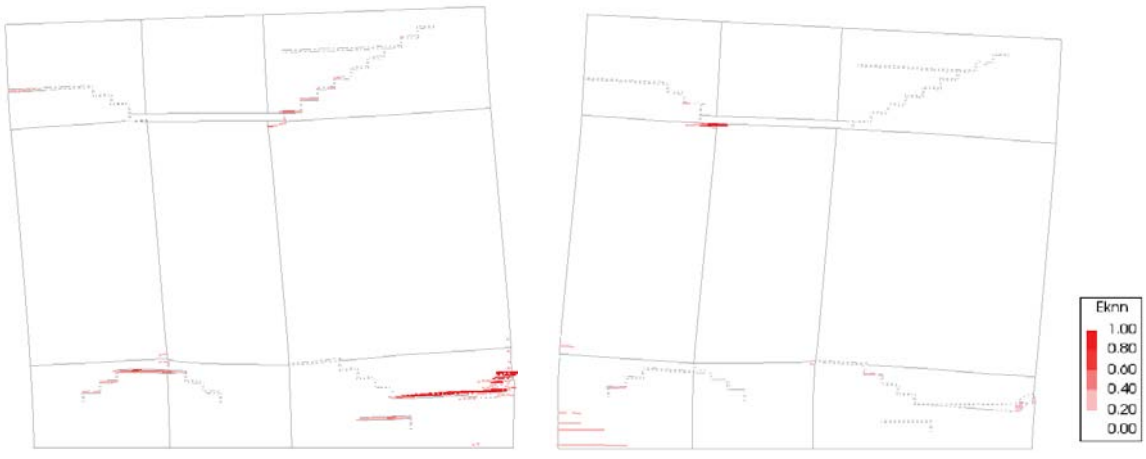
The cracking pattern obtained numerically for phase 3 is shown in Figure 6. In the negative loading direction the network of mostly horizontal cracks formed at the lower right portion of the base of the wall is reproduced numerically. The cracks at the lower left of the window are partially reproduced, while the horizontal crack starting at the upper right edge of the window is partially reproduced in the simulation. For applied positive displacement, the horizontal crack at the upper left edge of the window propagates to a greater degree and is in better agreement with the experimental results. The length of the crushed toe is negligible due to the low ratio of applied vertical stress over the compressive strength.



(a) (b)

Figure 6: Numerically obtained crack patterns, as crack strain vectors parallel to the crack in red, for phase 3 at: a) peak negative displacement and b) peak positive displacement.

Similarly to the results obtained in phase 1 and 2, slipping in the horizontal bars is negligible.

However, the peak axial stress registered at the lower right of the opening for maximum applied horizontal displacement was 239.1 N/mm^2, which is slightly higher than the yield strength. The maximum slip of the diagonal anchors was 8.2 *mm* and the maximum axial stress 21.9 N/mm^2.

The behaviour of the reinforcement at key locations on the structure is detailed in Figure 7. The axial stress of the bed joint reinforcement follows a generally linear correlation with the applied net displacement, up to an applied displacement of 40 *mm*. For higher applied displacement the peak axial stress hovers at a plateau of roughly 230 N/mm^2, which is higher than the yield stress of 215 N/mm^2. The bond-slip at the diagonal bars above the window opening remain below than 1 *mm* for an applied displacement lower than 7.91 *mm*. For higher levels of applied displacement, the bond-slip obtained at the peak of the load cycle increases linearly with the net horizontal displacement.

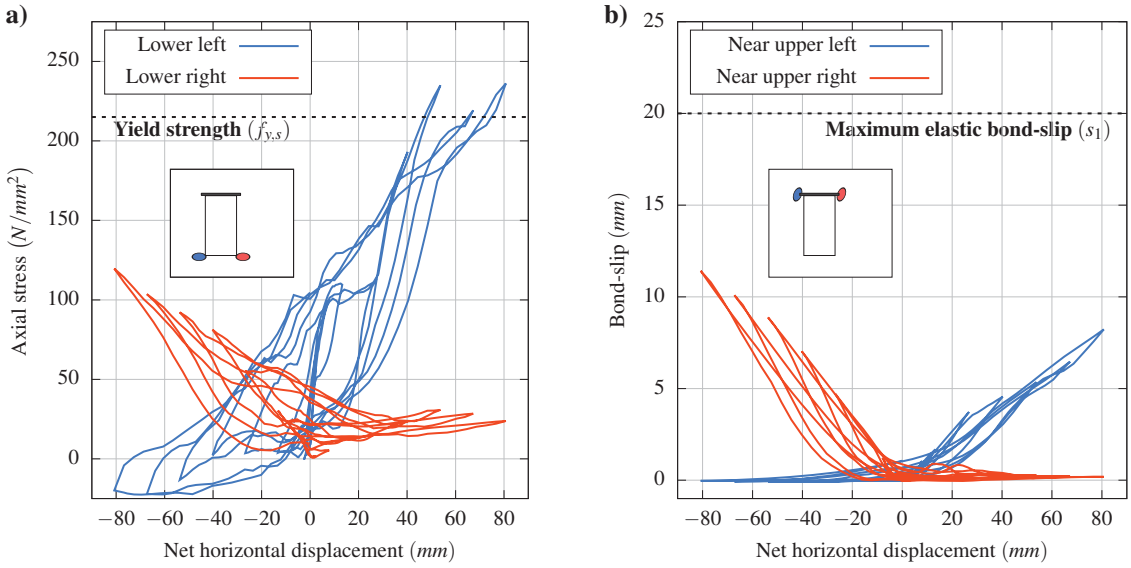


Figure 7: Numerically calculated behaviour of reinforcement during phase 3: a) axial stresses at bed joint reinforcement bars below the window opening and b) bond-slip of diagonal anchors above window opening. Locations of measurement indicated in colour-coded wall drawing insets.

It is generally concluded that the diagonal anchors, due to the low stiffness of their bond with the masonry, develop very low axial stresses and exhibit substantial bond-slip. Increasing the bond with the masonry through an enhancement of the mechanical anchoring of these bars could potentially increase their contribution to the behaviour of the strengthened wall. Conversely, the bed joint bars, which feature a stronger bond with the repair mortar, contribute more substantially to the response of the wall through the restraint of diagonal crack propagation. Bond-slip is negligible but yielding occurs below the window opening for high applied net displacement. Due to their orientation, these bars do not contribute to the rocking mode capacity of the piers, but are nevertheless effective in reducing crack propagation, particularly in the spandrel.

Overall, without resorting to any undue calibration of material parameters, the numerical effort is able to reproduce the main characteristics of the response registered in the experiments. This renders the numerical results a valuable tool in the assessment of the performance of the reinforcement, direct measurements of which were not possible to be acquired during the experiments. Finally, the capture of the main characteristics of the response through the model paves the way for application in larger and more complex cases.

5 CONCLUSIONS

The performance of bed joint reinforced repointing as employed for masonry structures in the Groningen region of the Netherlands was investigated. A masonry structure subjected to settlement-induced damage, followed by in-plane seismic loading was experimentally tested. The structure was strengthened using a technique widely employed in practice but lacking in rigorous experimental validation.

The reinforcement was experimentally shown to provide a modest increase to the in-plane stiffness and force capacity of masonry walls, in addition to a substantial increase in displacement capacity. This is accomplished despite the presence of damage induced by settlement and prior seismic loading. The strengthening is shown to prevent new diagonal cracks from forming in the spandrels, reduces the obtained crack width and reduces the crack propagation length.

The experimental tests were simulated numerically for assisting in the interpretation of the experimental results and for the investigation of the performance of the bed joint reinforcement and anchors. The numerical reproduction of the tests highlights crucial aspects in the performance of the reinforcement. Minimal bond-slip occurs and high axial stresses are developed in the bed joint bars. Conversely, the diagonal anchors exhibit substantial slipping and low axial stresses. It is therefore concluded that the contribution of the bed joint reinforcement is more substantial than that of the anchors.

Keywords: Masonry pagoda, FE simulation, Damage characteristics, Dynamic analysis, Earthquake

Abstract. *As an important historical relic of human being, masonry pagoda is the great significance in the eastern and western architectural cultures. These pagodas usually have large self-weight, low material strength, complex structure, which have been seriously affected by nature and man made because of their ages. Most of the existing masonry pagodas in China which have been seriously damaged urgently need detailed structural safety assessment, repair and reinforcement. In this paper, a simplified 3D model was used to evaluate the seismic vulnerability of masonry pagodas reliably. According to the previous numerical research in the field and post-earthquake surveys experience, assume for masonry a Concrete Damage Plasticity CDP material model, pushover analyses and non-linear dynamic analyses are carried out by Abaqus software. The aim is to predict the state, characteristics and distribution of damage of the structure in an accurate way. The approach is applied to Longhu pagoda (built in 1342 A.D.) which is the only yuan dynasty masonry pagoda in Sichuan province of China. Longhu pagoda is a brick pagoda with dense eaves, with a square plane and a height of about 33 meters. Affected by the Wenchuan earthquake in 2008, a north-south crack appeared from the bottom to the top of the pagoda's body. Despite the artificial repair of the cracks, the pagoda still faces the risk of structural damage. Through numerical simulation, the seismic performance of the pagoda can be evaluated, which can not only predict the hidden danger and weak link in its structure, but also provide useful reference for the reinforcement and repair of the pagoda.*

1 INTRODUCTION

China is an ancient country with a history of 5,000 years, and has countless architectural wonders with exquisite structures and beautiful shapes [1]. The ancient masonry pagoda which is one of Chinese significant art treasures draws on the basic mechanical principles of the barrel structure, and integrates into the history and culture of the China. It is a reflection of the skills of high-rise buildings in ancient, is an important milestone in the development of Buddhism, and is also a distinctive sign on human masonry architectures [2-7].

The ancient Chinese pagoda was introduced with Buddhism and first appeared in Han Dynasty They were large-scale constructed in Sui Dynasty and reached its peak in Tang and Song Dynasties. The early plane of pagoda was square, evolved into octagon with time, and the height of pagoda became higher and higher. The construction method of them is using stacked bricks in traditional Chinese techniques, which is similar to other masonry buildings. Although their shape is ever-changing, and the use and functions are also different, almost all pagodas contain three parts (Figure 1): pagoda pedestal, pagoda body, pagoda spire, and some of them built underground palaces with scriptures reserved in it [8-15].

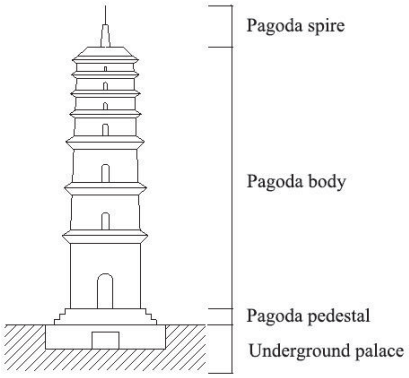

Figure 1: Schematic diagram of ancient pagoda structure

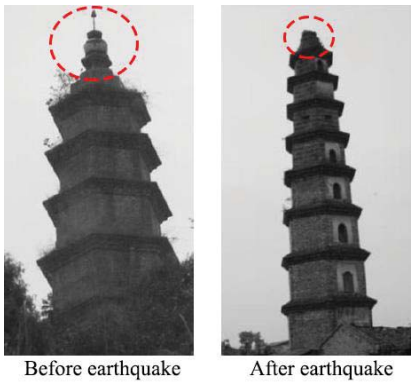
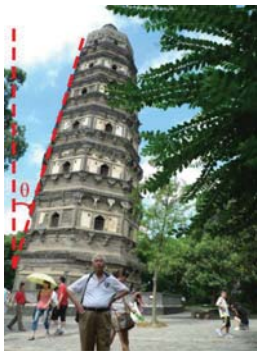
As far as pagodas' structures and material properties are concerned, they have the advantages of high compressive strength, weather resistance, fire resistance, corrosion resistance, low cost and so on. However, because Chinese masonry materials are mostly a mixture of glutinous rice juice, lime and sand, the pagodas' ability to resist tensile, shear and bending is poor. After hundreds of years influence from weather, war and other artificial destruction, these Chinese pagodas have suffered sorts of damages. Meanwhile, relevant research depicts that most structural damage and collapse of pagodas were caused by earthquakes [16]. China is located in the intersection of the Pacific Rim earthquake belt and the Eurasian earthquake belt. According to the collection of statistics, there were three major earthquakes with seismic wave magnitudes greater than or equal to 8.5 in the 20th century, and two of them occurred in China. Therefore, It is one of the countries most severely affected by earthquake disasters in the world. The seismic activity in this area has characteristics of wide distribution, high intensity, high frequency [17-19].

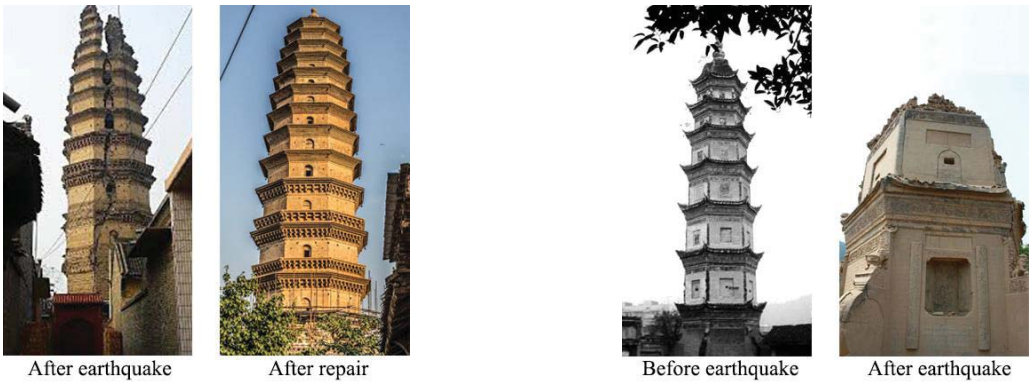


(a) Damage characteristics 1)



(b) Damage characteristics 2)

(c) Damage characteristics 3)



(d) Damage characteristics 4) (e) Damage characteristics 5)

Figure 2: Damage characteristics of pagodas [19]

After subjected to earthquakes, the accumulation of damage will lead to collapse of pagoda that is major threat of structural safety. The main damage characteristics of pagodas which were made by earthquake are following (Figure 2): 1) the tilt and collapse of pagoda spire, 2) the tilt and bend of pagoda body, 3) the break in the middle part of the pagoda, 4) the split of pagoda body along the central axis, 5) overall collapse [19].

In recent years, scholars have made outstanding contributions to the research on the dynamic performance, seismic resistance and structural damage of masonry pagoda structure. Y.G. Shen et al. discussed the seismic mechanism and dynamic performance of ancient masonry pagodas in China based on site surveys, subsequent reinforcement data, and the structural characteristics of Xi'an Xiaoyan pagodas [20-21]. J.L. Yuan et al. used a classical theoretical method to calculate the model, combined with the actual pulsation method test results, established a more accurate numerical analysis model of Wenfeng Pagoda which is located in Yangzhou, and guide the seismic identification and reinforcement [22-25]. J.L. Lu, F. Zhu et al. also carried out dynamic characteristic tests and numerical calculations on various Chinese ancient pagodas. The weak links and damage mechanisms of the model structure under the action of earthquakes were also be observed which can provide a reference basis for further pagodas' damage identification, seismic response, maintenance and repair [26-31]. Subsequently, more and more scholars began to use FE software to build 3D models of pagodas to analyse the elastic and plastic properties of structures and materials, then obtained their seismic performance [32-40].

On the other hand, western scholars have also studied the seismic performance of pagoda structures such as churches, bell towers, castles, and tobacco countries. Anzani et al. took the Italian Civic Tower and the Noto Church as research objects, and analysed the effects of vertical cracks on masonry buildings. They concluded that these cracks were the main cause of the collapse of the tower [41]. G. Milani et al. also applied nonlinear static and dynamic analysis methods to assess the seismic performance of bell towers, churches, pagoda, and promoted the advancement of numerical simulation technology for masonry buildings [42,43]. Marco Valente et al. researched eight masonry towers in northeastern Italy, and conducted nonlinear static and dynamic analysis. The conclusion is drawn that the results obtained by the nonlinear static analysis method are slightly conservative [44].

In general, the current FE simulation technology has been widely used in the research of seismic vulnerability of ancient pagodas, and most of them has focused on the dynamic characteristics testing, seismic response analysis, seismic performance, reinforcement and structural damage. However, because of the complex and divers destruction factors, it is easy

to find that the current research selection of pagodas' structure features are not diversified and typical, the results which have been concluded is still limited.

Therefore, the theory and technology of the vulnerability analysis of masonry structures of pagodas in China still need to be improved. With the help of FE simulation, analysing the response of typical pagodas influenced by earthquakes, deducing the possible damage patterns, especially after the earthquake, finding the damage parts in time, predicting the development of damage, evaluating the extent of damage effectively, and proposing reasonable protection and reinforcement measures are still topics which are worthy to be focus on and need more in-depth research.

This paper selects Longhu pagoda which is a typical masonry pagoda as a case study. The pagoda has been damaged (now partially repaired) by Wenchuan earthquake which was the largest earthquake since the founding of China, and its main damage is cracks. Through Abaqus simulation, this research studied the seismic reaction and damage characteristics of Longhu pagoda during the Wenchuan earthquake, and provided the vulnerability analysis and seismic reinforcement repair of masonry pagoda, and all of the research results have important practical significance.

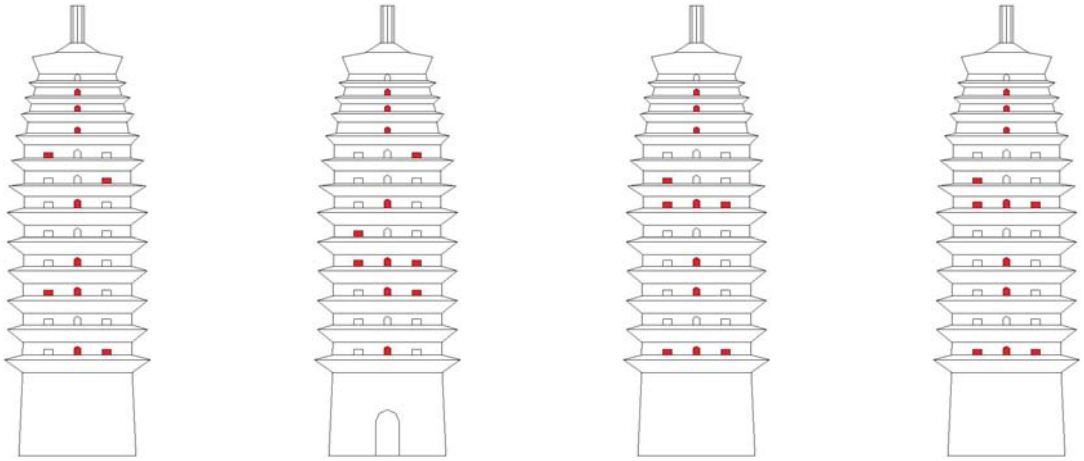
2 HISTORICAL CONTEXT AND LOCATION

Longhu pagoda (Figure 3) which was built in 1342 A.D. is located in Xiaoquan, Deyang, Sichuan province (East longitude 104°17′, North latitude 31°15′) and is the only preserved masonry pagoda made in Yuan dynasty (Figure 4). Because of its tall and straight appearance (around 12 m), it is the commanding point and visual center of Xiaoquan town. The early architectural features of Longhu pagoda are obvious, which is an significant evolution illustration of Chinese masonry pagoda. Meanwhile, it occupies an special position in the urban space with an important historical value [8, 9].

Figure 3: Longhu pagoda

Figure 4: Location of Longhu pagoda

Longhu pagoda has a square plan with 13 layers of eaves outside it, and is roughly 33 meters tall which contains 2 meters of stylobate and 31 meters of body. The main entrance of the pagoda is in the south, and the size of its eaves shrink from bottom to top especially above 8th layer, depicting a parabolic shape facade. The pagoda's body has windows on four sides, some of them are real, while others are decoration (Figure 5). From second to ninth layer, there are three windows on each side, but the number decreased to one on the upper layers [8].



(a) East facade (b) South facade (c) West facade (d) North facade

Figure 5: Real windows of Longhu pagoda

Actually, there are only five real floors (Buddhas can be found in each of them) and a heavenly palace (a dome that penetrates the eleventh to thirteenth eaves) inside the pagoda (Figure 6). In each floor, there is a central room, with caissons and Dougongs on the roofs of the first to fourth floors, while the caisson of the fifth floor is empty that through to heavenly palace. Between the exterior and the central room, stairs spiral up clockwise connecting each center room (Figure 7).

3 EARTHQUAKE HISTORY

Sichuan province which is known as Chinese earthquake-prone area sits in the hinterland of southwest China (between east longitude 97°21′-108°33′ and north latitude 26°03′-34°19′). The province which shows various geomorphology from east area to west area is composed of mountains, hills, plain basins and plateaus. Its terrain is complex and diverse, and has a large height difference (Figure 8).

On May 12, 2008, a 8.0 magnitude Richter earthquake occurred in Wenchuan, Sichuan province, China, and the epicenter was in a small town whose name is Yingxiu. It was caused by the sudden release of long-term accumulated tectonic stress energy in the Longmen Mountain fault zone between the Qinghai-Tibet Plateau and the Sichuan Basin. The hypocenter depth that close to the surface is 10 km to 20 km, and whole earthquake lasted a long time (182 s - 194 s). Wenchuan earthquake is destructive and has a strong impact, its maximum acceleration peak value which appeared after the start of the crustal movement (65 s - 82 s) is nearly 424 cm/s^2. According to incomplete statistics, the earthquake killed around 69227 people, injured 376443 people, and 17923 people were missing. Large numbers of architectures were collapsed and cultural relics were severely damaged, which resulted immeasurable losses [45].

The position of Longhu pagoda is not very far away from the epicenter (about 100 km), and it was influenced by the east-west seismic wave. Because of the seismic intensity distribution map of Wenchuan earthquake, issued by the China Seismological Bureau (Figure 9), the earthquake damages to Longhu pagoda's structure should be analysed according to 8 degrees.

After Wenchuan earthquake, the aftershocks, which continued in Deyang area, also caused further damages of the pagoda. On July and August in 2008, Longhu pagoda suffered by many aftershocks which brought a long-term swing, and further increased the width, depth and length of the pagoda's cracks. Fortunately, with the earthquake rescue project, the pagoda received timely and effective protection that help it to defend against risks made by aftershocks.

Figure 8: Chinese Earthquake Belt

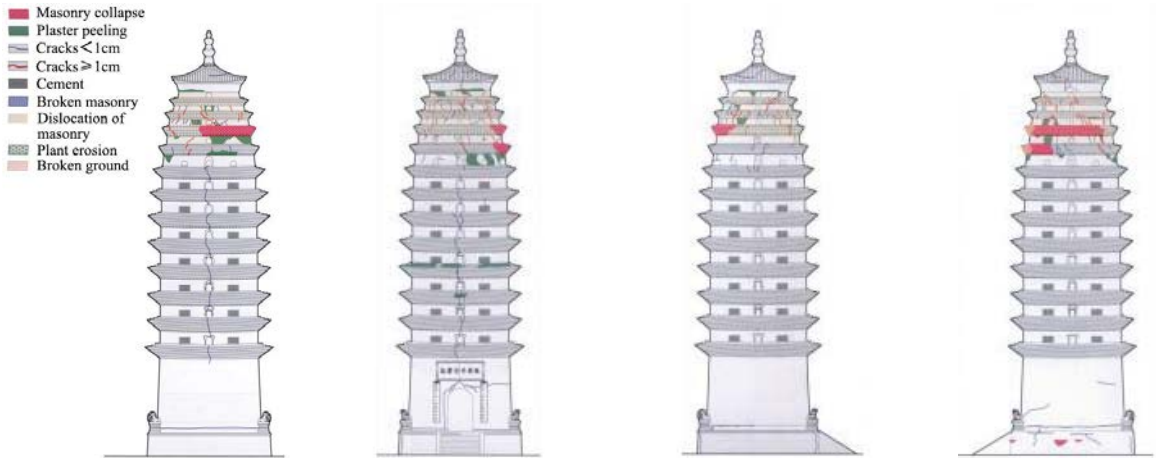
4 GEOMETRICAL AND DAMAGE SURVEY

The Longhu pagoda, which has been subjected to a huge earthquake load, suffered great damage during the Wenchuan earthquake, but it did not collapse. All of the damage can be concluded in the following [45]:

1) Through on-site observation, no significant tilt of the pagoda body was found, the status of its foundation was good, and only the lower part collapsed.

2) From the bottom to the top of the pagoda, a north-south crack appeared. The crack developed along the height, and the higher the position, the wider the crack width (Figure 10).



(a) North facade (b) South facade (c) West facade (d) East facade

Figure 10: Cracks on the Longhu pagoda (Source: Adapted from document available in [45])

3) The damage of Longhu pagoda from the outer 9 layers (the inner 5 floors) to the top was severe. The diagonal cracks at the four corners were wide and the maximum crack width was 10cm, which caused the pagoda instability.

4) Corresponding to the mentioned cracks, some cracks could also been found on the roofs or the walls around the doors which connect it central rooms and stairs.

5) There are dense and severe oblique cracks around the walls of the central rooms, these walls are facing collapse and the surrounding eaves (from outer 9 to 11 floor) already collapsed in many places.

6) Cracks also appeared in the central rooms of each floor. Their width increased along the height, and the tops of the five floor partially collapsed.

7) The windows on both the south and north sides of each floor were severely damaged, and some of them which located above outer 8 floors (inner 5 floors) were severely collapsed.

8) The pagoda spire is basically intact, and only a few cracks can be found.

5 NUMERICAL SIMULATIONS

With the aim to analyse the seismic vulnerability of the pagoda and to study how the damage spread within the structure, several non-linear numerical simulations are performed by means of FE-based software Abaqus.

A numerical model based on a macro-modeling approach is here proposed. The discretization of the pagoda is made by means of around 87000 solid linear elements (Figure 12 (a)). Such an amount is a reasonable compromise between reliability and computational speedy. Concerning the boundary conditions for the purpose of the study, as the condition of foundations results to be in good condition, fixed supports are considered at the base of the pagoda. The non-linearities of the material are introduced taking advantage of the already implemented constitutive model Concrete Damage Plasticity. CDP is a isotropic plastic-damage based model which allows a differential behavior under compression and tension. Its yield surface follows the Drucker-Prager function, which shape is opportunely modified in order to approximate a Mohr-Coulomb surface. Other parameters are input with the scope to smooth the yield surface and tackle computational issues. However, a lower value of the viscosity parameter is always preferable in order to not lead to an overestimation of the capacity of the structure. The behavior under compression is described by a parabolic softening (Figure 11), whereas the tensile behavior follows a linear or exponential softening. In this work as the tensile non-linear properties are input through a fracture energy approach (Table 1) a linear softening is accounted. The degradation of the elastic stiffness is determined by two variables of damage dt and dc, functions of the plastic strains. Such variables vary between a value of 0 for the undamaged material and 1 for the material that has completely lost any stiffness In the following tables a list of material properties is provided along with the parameters related to the definition of yield surface of CDP (Table 2).

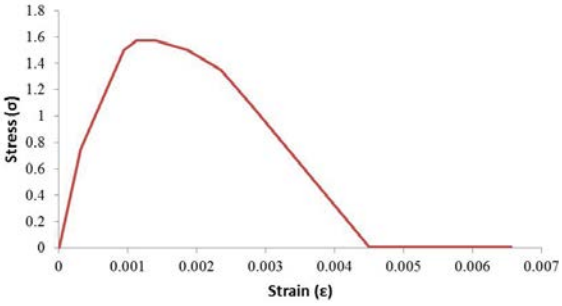


Figure 11: Stress-strain curve for the masonry material

Young's Modulus	1600 MPa
Specific Weight	18 kN/m^3
Compression Strength	1.5 MPa
Tensile Strength	0.05 MPa
Tensile Fracture Energy	0.007 N/mm

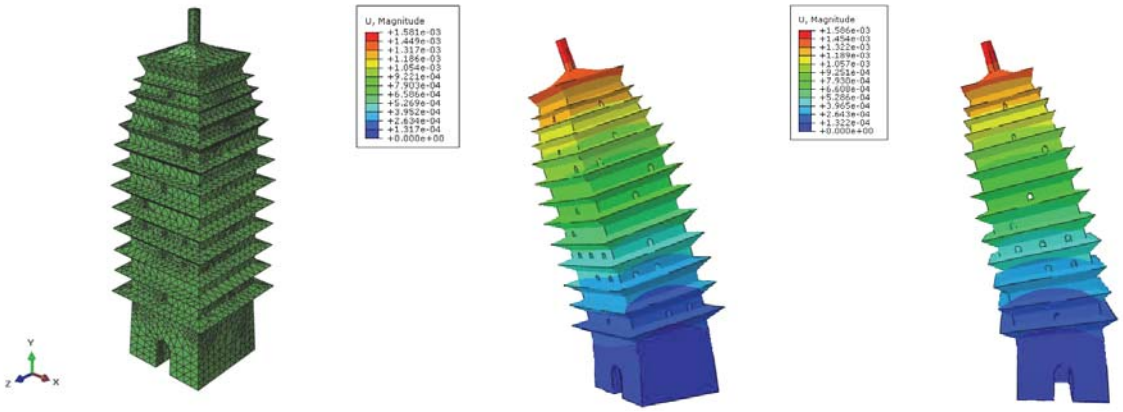
Table 1: Mechanical properties

Dilatancy Angle	Eccentricity	fb0/fc0	Viscosity Parameter
10°	0.1	1.16	0.0001

Table 2: Input parameters in the CDP

Firstly, an eigenvalues analysis is carried out with the scope to validate the efficacy of the model and to obtain the different vibration modes (Figure 12). As expected from a structure like-tower the first two vibration modes are translational modes respectively along the Z^- direction and X^- direction. The frequencies related to the first and second mode are very close

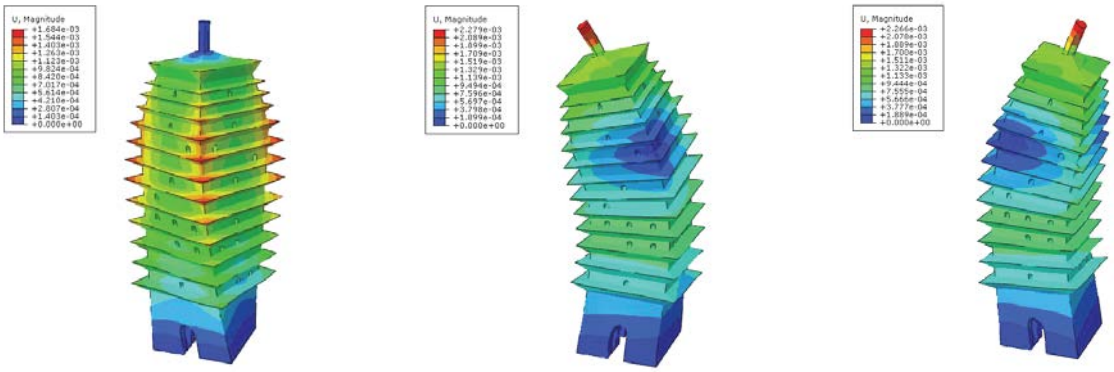
(1.61 Hz and 1.67 Hz) giving a clear indication of an almost equal stiffness of the structure in the two directions. The third mode is the rotational one corresponding to a frequency of around 5.17 Hz.



(a) Geometric configuration and discretization of the pagoda in Abaqus

(b) 1st mode: 1.61 Hz

(c) 2nd mode: 1.67 Hz



(d) 3rd mode: 5.17 Hz

(e) 4th mode: 6.97 Hz

(f) 5th mode: 6.99 Hz

Figure 12: Different vibration modes in numerical simulations

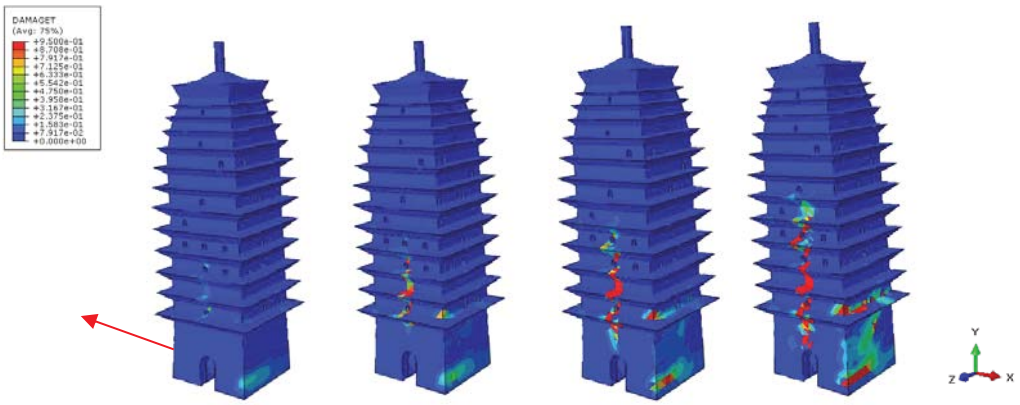
6 PUSHOVER ANALYSIS

Four different pushover analyses are performed (one for each direction) by applying a uniform distribution along the height. Despite of the symmetry of the structure, some differences in the damage among the four analyses deserve to be deeply discussed. For each analysis it is provided the progressive crack configuration along with the capacity curve Load Factor-Displacement.

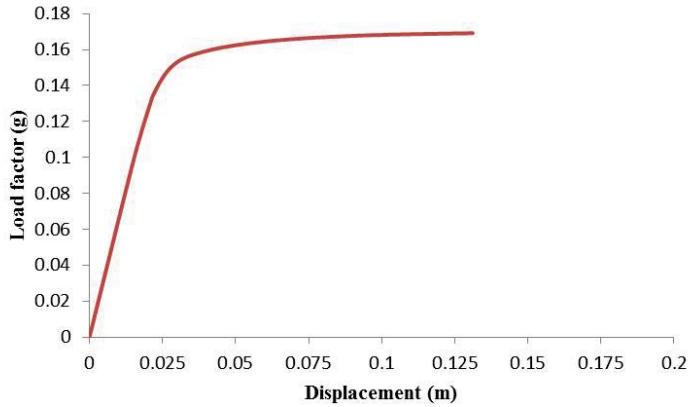
6.1 Pushover X^- direction

The first analysis is carried out by "pushing" the structure along the direction E-W. The damage starts to spread at the bottom of the structure and just above the main entrance. This latter then develops in a vertical crack which involves almost 2/3 of the total height on the south facade. On the north facade it is provided the damage configuration at the last step where a diagonal crack occurs. The global behavior of the structure is described by the capacity curve. From this latter it is possible to identify that around a load factor of 0.15 g the pagoda stopped working under elastic regime (in correspondence of almost 0.03 m).

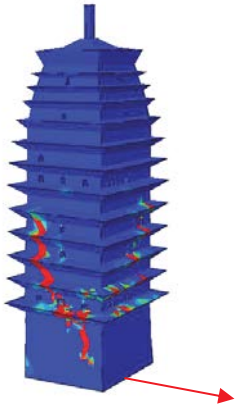
Afterwards, the non-linear response is described by a plateau in correspondence of a load factor nearby 0.16 g and a final displacement of about 0.13 m (Figure 13).



(a) Damage on the east facade and south facade



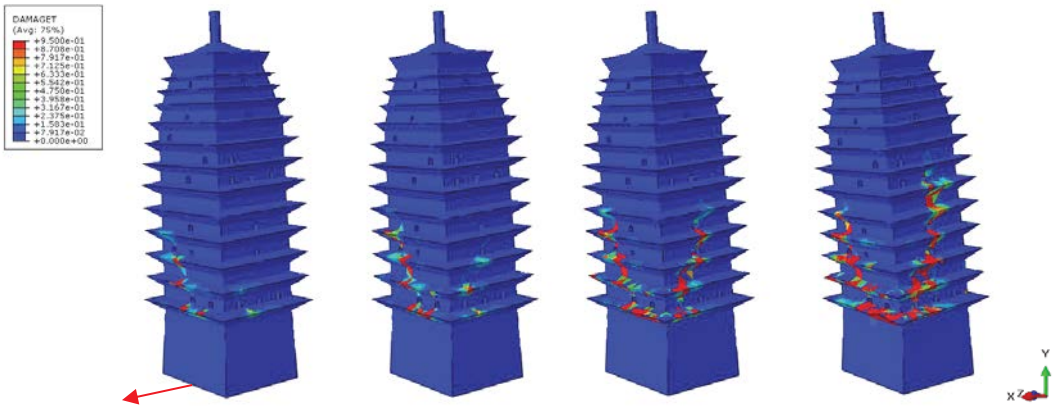
(b) Load factor-displacement curves



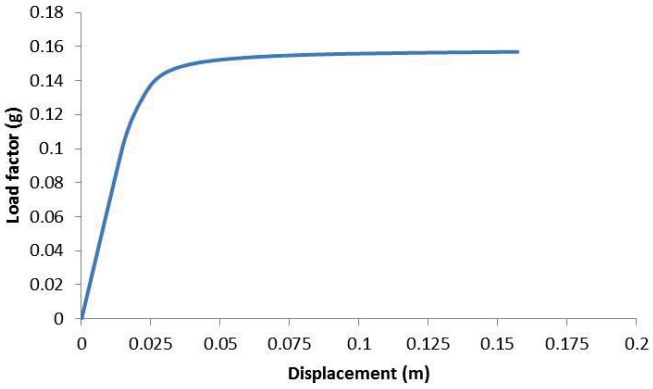
(c) Damage on the west facade and north facade

Figure 13: Results of pushover analysis in X^- direction

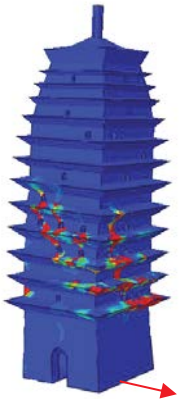
6.2 Pushover X^+ direction



(a) Damage on the east facade and north facade



(b) Load factor-displacement curves



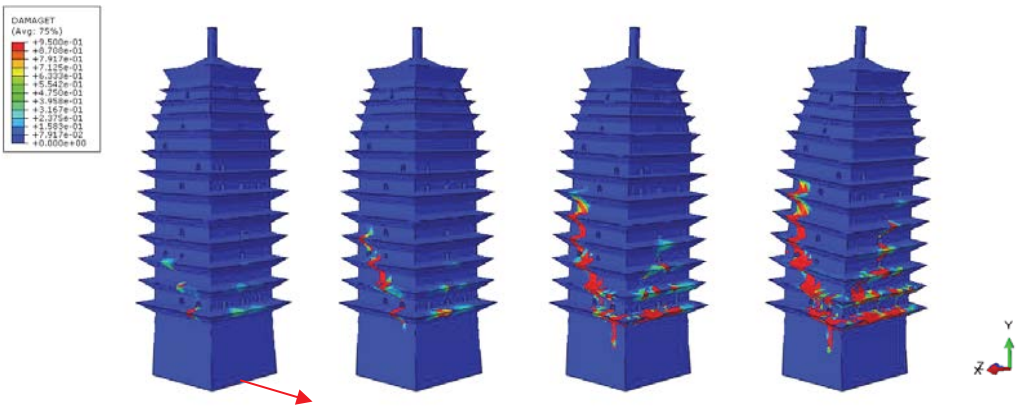
(c) Damage on the east facade and south facade

Figure 14: Results of pushover analysis in X^+ direction

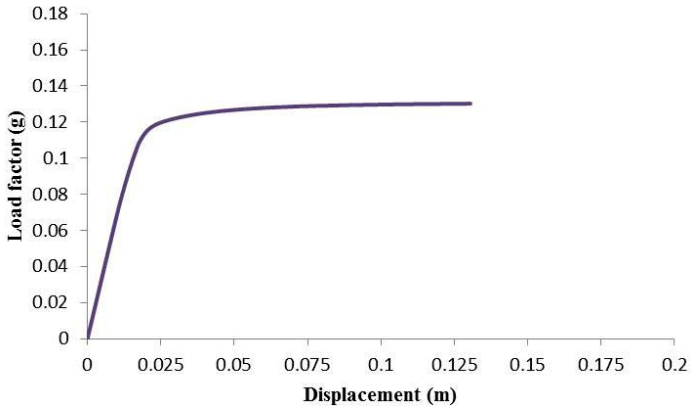
From the pushover along the W-E direction a similar capacity curve is obtained. However, a different spread of the damage can be noticed. Indeed, the first crack occurs on the East facade where the presence of the stairs represent a weakness of the structure (Figure 14). On the North facade the crack is pretty similar with the one obtained in the previous analysis but involving more the upper part of the structure. Even on the South facade it is noticeable a difference. In place of a vertical crack, a more diffused damage characterizes the center of the structure.

6.3 Pushover Z^- direction

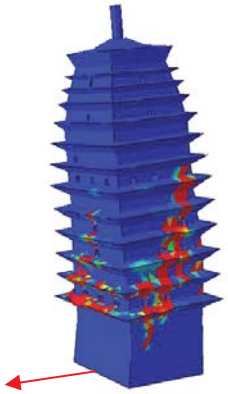
The pushover analysis along S-N direction is characterized by the lowest value of load factor (0.12 g) and displacement (0.13 m). Again, the presence of the stairs probably induces on the East facade a concentration of damage, leading to a overturning mechanism just above the first floor (Figure 15).



(a) Damage on the east facade and north facade



(b) Load factor-displacement curves

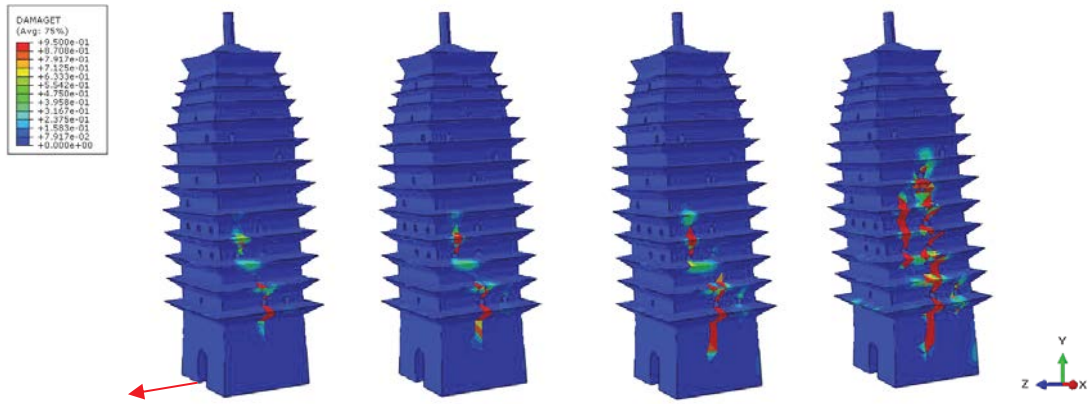


(c) Damage on the west facade and north facade

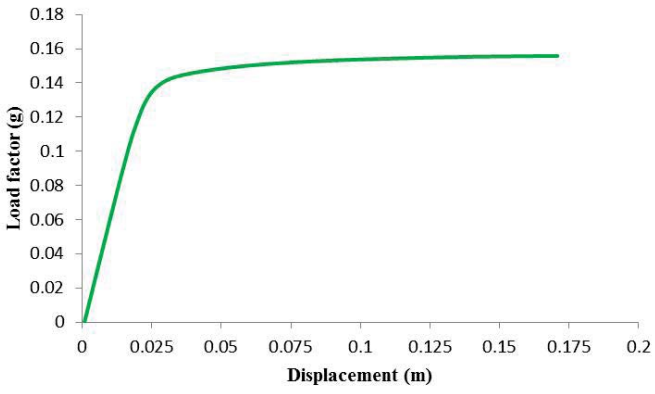
Figure 15: Results of pushover analysis in Z^- direction

6.4 Pushover Z^+ direction

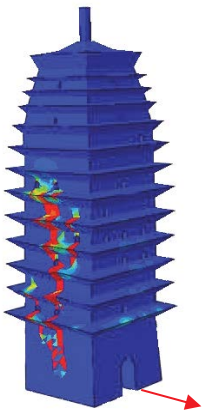
The analysis along the N-S direction leads to a damage configuration almost purely vertical on both facades. The capacity load factor results close to 0.16 g with a final displacement slightly above the previous analyses: 0.18 m (Figure 16).



(a) Damage on the east facade and south facade



(b) Load factor-displacement curves

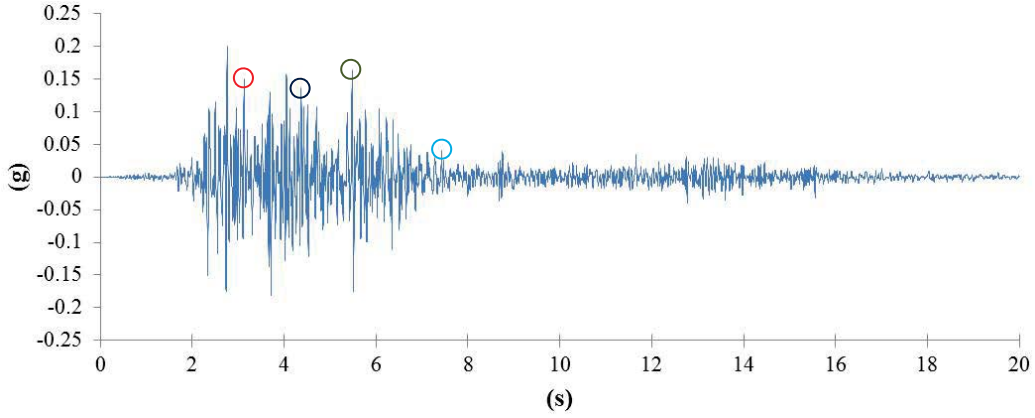


(c) Damage on the south facade and west facade

Figure 16: Results of pushover analysis in Z^+ direction

6.5 Dynamic Analysis

Along with the above discussed non-linear static analyses, a dynamic non-linear analysis is presented in this section. A real accelerogram recorded on 12 May 2008 has been filtered and corrected and applied to the pagoda along the E-W direction in order to provide a numerical comparison with pushover analyses and even with the real damage configuration observed after the Wenchuan earthquake. The PGA is almost equal to 0.2 g in correspondence of 2.76 sec. As it is noticeable from the crack evolution, by means of dynamic analysis it is possible to track the damage of the pinnacle, impossible to obtain with pushover analysis. The rest of the damage is pretty similar with the one resulting from the Pushover X^- (Figure 17). A vertical crack occurred on the North facade along with a diagonal crack on the East facade, involving even the upper part of the structure in correspondence of the openings.



(a) Accelerogram of Wenchuan earthquake which has been filtered and corrected

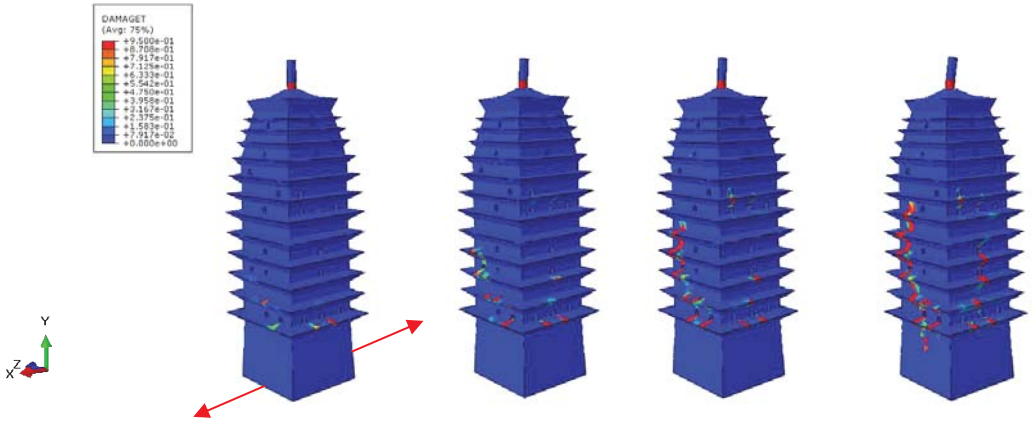


Figure 16: Results of dynamic analysis

7 CONCLUSIONS

In this paper, the Longhu pagoda which is located in the high-intensity area of the Wenchuan earthquake was taken as the case study.Combined with relevant survey data, a solid model was created by CAD, and Abaqus was used for seismic dynamic response analysis. In the numerical simulation, the load factors and displacement were used as the analysis objects. The damage process of the pagoda was evolved, and its weak parts were found out. By comparing with the relevant data, the damage characteristics of the Longhu

pagoda in the earthquake were attempted to be summarized. The main conclusions are as follows:

1) The Abaqus software is used for mode analysis and dynamic analysis. The mode analysis can reflect the dynamic characteristics of the structural model, and illustrates the reliability of the FE simulation. In the numerical simulation, the stress concentration in the windows is more obvious, and the cracks show X shape along them. At the same time, the location of the internal staircase is also the main weak link of the structure, and the cracks develop diagonally on the building surface along the direction of the stair construction.

2) Without considering the dynamic interaction between soil and structure, the cracks of Longhu pagoda first appeared at the door and window openings of the first floor, and gradually developed along the weak links of each floor. The final simulation results indicate that the structure of first floor is in an elastic state, and the structures of second, third, and fourth floors are in a state of slight damage. More than five floors, its structure may reach a serious damage state, which is close to the ultimate damage.

3) Several non-linear static and dynamic analyses have been presented on the particular case of the Longhu pagoda, severely affected by Wenchuan earthquake. The most remarkable outcome to highlight is the great efficacy of pushover analyses in reproducing the damage observed after the earthquake, specifically the vertical crack on the South and North facades. On the one hand the non-linear dynamic analysis allows to put in evidence the accuracy provided by the pushover analyses but moreover gave useful information about the crack propagation of the upper part and nearby the pinnacle. On the other hand, pushover analysis seem to underestimate the capacity load that in average settles down around 0.16 g.

ACKNOWLEDGEMENTS

Keywords: Historical masonry structures, NURBS, adaptive limit analysis, genetic algorithm.

Abstract. *In this work, we propose an adaptive upper bound limit analysis based on the representation of geometry through NURBS-solids. A NURBS-solid is a closed volume identified by boundary NURBS surfaces (Non-Uniform Rational Bezier Spline). Differently from using NURBS surfaces representing masonry shell-elements, NURBS-solids allow an accurate representation of masonry three-dimensional macro-blocks, such as vaults or walls with variable thickness. The initial model is subdivided into very few macro-elements, each one is still a NURBS solid and is considered as a rigid block. Since dissipation occurs only along interfaces, NURBS boundary surfaces represent possible fracture zones. An upper bound limit analysis is applied. The minimum kinematic multiplier is found by modifying the initial subdivision of solids until the real collapse mechanism is reproduced. This automatic research is performed through a Genetic Algorithm. A simple numerical example is finally reported.*

1 INTRODUCTION

The field of historical masonry structures includes a wide range of different masonry construction typologies, such as vaulted structures, churches, towers, castles, monumental buildings, and aggregates.

The interest in the study of these structures through new advanced computational strategies became higher after recent seismic events, which underlined the strong vulnerabilities of historical masonry constructions to horizontal loads [1–3]. In the analysis of masonry structures, the peculiar characteristics of historical masonry structures have to be taken into account: the nonlinearities of masonry material (i.e. negligible tensile stress compared with good compressive behavior), typical presence of curved geometries, uncertainties on interlockings, coexistence of different and irregular masonry textures and presence of damage. Above all methods adopted [4], one of the most suited numerical tools is limit analysis. The limit analysis of masonry structures has been introduced for the first time by Heyman [5], who suggested to treat masonry as a no-tension material. In this theory, the structure is simplified as an assembly of rigid bodies with null tensile resistance and both crushing and sliding failures avoided. This allowed to analyze of the statics of curved masonry structures through simple procedures based on the static theorem of limit analysis [6,7], such as the construction of the thrust surface for the analysis of masonry arches. Among the methods proposed in last years, it is worth mentioning the so-called Thrust Network Method [8], which consists of a lower bound limit analysis of masonry vaults through the construction of the thrust surface, which is the three-dimensional extension of the thrust line.

As regards methods based on the kinematic theorem of limit analysis, procedures based on the finite element method have been proposed [9]. Here, rigid elements with nonlinear interfaces are often adopted. Nonlinearities are represented by assigning a three-dimensional failure domain which allows a refined representation of mechanical parameters of masonry. Moreover, recently some homogenization procedures have been presented for a reliable determination of the three-dimensional failure surface, opening the access to a wide field of applications [10–12].

However, analyses based on the kinematic theorem of limit analysis can lead to inaccurate results if the geometrical representation and the mechanical models are not able to reproduce the real collapse mechanism. In order to overcome such limitations, a new adaptive upper bound limit analysis has been proposed by the authors [13]. In this method, the geometry of a masonry vault is modeled through NURBS surfaces (Non-Uniform Rational Bezier Spline, [14]). The use of NURBS is particularly suited for curved masonry structures, because it allows an accurate representation of complex geometries [15]. The masonry vault is discretized through very few shell elements, each one is still a NURBS surface. An upper bound limit analysis is applied. Elements are idealized as curved rigid blocks and jump of velocities are allowed only along interfaces according to an associated flow rule. A properly defined homogenized failure domain is required. Therefore, interfaces assume the meaning of possible fracture lines. In order to find the real collapse mechanism, i.e. the real position of fracture lines, a mesh adaptation procedure is applied. By maintaining a low total number of elements, the mesh is adaptively modified until the minimum kinematic multiplier is reached. This optimization procedure is conducted through a Genetic Algorithm (GA) [16], even if other metaheuristic approaches can be followed [17]. Different typologies of masonry structures have been studied through this GA-NURBS limit analysis [18–26].

Despite the great versatility of the method, it is still limited to constructions which can be described through plate or shell elements. However, there are many masonry structures which do not behave as assemblies of surfaces, such as arches and vaults with variable thickness,

monumental triumphal arches, and complex buildings. Therefore, a new adaptive upper bound limit analysis based on the use of NURBS solids is presented. A NURBS solid is a closed region of space delimited by NURBS boundary surfaces.
The use of solids, which can be characterized by curved boundaries, allows the representation of curved objects without geometrical limitations. In this new method, a masonry structure is modeled in Rhinoceros by using NURBS solid-entities and then imported into MATLAB, in which an adaptive upper bound limit analysis is applied. A simple example on a masonry arch with variable thickness is presented to prove the effectiveness of the method.

2 NURBS SOLIDS: GEOMETRIC DESCRIPTION

In the geometrical description of three-dimensional objects, NURBS functions (Non-Uniform Rational Bezier Spline, [14]) are commonly adopted in the modern modeling software, such as Rhinoceros or SolidWorks. NURBS basis functions are built on B-splines basis functions, which are piecewise polynomial functions defined by a non-uniform knots vector (i.e. non-equidistant points in a parametric domain) $\Xi = \left\{\xi_1, \xi_2, ...\xi_{n+p+1}\right\}$, where p and n denote respectively the polynomial order and the total number of basis functions. Given a set of weights w_i and the i-th B-spline basis function $N_{i,p}$, then the NURBS basis function $R_{i,p}$ can be written as follows:

$$R_{i,p}(\xi) = \frac{N_{i,p}(\xi)}{\sum_{j=1}^{n} N_{j,p}(\xi)\, \mathrm{w}_j} \tag{1}$$

Starting by NURBS basis function, a NURBS surface $\mathbf{S}(u,v)$ of degree p in the u-direction and q in the v-direction is a parametric surface in the three-dimensional Euclidean space defined as follows:

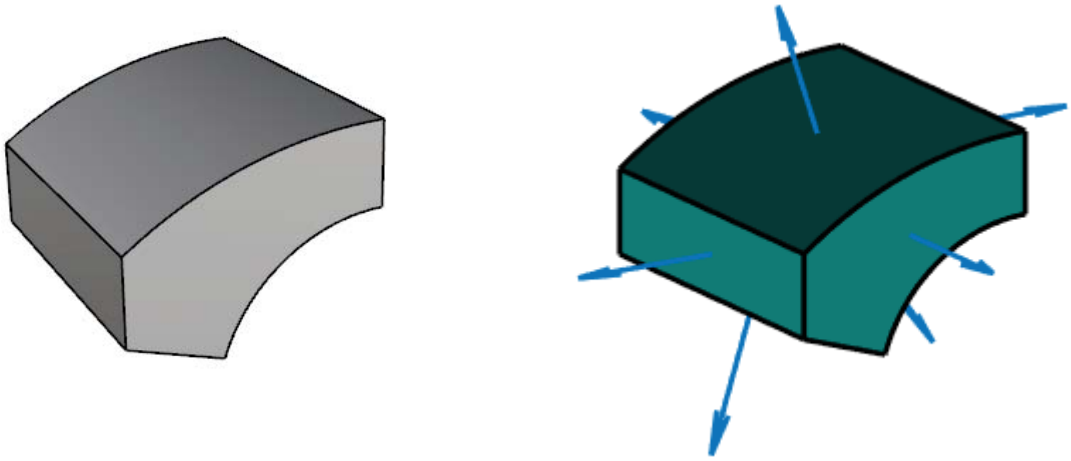
$$\mathbf{S}(u,v) = \sum_{i=0}^{n}\sum_{j=0}^{m} R_{i,\mathrm{j}}(u,v)\mathbf{B}_{i,j} \tag{2}$$

where $\mathbf{B}_{i,j}$ are the control points.

Consider now a limited region of space $D \subset \mathbb{R}^3$ whose frontier ∂D is a piecewise regular and oriented surface. A NURBS solid is defined as a closed region of space D in which the boundary ∂D is an assembly of NURBS surfaces and no information is provided for the space internal to the boundary. In other words, a NURBS solid is exhaustively described by its frontier ∂D as follows:

$$D = \partial D = \bigcup_{k=1}^{M} \mathbf{S}_k\left(u,v\right) \tag{3}$$

where M is the total number of boundary NURBS surfaces, and each boundary surface is identified by the classical NURBS description (see Equation 2).
Geometrical models composed of NURBS surfaces can be easily imported in MATLAB from Rhinoceros through the IGES standard file [27] and the available functions within the IGES toolbox [28]. However, this is not the case of NURBS solids, which are not supported by the IGES standard file. Therefore, a new IGES format, called "IGESsolid" and a new function "iges2matlab" [29] has been written specifically to import solids in the MATLAB environment. An example of NURBS solid in Rhinoceros and in MATLAB, representing a portion of a masonry arch with variable thickness, is reported in Figure 1.



(a) (b)

Figure 1. NURBS solid in (a) Rhinoceros and (b) MATLAB.

A NURBS solid can be subdivided into one or more solids directly within MATLAB. The subdivision of solids is a fundamental step for the adaptive limit analysis procedure which will be described in the next Section. This operation is conducted through a new algorithm written by the authors specifically for the subdivision of solids in MATLAB. Without going in detail about this algorithm, the subdivision is performed by defining an additional NURBS surface, which represents the "splitting object". For each boundary surface, a surface-surface intersection problem (SSI) is solved. Once the common curve between the boundary surface and the splitting surface is determined, the boundary comes split into two (or more) boundaries, in which each one is a partition of the original boundary. After a procedure of re-assembling of the new sub-boundaries, two new NURBS solids are obtained (see Figure 2).
Therefore, the core of this subdivision procedure is the SSI algorithm. The SSI problem has been widely investigated in the scientific literature [30], the procedure here implemented has been developed by improving the formulation presented in [31].

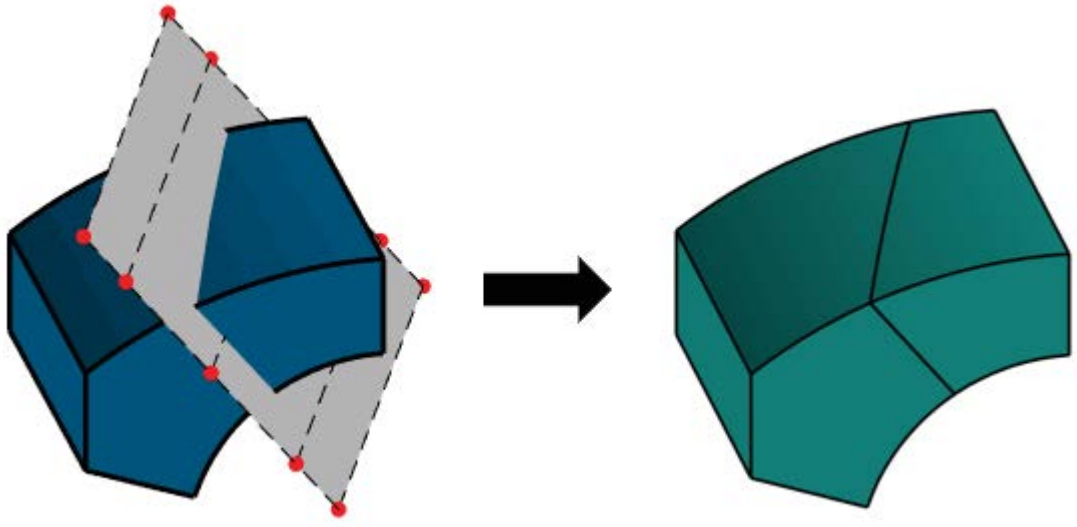


Figure 2. NURBS solid subdivided through a planar NURBS surface.

Once the subdivision of solids is completed, the volume V and the centroid $\mathbf{G}$ of each solid can be evaluated. As it is well known, these properties are determined as follows:

$$V = \iiint_D dxdydz \tag{4}$$

$$\mathbf{G} = \frac{\iiint_D \nabla \cdot \mathbf{F}(x,y,z)\, dxdydz}{V}, \text{ such that } \nabla \cdot \mathbf{F}(x,y,z) = x\mathbf{i} + y\mathbf{j} + z\mathbf{k} \tag{5}$$

These volume integrals can be easily converted in surface integrals by applying the divergence theorem (also known as the Gauss's theorem), for which:

$$\iiint_D \nabla \cdot \mathbf{F}(x,y,z)\, dxdydz = \iint_{\partial D} \mathbf{F}(x,y,z) \cdot \mathbf{n}_e dS \tag{6}$$

where $\mathbf{n}_e$ is the normal external unit vector for ∂D. For NURBS surfaces, the normal unit vector is so defined:

$$\mathbf{n}_e = \frac{\mathbf{S}_u(u,v) \times \mathbf{S}_v(u,v)}{\left\| \mathbf{S}_u(u,v) \times \mathbf{S}_v(u,v) \right\|} \tag{7}$$

where $\mathbf{S}_u(u,v)$ and $\mathbf{S}_v(u,v)$ denote respectively the two partial derivative vectors. Provided that in a NURBS solid the frontier ∂D is a composition of NURBS surfaces (Equation 1), Equation 6 can be re-written as follows:

$$\iiint_D \nabla \cdot \mathbf{F}(x,y,z) dxdydz = \sum_{k=1}^{M} \iint_{Q_k} \mathbf{F}\left(x(u,v), y(u,v), z(u,v)\right) \cdot \left(\mathbf{S}_{k,u}(u,v) \times \mathbf{S}_{k,v}(u,v)\right) dudv \tag{8}$$

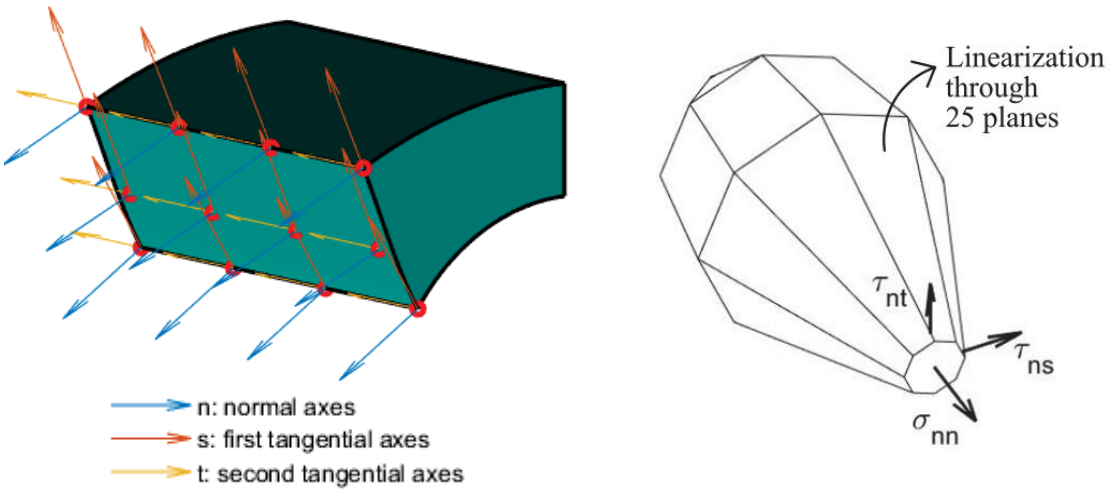
in which Q_k is the standard parametric domain associated to the *k*-th surface. This integral can be solved in MATLAB through the Gauss integration. Equation 8 is applied to solve all volume integrals on NURBS solids. Therefore, it is adopted in the evaluation of volumes, weights, centroids, and in the application of volume forces.

3 ADAPTIVE KINEMATIC LIMIT ANALYSIS

A masonry structure is here represented as an assembly of few rigid blocks, in which each block is a NURBS solid. A procedure of kinematic limit analysis is defined. The kinematic of each block is defined through the six degrees of freedom $\left\{u_x^i, u_y^i, u_z^i, \Phi_x^i, \Phi_y^i, \Phi_z^i\right\}$ of its centroid in the three-dimensional space *Oxyz*. Interfaces between elements, which are the NURBS surfaces of the common boundaries, are the only zones where jumps of velocities are supposed to occur. Therefore, dissipation is allowed only at interface according to a rigid-plastic behavior. A three-dimensional failure surface, which consists of a Mohr-Coulomb failure surface with tension cut-off and linear cap in compression [32], is assigned to the masonry material. In this way, crushing and sliding failures are automatically included in the computation. It is clear that, by using high values of ultimate compression strength and friction angle, the typical Heyman condition [5] can be reproduced. The internal plastic dissipation at the generic interface is evaluated according to the associated flow rule:

$$\Delta\tilde{\mathbf{u}} = \left(\dot{\boldsymbol{\lambda}}^T \frac{\partial f}{\partial \boldsymbol{\sigma}} \right)^T \tag{9}$$

where $\Delta\tilde{\mathbf{u}}$ is the jump of velocity in the local reference system, $\dot{\boldsymbol{\lambda}}$ is the vector containing the non-negative plastic multiplier, f is the three-dimensional failure domain, and $\boldsymbol{\sigma}$ is the stress vector. The associated flow rule is applied by discretizing the interface into a series of points. Since the use of NURBS allows the presence of curved interfaces, the discretization is conducted by defining a triangularization of the NURBS surface (the procedure described in [33] is used). In Figure 3(a) and example of discretization with local reference systems is showed, whereas Figure 3(b) reproduces a linearization of the adopted three-dimensional failure surface.



(a) (b)

Figure 3. (a) Discretization of the curved interface into points and local reference systems, (b) linearized three-dimensional failure surface.

The total internal dissipation is thus determined as follows:

$$P_{\text{int}} = \sum_i \int_{S_i} \left(\boldsymbol{\sigma} \cdot \Delta\tilde{\mathbf{u}}\right) dS = \sum_i \int_{S_i} \dot{\boldsymbol{\lambda}}^T \cdot \left(\boldsymbol{\sigma}^T \frac{\partial f}{\partial \boldsymbol{\sigma}} \right)^T dS \tag{10}$$

A configuration of loads, distinguished in dead loads (permanent) $\mathbf{F}_0$ and live loads (depending on a multiplier λ) $\lambda \cdot \boldsymbol{\Gamma}_0$, is defined. If the vector of velocities is indicated as $\mathbf{U}$, the power dissipated by the external loads is defined as:

$$P_{ext} = \left(\mathbf{F}_0 + \lambda \cdot \boldsymbol{\Gamma}_0\right)^T \mathbf{U} \tag{11}$$

The solution of the kinematic problem is obtained by applying the Principle of Virtual Powers. By normalizing the power dissipated by live loads, i.e.:

$$\boldsymbol{\Gamma}_0^T \mathbf{U} = 1 \tag{12}$$

the problem can be written with the following linear programming formulation:

$$\min\left\{\lambda = P_{\text{int}} - \mathbf{F}_0^T \mathbf{U}\right\} \text{ such that } \begin{cases} \mathbf{A}\mathbf{x} = \mathbf{b} \\ \dot{\boldsymbol{\lambda}} \geq 0 \end{cases} \tag{13}$$

where $\mathbf{x} = \left[\mathbf{U}, \dot{\boldsymbol{\lambda}}\right]$ is the vector of unknowns, $\mathbf{A}$ and $\mathbf{b}$ are respectively the overall equality constraints matrix (which include geometric constraints, compatibility constraints and normality condition) and the corresponding right hand side vector.

The presented upper bound formulation provides the configuration of velocities of each block at failure, i.e. a kinematic mechanism, and an associated load multiplier, which is an upper bound of the collapse multiplier. In order to optimize the kinematic multiplier, the real collapse mechanism has to be found.

The mechanism depends on how solids have been initially subdivided. Therefore, changing the position and/or the shape of the NURBS surfaces adopted as splitting objects, different mechanisms can be found. A genetic algorithm (GA) [16] is applied to move these NURBS surfaces and find the subdivision associated to the minimum kinematic multiplier. Given the lower number of parameters involved in the meta-heuristic optimization, the optimized mechanism is usually found after very few iterations.

4 NUMERICAL EXAMPLE

The first result obtained through the novel NURBS solids-based formulation is here presented. A masonry arch characterized by variable thickness is here analyzed under a simple pointed load. Geometry and load condition are depicted in Figure 4(a). This type of arch has been originally presented by Lamé and Clapeyron [34] and successively studied in [35]. These arches are constructed with a layer of radial voussoirs disposed at the intrados and additional horizontal layers of masonry above. Therefore, the shape of the arch is different between intrados and extrados, resulting in a variable thickness. In presence of simple vertical load, Lamé and Clapeyron observed that this kind of arches fails by developing fracture lines that start radially at the intrados (i.e. following the radial joints given by voussoirs), and then propagate upward becoming almost vertical. A representative scheme of this crack pattern is shown in Figure 4(b). This observation has been confirmed in [35].

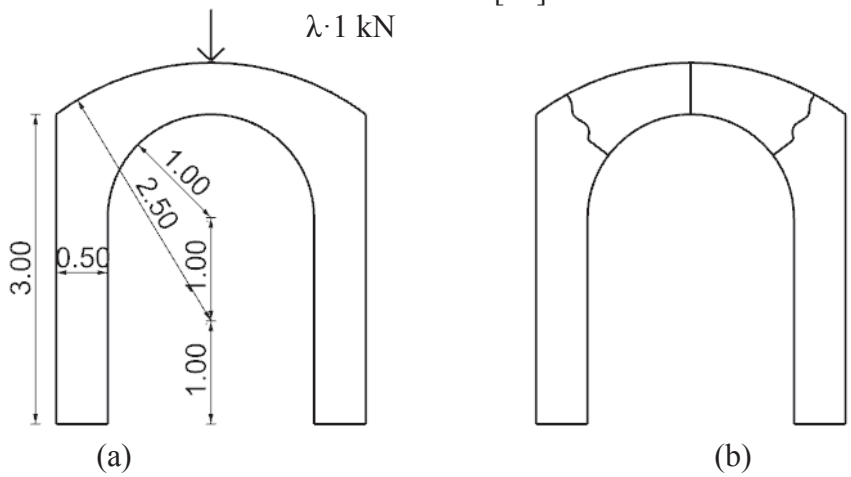


Figure 4. Arch with radial voussoirs at the intrados and a horizontal layer of masonry above: (a) geometry and load condition analyzed, and (b) typical crack pattern under vertical loads [34,35].

As a preliminary evaluation, the masonry arch has been analyzed as 2D problem (width has been assumed unitary) through a heterogeneous kinematic limit analysis. Two different subdivisions into rigid blocks have been adopted. In the first one, the arch is subdivided through radial joints starting from the intrados, whereas horizontal joints have been adopted for piers, see Figure 5(a). In the second one, two different mesh have been adopted for the intrados and the extrados, in order to better take into account the two different layers of voussoirs. Whereas radial joints have been maintained at the intrados, triangular blocks have been assigned to the masonry material located above the radial voussoirs, see Figure 5(b). A value of 18 kN/m3 has been adopted as specific weight. A null tensile strength has been assigned, cohesion and friction angle are respectively equal to 0.02 MPa and 30°, and finally the compression strength has been assumed equal to 2.6 MPa. Results obtained for both the mesh are shown in Figure 5(c,d). It can be noted that a lower load multiplier has been found for the second mesh, in which the crack pattern observed in [34,35] can be better reproduced.

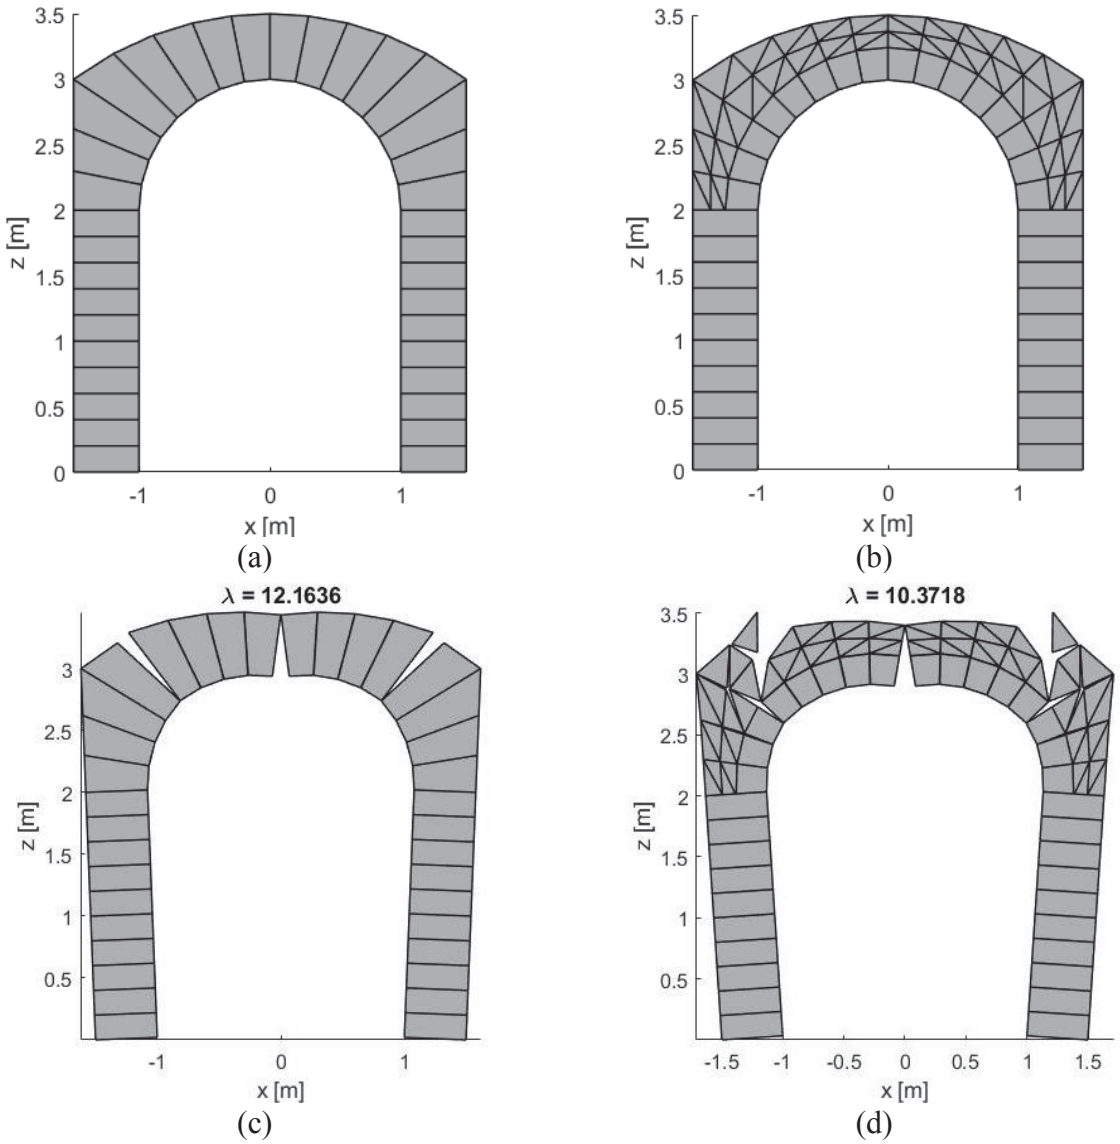

Figure 5. Limit analysis of the masonry arch with heterogeneous approach: (a,b) two different initial mesh, and (c,d) corresponding collapse mechanism and load multiplier.

The study through adaptive limit analysis through NURBS solids is now presented. A representation through two NURBS solids is reported in Figure 6(a). A width equal to 2 m has been assigned. In order to correctly compare this example to the previous ones, the live load condition here used consists of a linear load equals to 1 kN/m distributed along the extrados line belonging to the symmetry plane of the arch. According to the symmetry of the problem, the subdivision of the masonry arch is governed by two planar NURBS surfaces that move symmetrically. The shape of these surfaces is governed by three parameters, summarized by the vector **a** and depicted in Figure 6(b). It can be observed that, if the second or the third parameter are not null, the surface is not more planar and the resulting fracture surface on the solid is curved. The same material parameters have been adopted for this model.

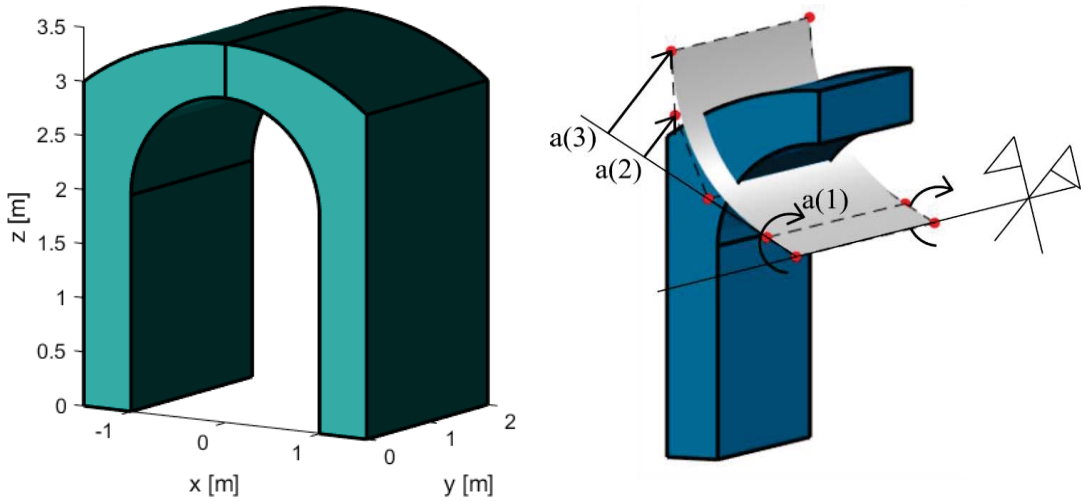

Figure 6. (a) NURBS model of the arch, and (b) NURBS surfaces adopted for the subdivision.

Results are shown in Figure 7. Figure 7(a, b) depicts the collapse mechanism found and the corresponding live load multiplier, whereas in Figure 7(c) the convergence diagram deriving from the application of the GA is reported. As it was expected, the arch collapses for the formation of curved cracks that are almost vertical near the extrados. The load multiplier resulted lower than values obtained through the heterogeneous approaches (9.37 compared with 10.37 and 12.16), denoting a higher precision in the definition of the collapse mechanism for the adaptive approach.

This method is computationally cheap because it allows to study complex geometries by using a very reduced number of elements, still maintaining the exact geometry of the case study.

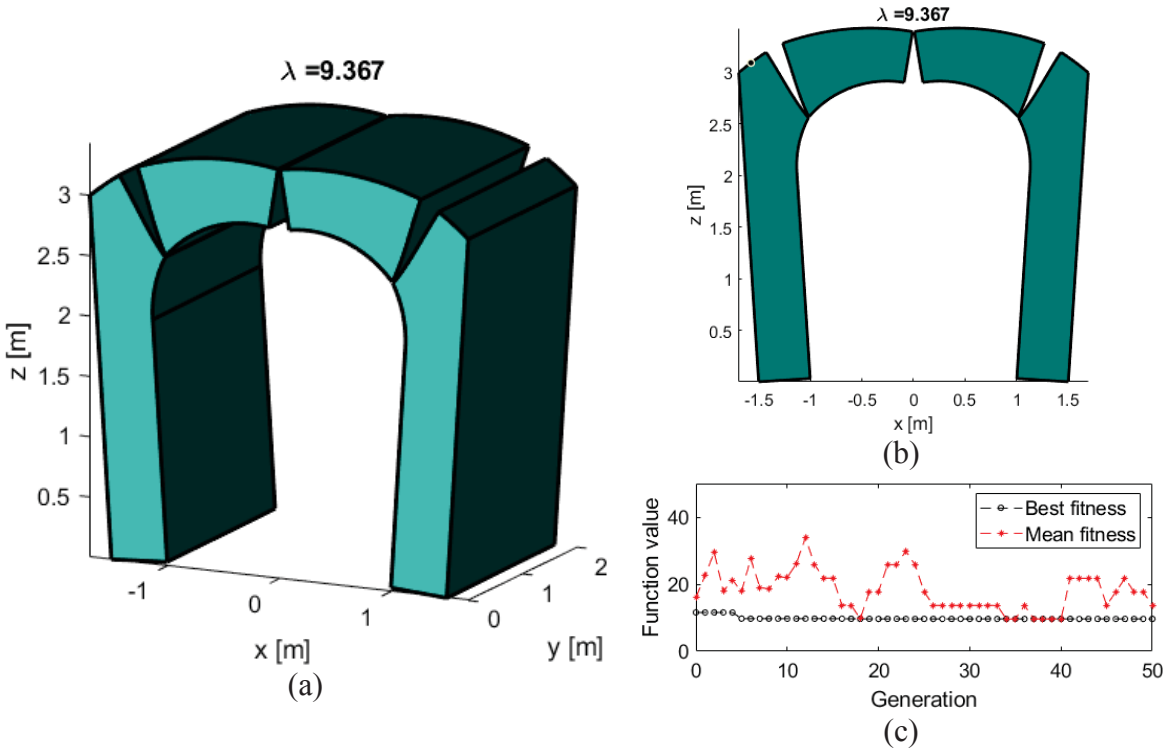

Figure 7. Results obtained through adaptive limit analysis: load multiplier and collapse mechanism in (a) axonometric and (b) frontal view, and (c) convergence diagram.

5 CONCLUSIONS

A new adaptive upper bound limit analysis based on the use of NURBS solids has been presented. A given masonry structure is modeled through NURBS solids and then imported into MATLAB. The model is then subdivided through NURBS surface and analyzed through an adaptive upper bound limit analysis is applied. By using a Genetic Algorithm, the initial subdivision is then modified to reproduce the real collapse mechanism and identify the collapse multiplier.

The presented method has been applied on a masonry arch with variable thickness and results have been compared with classical heterogeneous limit analysis procedures. A good agreement has been observed between results obtained. The use of NURBS solids allowed the exact representation of curved geometries of structures that cannot be represented with standard shell elements. The collapse mechanism is identified with good precision thanks to the automatic mesh adaptation. Moreover, the subdivision of solids through NURBS surfaces allows the identification of curved fracture zones within the macroblocks in easy way.

Future research will be focused on the use of the presented method for the analysis of monumental masonry constructions subjected to horizontal actions.

Keywords: discrete model, auto-mesh, homogenization, masonry vault.

Abstract. *A fast and innovative discrete model approach coupled with homogenization procedure is here presented. The method is able to comply with the main features required for an accurate simulation of masonry curved elements, such as the orthotropy and the typical in-and-out-of-plane coupled behavior exhibited by masonry vaults. Furthermore, homogenization techniques directly implemented in the method allows reducing consistently the number of variables, leading to a fair combination of accuracy and reasonable computational time. The discrete model is an assembly of elastic units joint by non-linear interfaces. These latter are modeled with 3D linear brick elements and Concrete Damage Plasticity (CDP) is used for modeling the non-linear mechanical properties coming from the homogenization step. In order to overcome potential difficulties during the preparation of the model, the discretized mesh is obtained automatically by means of an ad-hoc script implemented by the Authors. The proposed approach is validated taking advantage of numerical data already available on a cloister vault. The numerical comparison shows the reliability of the method and its efficacy in the simulation of both global behavior and crack pattern, requiring a low computational effort.*

1 INTRODUCTION

The vulnerability of historical masonry structures when subjected to seismic loads is well known and preservation is a fundamental task in order to preserve the structures that assumed the role of a cultural landmark. In such historical buildings, the most fascinating and peculiar elements are represented by arches, vaults and domes. However, at the same time, these elements represent often the most vulnerable part of the whole structure. The methodologies according to which curved masonry elements were designed in the past result highly effective for static loads [1]. On the other hand, strong knowledge about the behavior of such elements when subjected to dynamic loads is still missing. From the numerical point of view, the issues are related to the difficulty of balancing reliable results with a reasonable computing time. Several approaches have been developed in literature ranging from methodologies enable to effectively combine ancient and current methods as kinematic limit analyses [2] to approaches that allow a full non-linear analysis. This latter can be faced with both macro-modeling [3] and micro-modeling [4]. The first case leads to an easy numerical implementation simulating the material as a continuum, but the choice of a suitable constitutive model may result cumbersome. On the contrary, a micro-modeling procedure can allow a distinction of all the different constituents but my lead to a huge number of variables and to not practical computing time. These numerical issues can be overtaken by applying homogenization procedures, that ensure a detailed evaluation of the non-linear behavior of masonry at meso-scale [5,6] Such information is then transferred at the structural level in a second step.

In this paper, an innovative and automatic procedure for the non-linear analysis of curved masonry structures is presented.

At the macro-scale level, the structure is described as a repetition of elastic cells joint by interfaces. Such a discrete approach allows reproducing properly the orthotropic behavior of masonry. The non-linear properties coming from homogenization are lumped exclusively at the interfaces, that are modeled as flat brick elements along with a Concrete Damage Plasticity model already available in Abaqus. The main advantage of the method is the direct implementation of the homogenized parameter at the structural level, where even the mesh of the discrete model is created automatically employing a MATLAB script.

The efficacy of the method has been already described for the case of brick walls loaded out-of-plane, in the unreinforced and TRM-reinforced configuration in [7]. The extension of the method even to curved structures is suitable as the modeling of interfaces with flat 3D elements leads to a full coupling of in-and-out-of-plane actions. In such a way the influence of the normal stress related to the gravity loads on the non-linear behavior in flexion is automatically taken into account. The number of variables involved in the numerical simulations is very low when compared to micro approaches, opening the way to further application of the method on reinforced structures.

With the aim to validate the proposed approach, some non-linear simulations have been carried out on a cloister vault, of which experimental and numerical data are available in the literature [8].

2 METHODOLOGY

In this section, a general overview of the method is provided. The validation and its implementation are deeply discussed in [7] and the interested readers are directed to this research for a point of reference.

The first main step is the implementation of a discrete mesh of the curved structure. In the case of the wall, such a step resulted straightforward and without complexity due to the simplicity of the geometrical model. On the contrary, the realization of a discrete mesh for vaults

and domes may lead to a tedious procedure. In fact, the flat 8-noded brick elements employed as interfaces have a thickness that, even though negligible, implies the presence of gaps in the intersections. In order to overcome such limitations, a MATLAB script was implemented by the Authors, enable to provide an automatic discretized mesh. Moreover, the non-linear homogenized properties are assigned automatically to the interfaces according to their orientation. The non-linearity is introduced by taking advantage of the constitutive model Concrete Damage Plasticity (CDP), already available in Abaqus. Its applicability for modeling masonry structures has been widely proved in [9,10] where several non-linear analyses were performed. With such a model, a differential behavior in tension and compression is introduced, following a softening exponential law in the first case and a parabolic softening law in the second one.

Even if CDP is a continuum isotropic constitutive model, its use in a discrete approach allows preserving the orthotropy peculiar to masonry, opening the way to the implementation even in FEM-based software that does not provide an orthotropic constitutive model.

In this paper, a cloister vault, already numerically reproduced in literature, is selected in order to show the capability of the model. The automatic mesh procedure starts with the definition of a rough but structured mesh of the inner surface of the curved structure.

Each 4-noded shell element of the coarse mesh generates correspondent elastic units of the final discrete mesh. In order to create the space for interfaces, each element is scaled by acting on the 3D coordinates of four vertices. Then, the elements are automatically joined with the surrounding ones, generating additional 4-noded narrow elements. These latter will be converted to the non-linear 3D interfaces in the final model. After this stage, each 4-noded element is partitioned, creating a new mesh for the subsequent discrete model.

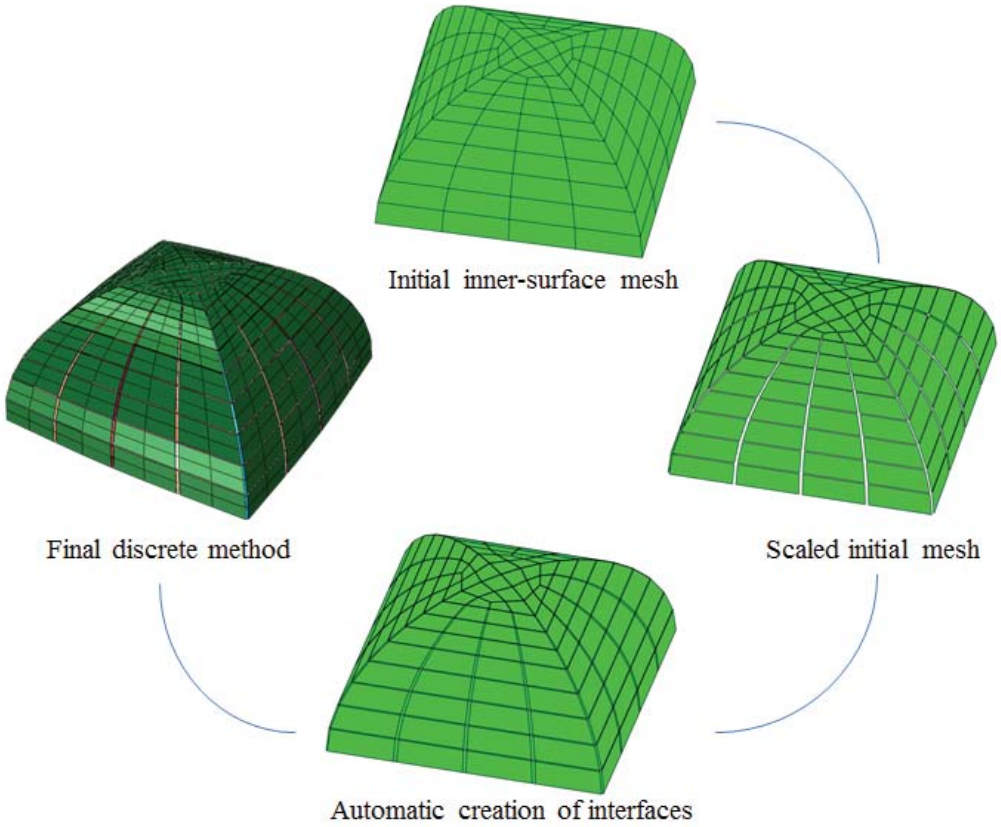

Figure 1: Steps for the automatic implementation of the discrete mesh.

The final model is then obtained by extrusion of the discrete shell mesh. A different quantity can be applied to each node, making possible the modeling of vaults with variable thickness.

In this work, the cloister vault has been modeled with 160 elastic units having a rough mesh of 4 elements on the plane r-s.

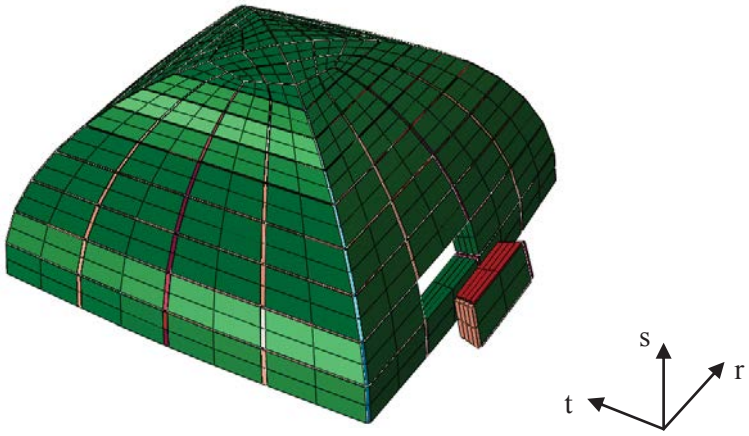

Figure 2: Mesh configuration in detail of the homogenized cloister vault.

According to the experience of the Authors, for reproducing properly the flexural behavior of curved masonry structures, 4 elements along the depth of the dome is a sufficient number.

The possibility to assign automatically the homogenized mechanical properties according to the orientation of the interfaces is a promising starting point for the upcoming research by the Authors. Indeed, semy-analytical approaches [6] might be directly implemented inside the script, leading to a full comprehensive homogenization procedure for curved structures.

Numerical analyses on the cloister vault are available in [8,12]. For the sake of consistency, the same homogenized mechanical properties defined in [8] for both directions, are input in the Concrete Damage Plasticity.

Figure 3: Detail of non-linear interfaces

3 RESULTS

The cloister vault, with a square base of 2.2 m*2.2 m, used for the validation of the method was tested by Foraboschi in 2006 and described in [11]. The test consisted in inducing the collapse of the vault by the application of a concentrated force applied at the top. Several non-linear FE simulations are already available by means of heterogeneous and macroscopic ap-

proaches. From these latter, a comparison in terms of load-displacement curves is here provided with the proposed method.

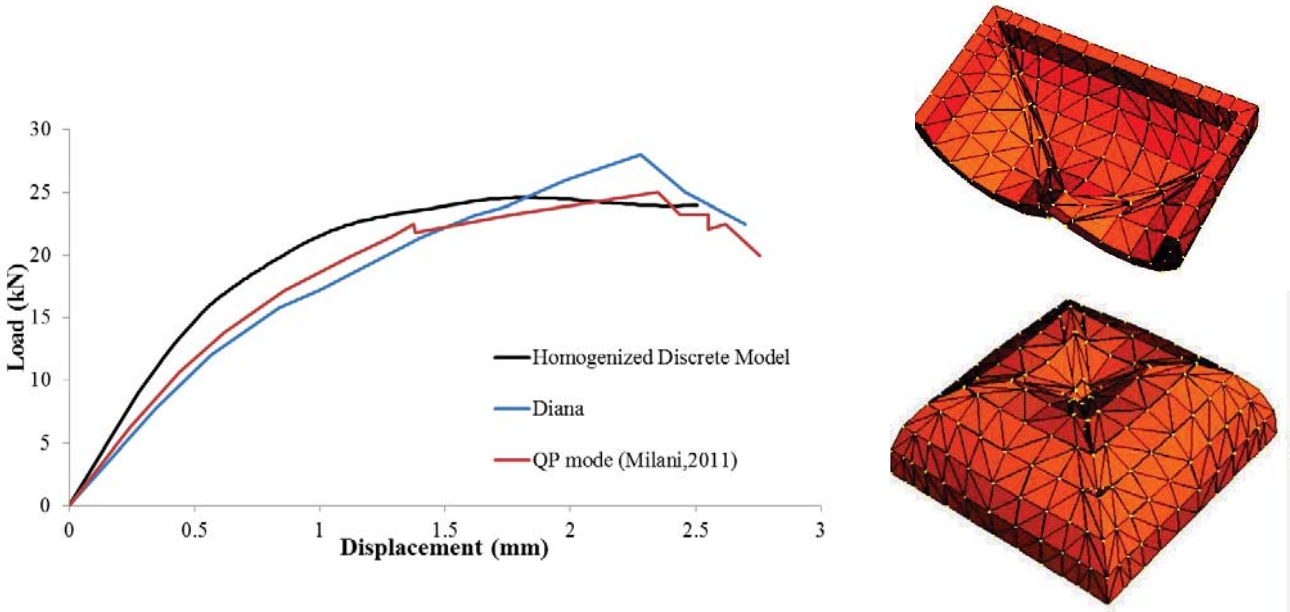

Figure 4: Comparison in terms of load-displacement curves of the proposed method with previous numerical analyses (Left); Collapse mechanism obtained by means of QP non-linear analysis by Milani, 2011 (Right).

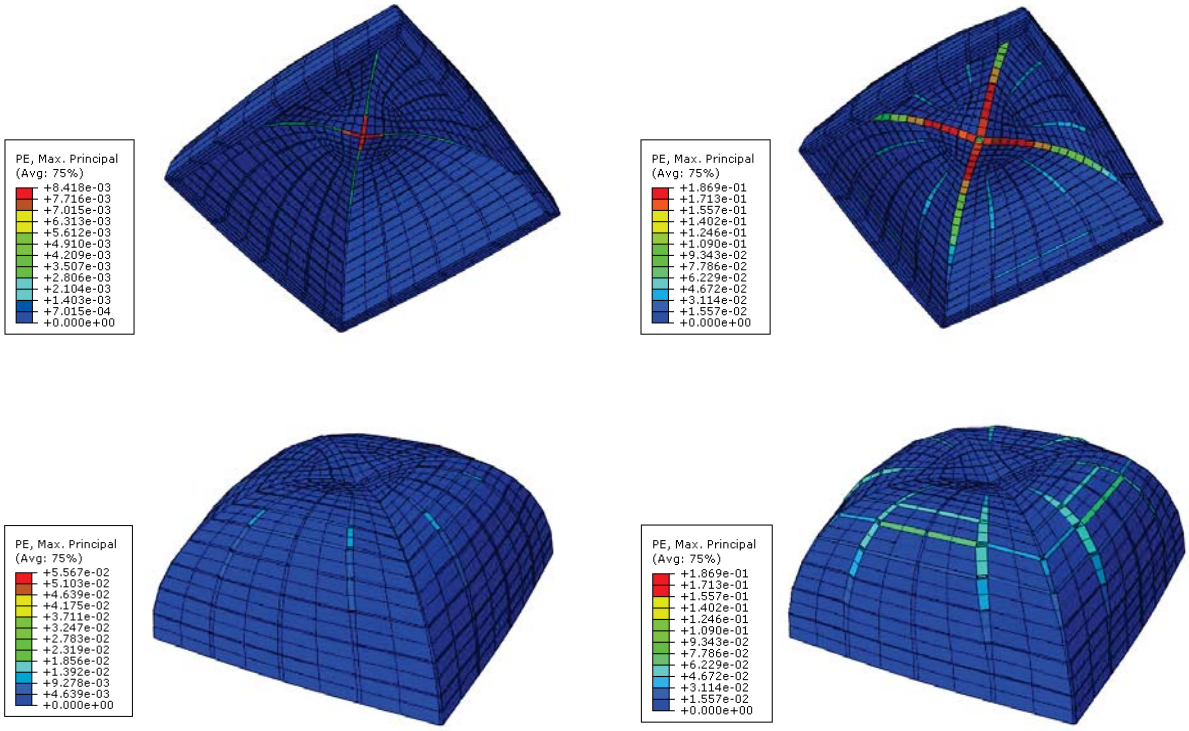

Figure 5: Evolution of crack pattern at the intrados (Top), at the extrados (Bottom).

The global behavior described by DIANA analyses and by other numerical approaches implemented in [8,12] presents a final displacement around 2.7 mm and a peak load within the range of 25-28 kN. The discrete homogenized approach provides a global behavior that fits

satisfactorily the numerical references, with a maximum load nearby 25 kN and maximum capacity in displacement around 2.5 mm. The slight difference in the first branch may be attributed to the discrete nature of the method, which does not allow the non-elastic behavior in all the structures but only at the interfaces.

The crack pattern is provided in terms of plastic strains (PE in Abaqus). The cracks start to spread symmetrically along the diagonal at the intrados. Afterward, a circular flexural hinge is determined by the openings at the extrados of the parallels at approximately 2/3 of the height, causing the impossibility to carry further loads.

4 CONCLUSIONS

In the present work, a validation of an innovative discrete homogenized method applied on a masonry cloister vault has been provided. First of all, a short overview of already existing methods is discussed to highlight the required features for a new approach and the necessity of implementing it. A discrete method, when complemented with previous homogenization procedures, is presented as the right approach for meeting the following requirements: non-linear simulation, low-number of variables involved, preservation of orthotropy of material like-masonry, necessity of keeping coupled the in-out-of-plane effects.

The method, already validated on UR and RE out-of-plane-loaded walls, is extended to the case of a cloister vault, experimentally tested in 2006 and numerically simulated several times by different approaches.

The numerical model of the vault is conceived as a repetition of elastic units jointed by non-linear interfaces. These latter are input as flat 8-noded bricks and the non-linearities are introduced by means of the constitutive model Concrete Damage Plasticity, available in the Abaqus library. The discretized mesh is obtained automatically through a MATLAB script implemented by the Authors and the homogenized mechanical properties are, as well, assigned by an automatic procedure to each interface according to their orientation, preserving the orthotropic behavior.

Finally, the homogenized outcome, in terms of load-displacement curves, revealed an excellent capacity to reproduce numerical results coming from more advanced and consuming approaches. Even the evolution of the crack pattern is fully consistent with the information available in the literature.

Moreover, given the low computational burden, it is the opinion of the Authors that interesting extension to reinforced curved elements may be proposed in future works, by applying in a second moment the reinforcement.

Keywords: Cultural Heritage, Masonry, Multiple Leaf Walls, Damage Assessment, Discrete Element Method, Non-Smooth Contact Dynamics method.

Abstract. *In the present paper has been reported the Non-Smooth Contact Dynamics method (NSCD) used for the damage evaluation of the multiple leaf masonry walls of the medieval fortress of Arquata del Tronto, strongly affected by the last Centre Italy earthquakes of August and October 2016. Pursuing this approach, a system of rigid blocks has been used for the assembly of the masonry structure. By means of contacts between blocks, which are governed by the Signorini's impenetrability condition and by dry-friction Coulomb's law, the building exhibits discontinuous dynamics. Finally, the NSCD method has proved to be an effective instrument for investigating the dynamical behaviour of the masonry structures under the ground seismic accelerations. Indeed, several possible failure mechanisms have been confirmed through the numerical results, which have given a deep insight into the seismic vulnerability of this damaged medieval fortress.*

1 INTRODUCTION

In the structural mechanics became relevant the attention for the damage assessment of historical masonry buildings, which are commonly complex, with irregular geometries, heterogeneity and absence of a box behaviour due to defective connections between different structural parts, in particular walls and floors, that often play a fundamental role. However, the knowledge of the dynamical behaviour is crucial for a reliable seismic vulnerability assessment, which became more and more important due to recent catastrophic earthquakes that stroked Italy in the last few decades (Umbria-Marche 1997–1998, Abruzzo 2009, Emilia-Romagna 2012, Marche-Lazio-Umbria-Abruzzo 2016) [1]–[3].

In October 2016, two major earthquakes occurred in the Marche region in the Centre of Italy, causing widespread damage especially on the historical structures. The epicentre of the second one stroked Norcia, Visso, Arquata del Tronto, Accumoli and Amatrice, and a lot of damages to cultural heritage were also done in the cities of Tolentino, San Severino, Camerino, and Matelica.

To investigate the mechanical behaviour of masonry structures, commonly Finite Element Methods is utilized, often including very sophisticated constitutive laws taking into account post-elastic behaviours and damage [4]–[8]. This method, while being very appealing, do not focus on the possible non-smooth nature of the dynamic response, which can come sliding and impacting between different blocks, and situation that is common just before and during the collapse [9]–[13].

Moreover, the ancient masonry structures can be considered as discontinuous structural systems, which is composed of units (e.g. bricks, stones, blocks, etc.), bonded together with or without mortar. Thus, defining the constitutive model and the material properties for a numerical model is meaningful to adequately represent the dynamical behaviour of a real structure, to take into account the variation of masonry properties and the range of stress state types that exist in masonry structures [14]–[16].

Hence, the progressive damage of the Arquata del Tronto medieval fortress, in the province of Ascoli Piceno (AP), is examined throughout the paper and it is based on an advanced numerical point of view. The measured damage evaluation is relative to the long sequence of strong earthquakes that struck Central Italy in 2016, plunging the area into chaos for several months (see Figure 1) [17].

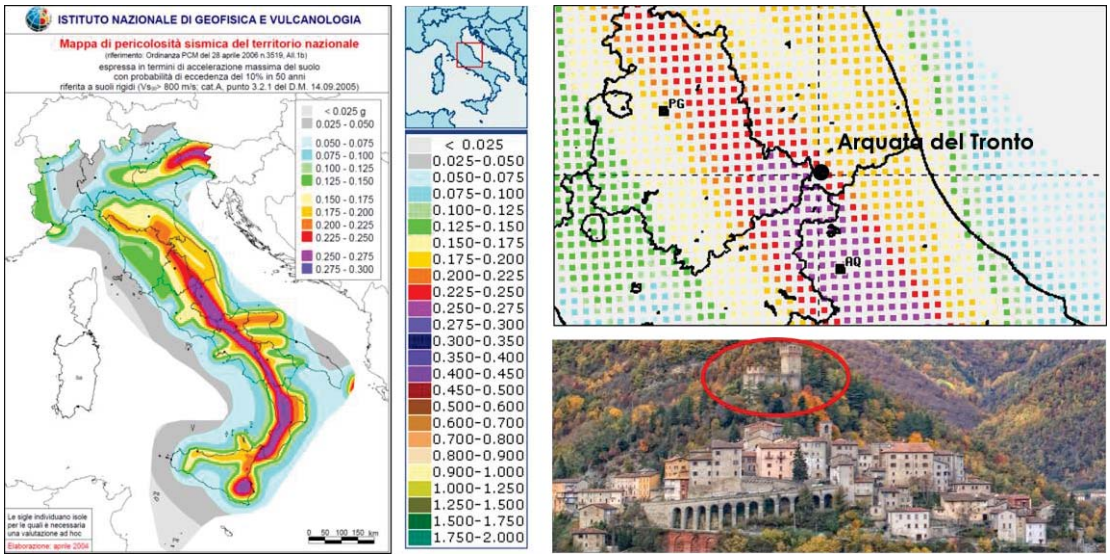

Figure 1: Macroseismic intensity map of the Central Italy area (https://emidius.mi.ingv.it/) and localization of the Arquata del Tronto (AP) medieval fortress

An advanced numerical model is here utilized to have an insight into the modalities of progressive damage and the behaviour of the structure under strong nonlinear dynamic excitations, namely a Non-Smooth Contact Dynamic method (NSCD) adopting a full 3D detailed discretization [18], [19].

In accordance with the NSCD method, the fortress is structured as a system of rigid bodies, assuming frictional sliding and perfect plastic impacts between the blocks. The structure exhibited a complex dynamic behaviour, because of the geometrical nonlinearity and the non-smooth nature of the contact laws [13], [20], with a focus on the possible non-smooth nature of the dynamic response, which can come commonly just before and during the collapse.

The main aim of the survey is to confirm the weakness zones, the efficacy of past interventions and to evaluate the acceleration of the activation of different mechanisms, by means of the discontinuous approaches, to address comparison between the numerical and the real damages, and, at the same time, to confirm the powerful of the model.

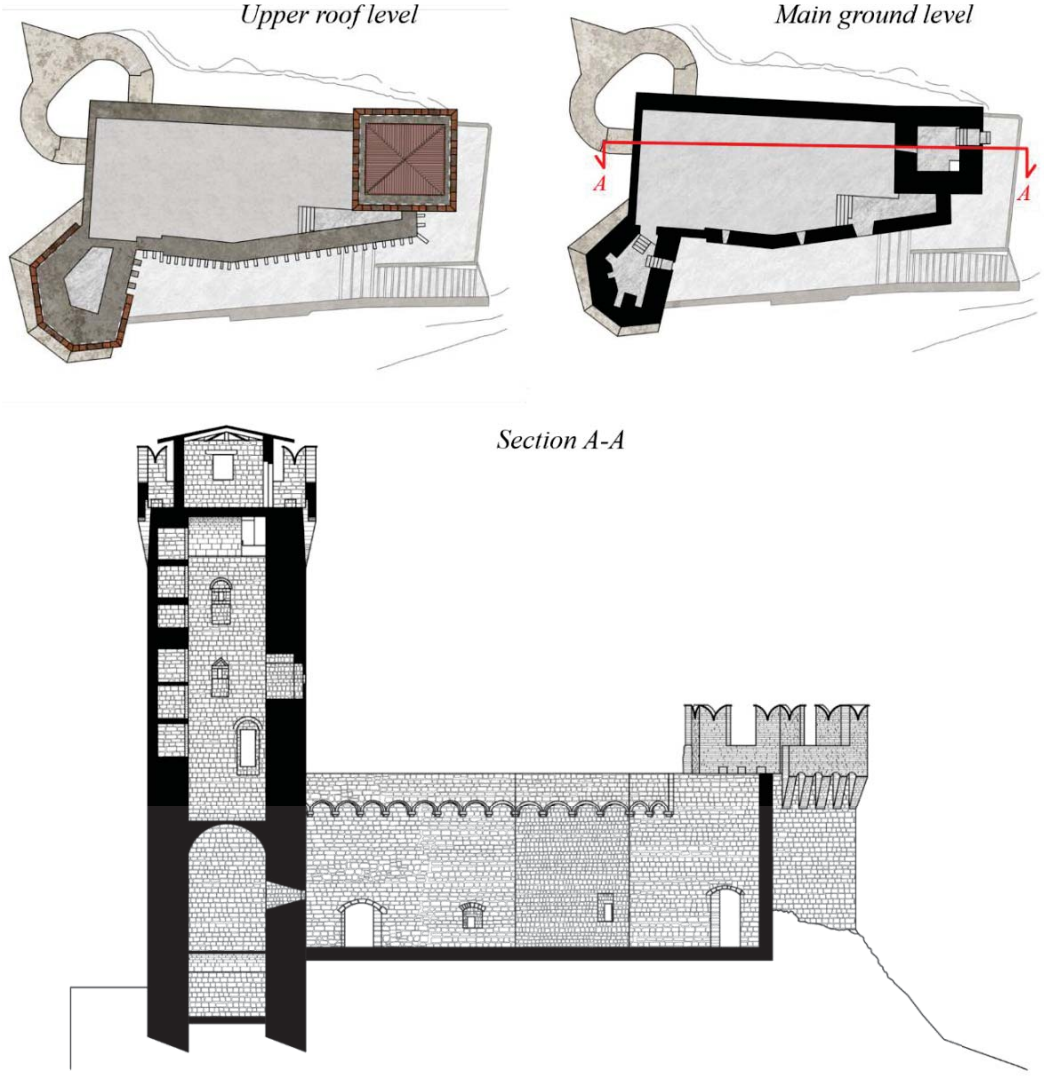

Figure 2: Geometric configuration of the Arquata del Tronto (AP) medieval fortress

2 HISTORICAL DEVELOPMENTS OF THE MEDIEVAL FORTRESS

The fortress of Arquata del Tronto, in Figure 2 and Figure 3, which is a typical example of Umbria-Marche Apennines fortified architecture of the XIII century, is mainly made by cal-

careous stone masonry walls made of multiple leaf, which can be prone to disintegration under strong dynamic actions. The fortress is in a strategical position, located on the border between the Ascoli and Norcia's administrations, and was damaged but left standing by the magnitude 6.2 earthquake event occurred in August 2016 that flattened the town centre. The medieval fortress lost *chemin de ronde* and was one of the few buildings in the town to remain still standing after the main shock. It was then severely damaged by further quakes that rattled the region in October 2016, demonstrating a not proper transverse bond for most of the masonry walls.

Moreover, the first built element of the fortress is the tower with the hexagonal plant and height of 12 m, located in the South-East edge, which encloses an irregular pentagonal environment. At the base, it is visible the gate of the ancient walled now escape tunnels. Between the XIV and XV centuries was built the North tower, with a square base and height of 24 m, which was destined sighting and extreme defence. On its top, there is a quadrangular room that was built in the early years of the XX century. The last built part is a circular tower with a diameter of 10 m and a height of 12 m, located at the South-West corner.

Following earthquakes occurred in 1703, the fortress of Arquata del Tronto suffered serious damages. Therefore, various retrofitting interventions were carried out in subsequent years. The last restoration work, before the seismic sequence of 2016, was made in the last decade of XX century.

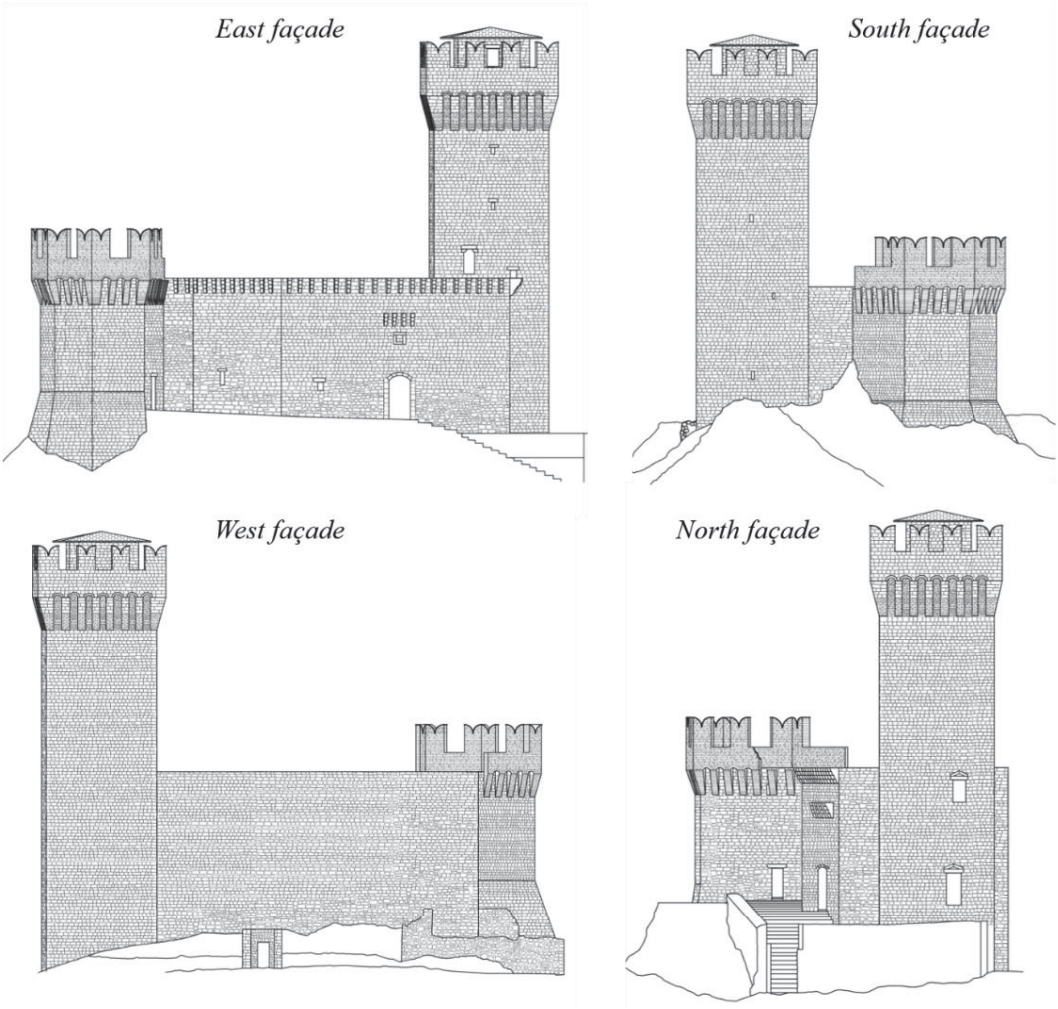

Figure 3: Geometric configuration of the Arquata del Tronto (AP) medieval fortress

2.1 Damage of the Arquata del Tronto fortress after the Central Italy earthquakes of 2016

Globally, the Arquata del Tronto medieval fortress has suffered extended damages after the shocks of the Central Italy seismic sequence of 2016.

The major cracks appeared on the upper part of the masonry towers, with the complete overturning of the merlons and the collapse of the protruding turret, visible in Figure 4a-b. Moreover, there are widespread crumbling of the multiple leaf masonry walls, partially showed in Figure 4c.

Figure 4: Views of the global (a, b) and of the multiple leaf masonry walls (c) damages of the Arquata del Tronto (AP) medieval fortress after the seismic sequence of 2016

3 THE NON-SMOOTH CONTACT DYNAMICS METHOD

The NSCD method belongs to the family of Discrete Element methods, distinguishing from the classical Distinct Element method for three differences: (i) it integrates the non-smooth contact laws directly, (ii) it uses an implicit integration scheme, and (iii) it does not account for any structural damping. It is important to stress the fact that the NSCD method is based on some modelling simplifications. The main assumption is that bodies are rigid, and their dynamics is governed by the equation of motion and by the frictional contact conditions. To describe the frictional contact laws, we must introduce some basic definitions. In the following, the notation adopted in [21] is used (scalars, vectors, and tensors are explicitly declared, and italic letters are used for all of them). Given two arbitrary bodies B_i and B_j, let P_i and P_j (Figure 5a) be the points of possible contact on the boundaries of B_i and B_j, respectively, and let n be the outer unit vector, orthogonal to the boundary of B_i in P_i. We define $g = (P_j - P_i)\cdot n$ the gap between P_i and P_j (a dot means scalar product), $(\dot{u}_n, \dot{u}_t)$ the normal and tangential velocities of P_j with respect to P_i, and (r_n, r_t) the normal and tangential reactive forces of B_i on B_j.

The contact conditions are:

1) The Signorini's law of impenetrability (Figure 5b)

$$g \geq 0, r_n \geq 0, g r_n = 0, \tag{1}$$

which, in the case of contact $g = 0$, is equivalent to the following Kuhn–Tucker conditions [18]

$$\dot{u}_n \geq 0, r_n \geq 0, \dot{u}_n r_n = 0, \tag{2}$$

written in term of relative normal velocity.

2) The dry-friction Coulomb's law (Figure 5c) that governs the behaviour in the tangential direction

$$|r_n| \leq \mu r_n; \begin{cases} r_t < \mu r_n \rightarrow \dot{u}_t = 0 \\ |r_t| = \mu r_n \rightarrow \dot{u}_t = -\lambda \frac{r_t}{|r_t|}, \end{cases} \tag{3}$$

with the friction coefficient and λ an arbitrary positive real number.

If q is the vector of the system configuration parameters (unknown translations and rotations of each body), and p is the global vector of reaction forces, the equation of motion can be written as follows

$$M\ddot{q} = f(q, \dot{q}, t) + p, \tag{4}$$

where M is the mass matrix, and f is the vector of external forces.

The local pairs $(\dot{u}_n, \dot{u}_t)$ and (r_n, r_t), characteristic of each contact, are related to the global vectors $\dot{q}$ and p, respectively, through linear maps which depend on q. Since the contact laws (1) - (3) are non-smooth, velocities $\dot{q}$ and reactions p are discontinuous functions of time. They belong to the set of bounded variation functions, i.e. functions which, at each time, have finite left and right limits. Since the accelerations are not defined when the velocities are discontinuous, Eq. (4) is reformulated in the integral form [18], [21], and it is solved numerically using a time-stepping approach, where t time is discretized into time intervals, and, within each time interval $[t_i, t_{i+1}]$, the equation of motion is integrated as follows

$$M(\dot{q}_{i+1} - \dot{q}_i) = \int_{t_i}^{t_{i+1}} f(q, \dot{q}, t)dt + \bar{p}_{i+1}, \tag{5a}$$

$$q_{i+1} = q_i + \int_{t_i}^{t_{i+1}} \dot{q}(t)dt. \tag{5b}$$

Where $\bar{p}_{i+1}$ is the impulse in $[t_i; t_{i+1}]$. The primary variables of the problem are the velocity vector $\dot{q}_{i+1}$ and the impulse vector $\bar{p}_{i+1}$ at the instant t_{i+1}. In the NSCD method, the integrals in (5a, 5b) are evaluated by means of an implicit time integrator. The overall set of global Eq. (5a, 5b) and local contact relations (1) and (2), where the reactions are approximated by the average impulses in $[t_i; t_{i+1}]$, is condensed at the contact local level, and then they are solved by means of a non-linear Gauss–Seidel by block method.

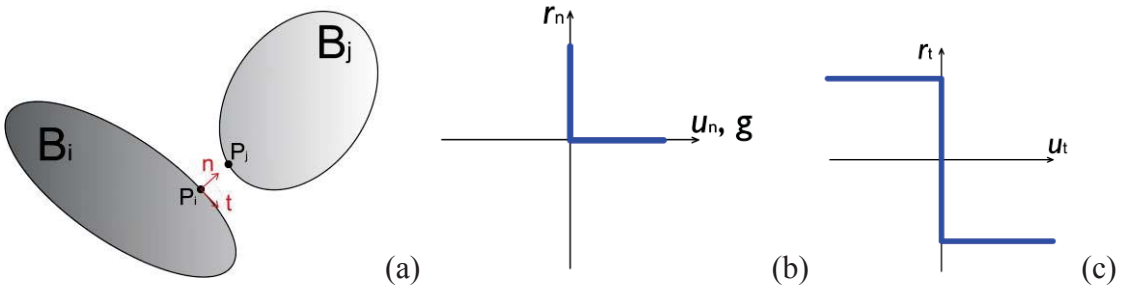

Figure 5: The interaction between two bodies (a) Signorini's law (b) Coulomb's law (c)

The relations (1) imply a perfectly plastic impact, i.e., the Newton law with restitution coefficient equal to zero. A perfect plastic impact law makes impossible to describe bouncing phenomena, and, furthermore, overestimates the energy dissipated during impacts. However, in case of systems of bricks or stones, the restitution coefficient has low values, and bouncing phenomena can be neglected. Since we are interested in the dynamical interactions between different parts of the fortress, we neglect blocks deformability. It follows that the numerical results obtained depict an overall picture of the fortress dynamics and describe the failure mechanisms of the whole structure, due to blocks rocking and sliding, but they do not describe the stresses and strain distributions within each block.

The values of friction coefficient range from 0.3 to 1.2, according to different combinations of units and mortars [22]. As a first attempt, we assume the value = 0.5 for the interface block/block of the external and internal leaf, = 0.3 for the infill and the interface between it and the leaf, and = 0.9 for the interface block/foundation to observe, mainly, the dynamics of the fortress without the structure-foundation interaction. Finally, we note that damping is not considered here and only friction and perfect plastic impacts dissipate energy.

The LMGC90© code is used, due to its ability to compute the interaction of a large number of bodies, based on the NSCD method, also assessing the seismic vulnerability of the structures [23]. As visible in Figure 6, very detailed models have been created to understand better the influence of local and global mechanisms within the analysed medieval fortress and, where possible, the presence of some past retrofitting interventions is also considered.

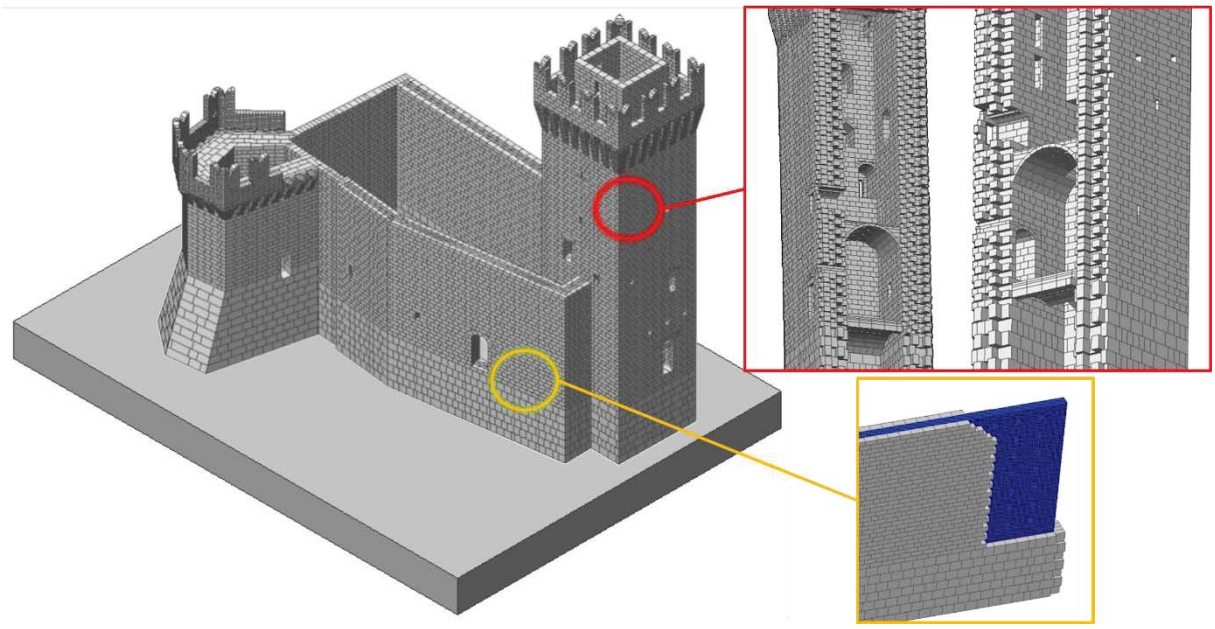

Figure 6: 3D discrete element model of the Arquata del Tronto (AP) medieval fortress

4 NUMERICAL RESULTS

The main results of the nonlinear dynamic analyses are reported in Figure 7. For this purpose, it has been applied to the main shock of the seismic sequence of 2016 in the Centre of Italy. The dynamic action used in the nonlinear analyses is recorded near Arquata del Tronto (AP) in 24th August 2016 Amatrice (AMT station in Italian Accelerometric Archive (ITACA)) with M_w=6.0.

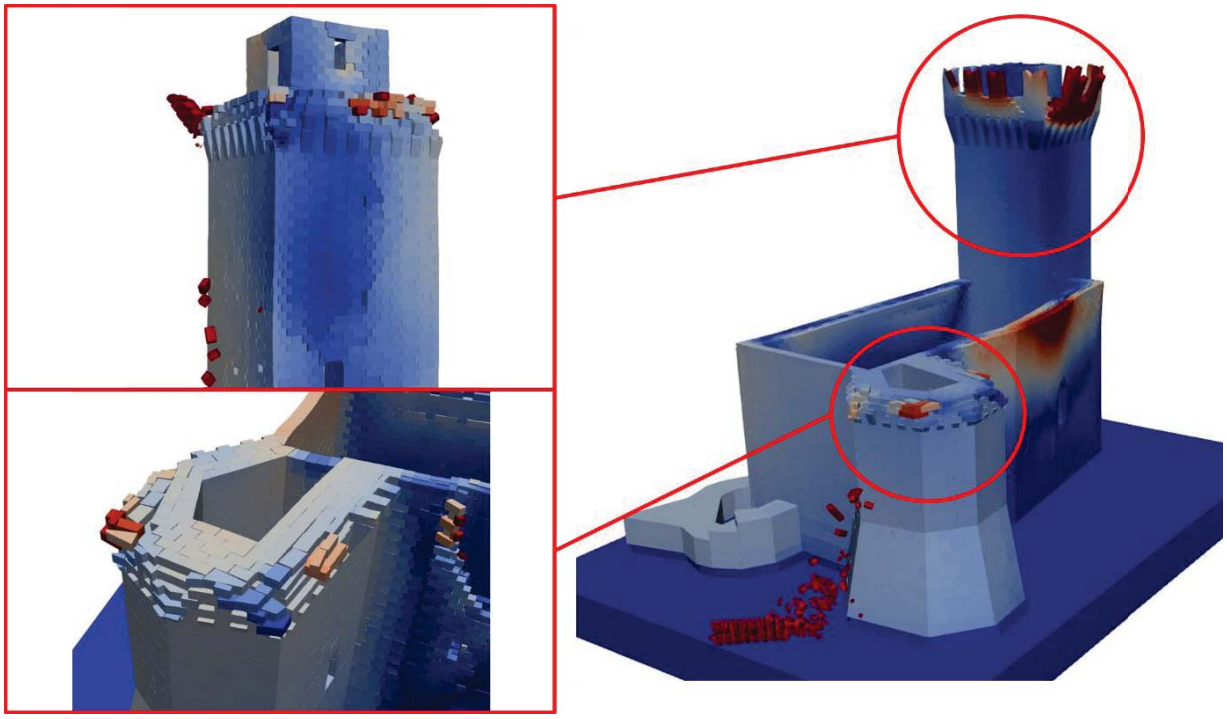

Figure 7: Failure mechanism of the Arquata del Tronto (AP) medieval fortress

Thus, from the numerical results, both the role played by the actual geometry and the insufficient resistance of the constituent materials are envisaged, showing a good match with actual crack patterns and collapses observed after the seismic sequence. Finally, the numerical analyses provide a valuable picture of the actual behaviour of the fortress, thus giving useful hints for the reconstruction and future effective strengthening interventions.

5 CONCLUSIONS

The results obtained for the Arquata del Tronto medieval fortress stroked by the Central Italy seismic sequence are here briefly reported and summarized, underline the high vulnerability of this type of multiple leaf masonry walls, and especially of the upper where merlons are placed.

A discontinuous approach and the NSCD method, implemented in the LMGC90© is used in order to assess numerically the real damage. The NSCD method combines modelling simplicity and great predictive capabilities.

Its simplicity comes from the following fundamental simplifying assumptions: (i) block rigidity; (ii) simple contact laws between blocks; (iii) absence of any damping. As a result, the mechanical behaviour of the masonry structures is influenced by only the friction coefficient. This is a significant consequence for modelling ancient buildings since the determination of the mechanical properties of these masonries is always uncertain and variable. Despite its simplicity, the model can predict a large variety of dynamical behaviours of the historical structures and their seismic vulnerability.

The numerical investigation pointed out that no collapse mechanism passes the safety check. This outcome suggests that the reconstruction of the collapsed parts on the top of the towers if pursued, should be complemented by specific strengthening devices.

Keywords: Central Italy Earthquakes, Masonry churches, Finite Element Model, Linear Dynamic Analysis, Total Strain Crack Model, Non-Linear Static Analysis

Abstract. *In the present work, the importance of considering the exact nonlinear and three-dimensional behavior of masonry structures is shown, in order to highlight all the structural deficiencies of different churches damaged by the last Centre Italy earthquake in the city of Camerino. For this purpose, the exact geometries of the structures are reconstructed, while information regarding the mechanical properties of masonry material are derived from previous investigations and literature references. Based on this information, different numerical models are used to reconstruct the damages.*
Different three-dimensional FE models, endowed with an elastic plastic (softening) damage constitutive law, are adopted to determine the seismic vulnerability of the building by means of nonlinear static analyses using the smeared fracture energy approach. With this method it is possible to establish, with a right degree of approximation, the areas where the most important cracks are expected and, in general, the location of the potential damage caused by horizontal forces.

1 INTRODUCTION

Italy in the last years was hit by several earthquakes, the last one was that of 2016/2017 Central Italy, characterized by four principal shooks: 24th August 2016 Mw=6.0, 26th October 2016 Mw=5.9, 30th October 2016 Mw=6.5 and 18th January 2017 Mw=5.5. This swarm interested a large area between Marche, Abruzzo, Lazio and Umbria regions. These areas are characterized by spread little villages with many religious buildings, having been territories belonging to Papal State up to 1870. The churches showed, again, their high vulnerability to the horizontal forces [1–12], due to their complex geometry and state of conservation. Whit the aim to find an appropriate method to evaluate the actual vulnerability and to predict the possible seismic damages of these structures, three different churches were analyzed. The case studies are in Camerino, a village in Marche Region hinterland. Camerino has been often hit by strong quakes (Figure 1), noteworthy is the 1799 swarm with a maximum intensity of 6.1 that provoked 60 dead in the village and heavy damages at the structures.

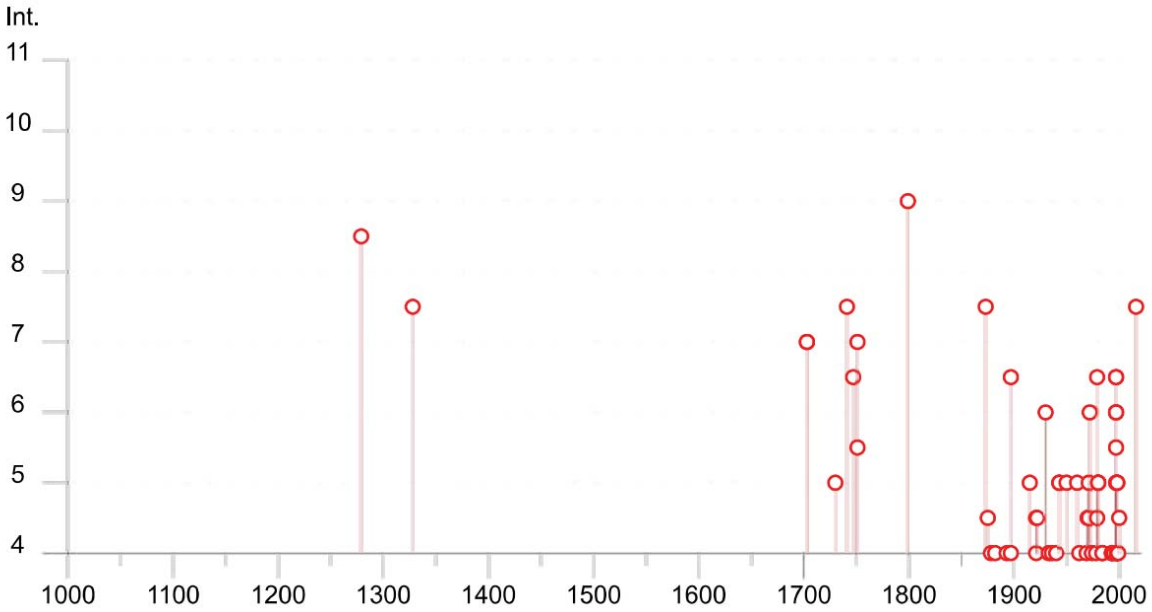

Figure 1 Earthquakes felt in Camerino during the years, from 1000 to 2017 (https://emidius.mi.ingv.it/ [13])

The analyzed churches are shown in Figure 2, they are:

- Santa Maria in Via Church
- San Venanzio Church
- Santa Maria Annunziata Church

Two of them are in the red zone, Santa Maria in Via and Santa Maria Annunziata, whereas San Venanzio is in Nord-Est neighborhood. The churches were studied using 3D Finite Element Models, on with whom linear and non-linear analyses were carried out in order to stress, once again, the capacity of this modeling type to predict the seismic vulnerability, since it would be a useful resource to design interventions to prevent cracks and failures occurrence [14,15].

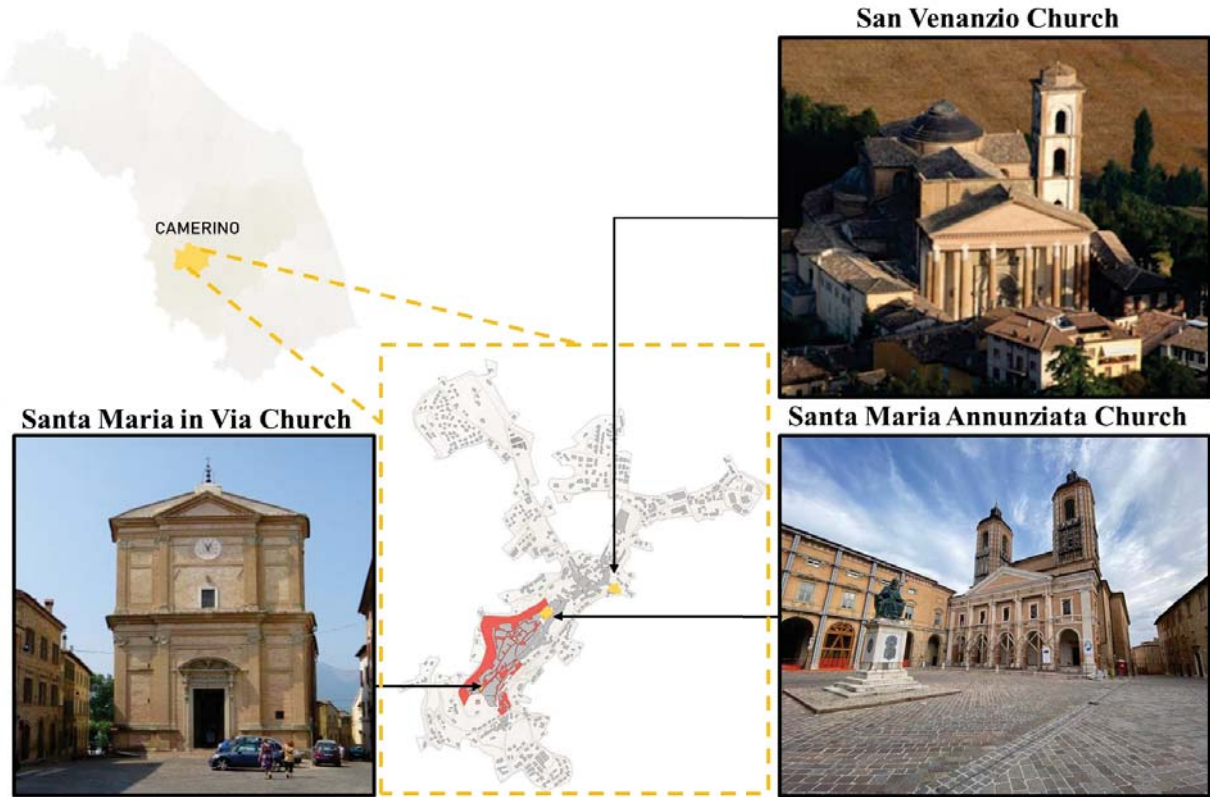

Figure 2 Geographical localization of the churches analyzed

2 CASE STUDIES

2.1 Historical development

Santa Maria in Via Church (S_M_V)

The firsts proofs of a church presence date back to 1299, it was probably a little church that was converted later to guard the Madonna enthroned with the child, painting brought by Crusaders from Smirne. The church reformation started in 1639 by the Angelo Giori Cardinal will and ended in 1642. The church was hit by different earthquakes during the centuries, the strong 1799 quake caused the collapse of the masonry vault that covered the principal room, that was replaced by a camorcanna vault (light vault). During the 1997 Earthquake, there were static damages and in the connections of the light vault with the trusses od roof. The work of restoration was completed only in 2006.

San Venanzio Church (S_V)

San Venanzio Church dates back to the XII century, it was built on the ruins of a little church erected on the place of Saint's martyrium. In the XIII century, the church acquired importance and became Collegiata. The church was subject to different works during the years, subsequently the 1799 earthquake was necessary a radical reconstruction for the heavy damage suffered. The works were carried out by the architect Luigi Poletti, they started in 1836 and ended in 1875 on the 9 of May. In 1979 the transept foundations were consolidated with micro piles and the principal walls were reinforced by concrete injections. In the “90s also the crypt columns' foundations were consolidated. During the “97 earthquakes, the failure of sac-

risty and apse foundations occurred. After this event also these foundations were reinforced with R.C. piles and the roofs and masonry walls were repaired.

Santa Maria Annunziata Church (S_M_A)
The first the structure edification seems to date back to the V century, while the first proof of a Romanesque church, consecrated to San Giuseppe, date to the XIII century. The first important interventions go back to 1259 when the Svevi's devastation and the population increment pushed on a complete renovation. In 1279 the church was hit by a strong earthquake, it provoked the bell-tower collapse, that was rebuilt subsequently. In 1748/49 the façade was transformed by a two hundred style at Barocco style. The 28th June of 1799 a new earthquake hit the church, followed by a heavy makeover carried out by Andrea Vinci architect, a Vanitelli's student. The new church had a portico in front as an extension of the Palazzo Vescovile. The works ended the 8th of September of 1932, when the church was devoted to Santissima Maria Annunziata. After the "97 earthquake the church was reinforced by steel connections on the roof base to provide the box-behavior.

2.2 Geometric survey

Santa Maria in Via Church (S_M_V)
The nave of the church has an elliptic shape with a larger diameter of about 28m and smaller of 13m, on both sides there are four chapels (Figure 3-a). On the two sides of the entry, there are two symmetric rooms that are a baptizer and a chapel. The sacristy and the oratory are on the sides of the presbytery. On the south side, there is the bell-tower high 15m. The bearing structure is made of solid bricks with an inner core of poor materials. The hall is covered by a camorcanna vault and the roof is made by wood trusses

San Venanzio
The basilica has a Latin-cross (39mx68m) layout with the principal nave of double-length respect the lateral ones Figure 3-b. The principal nave is divided by the others whit fourteen Corinthian columns built with blocks stone and solid bricks. Under the presbytery, there is the crypt covered by cross vaults supported by Porfido columns. The crypt is accessed through two symmetrical stairs in the transept. The bell-tower is on the north-west side with a height of 45 m, three different orders are visible on it. On the principle nave there is a light barrel vault covered by a wood roof. The bearing structure is made of solid bricks

Santa Maria Annunziata Church (S_M_A)
The church has a Latin-cross layout (29mx70m), the naves are divided by columns and pillars on which rest round arches Figure 3-c. Under the church, there is a large crypt cover by cross and barrel vaults. On the two sides of the facade, arrears of six meters, there are two identical bell-towers of 40 m high covered by domes. The naves are covered by camorcanna vaults and the roof is made of wood trusses. The bearing structure is made of solid bricks and stone blocks

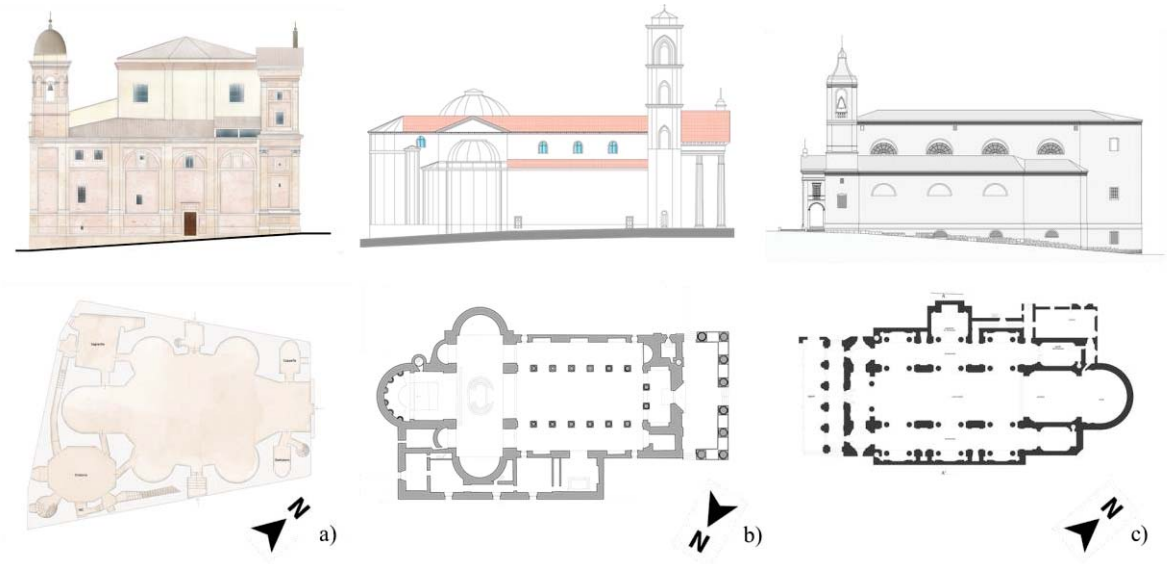

Figure 3 Geometric configuration; a) Santa Maria in Via; b) San Venanzio; c) Santa Maria Annunziata

2.3 Damage suffered during the Central Italy Earthquake

The 2016 earthquakes caused damages to all these churches. Indeed, comparing the accelerations recorded to Camerino during the 30th October quake with the maximum acceleration expected to preserve the human life, according to the Italian code [16], they have been, in North direction, twice respect to expected values Figure 4.

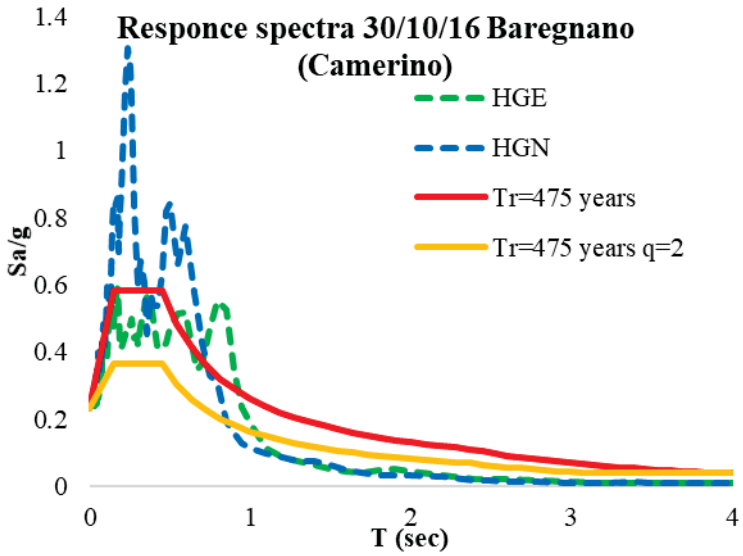

Figure 4 Comparison between the maximum acceleration expected for the SLV and accelerations recorded

The most damage church is Santa Maria in Via. After the 26th October earthquake, the bell-tower collapsed and a lot of spread cracks appeared, during the 30th October quake the cracks made worst, and partial collapses occurred on the two sides of the façade Figure 5-a. The roof collapse happened after the 18th January 2017 earthquake, provoking the tambour and light vault failure.

The second more damaged church is Santa Maria Annunziata Figure 5-c, it showed significative cracks in both the bell-towers in correspondence of the spiral stairs and near the façade connections. The narthex had cracks on the connection to the façade, probably provoke by a hammering mechanism. On the opposite sides of the presbytery, two symmetric cracks show the activation of its out-of-plane mechanism. The church internally had shear cracks on the pillars and between the change of materials.
San Venanzio, instead, had deep cracks on the light vaults, on the arches and walls Figure 5-b. All of them were declared unsafe after the earthquakes, today the only reopened is the less damage, or rather, San Venanzio.

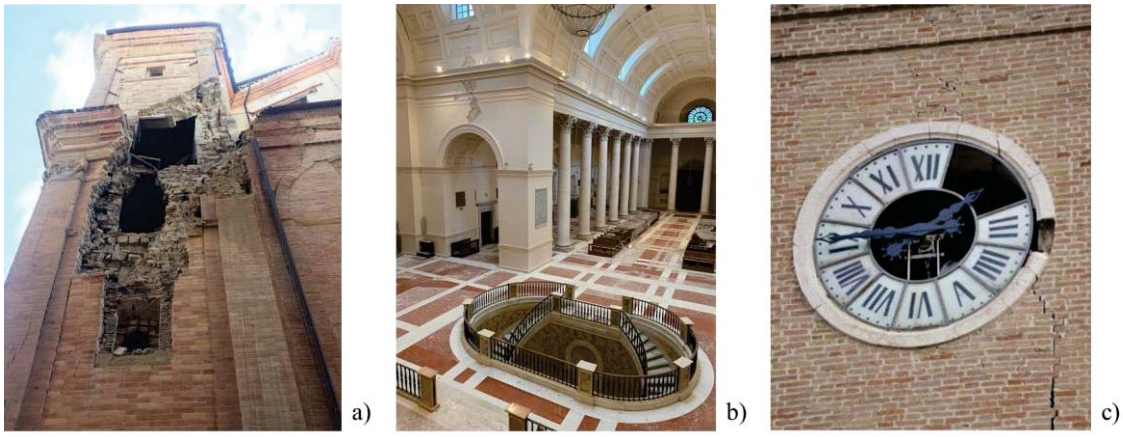

Figure 5 Some cracks after the Central Italy Earthquake, a) Partial collapse of one façade side of Santa Maria in Via; b) Cracks spread on the walls and the vault of San Venanazio; c) Crack in correspondence of the Clock of one Santissima Annunziata bell-tower

3 NUMERICAL MODEL

The churches were studied using Finite Element Models (FEMs), by means of MidasFEA© software [17], as it is impossible to simplify this type of buildings with the common softwares. The masonry was considered as homogeneous and isotropic material, whose post elastic behavior was considered using the Total Strain Crack Model, assign a parabolic law in compression, a Hordjik law in tension and a linear law for the shear [18–20].

The geometries were reproduced carefully and subsequently discretized with 4-nodes tetrahedral brick elements Figure 6. In the Table 1 are reported the number of elements, nodes and degree of freedom used for each case study.

Church	Element	Nodes	d.o.f.
S_M_V	483 885	109 694	345 414
S_V	230 046	61 422	175 723
S_M_A	601 019	163 030	489 090

Table 1 Finite Element Models characteristics

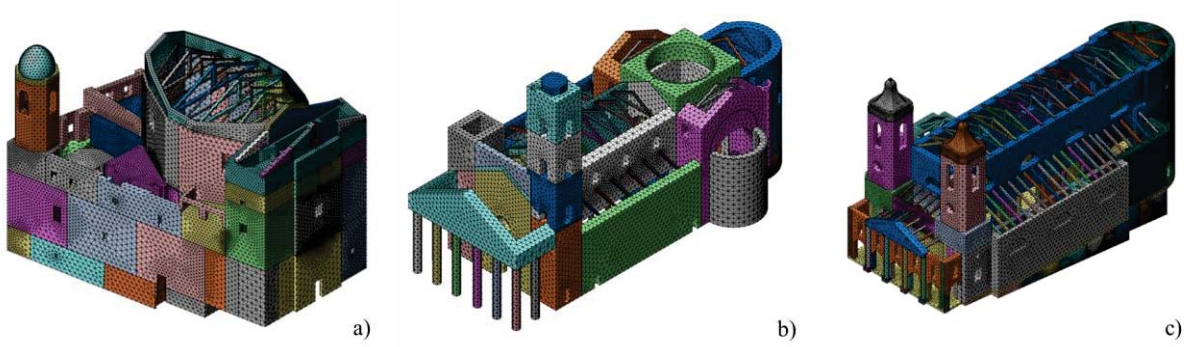

Figure 6 Numerical Models of a) Santa Maria in Via; b) San Venanzio; b) Santa Maria Annunziata

3.1 Dynamic analysis

Firstly, the numerical models were submitted to dynamic linear analyses using Lancoz method. A lot of modal shapes were necessary to move the 85% of the total mass in both the direction, the number of modes are respectively 414 for Santa Maria in via, 230 for the San Venanzio and 474 for the Santa Maria Annunziata

The principal modal shapes periods, for each church, are compared with the spectrums recorded during the strongest quake of the 2016 seismic swarm, the Figure 7 shows that their periods are near the maximum accelerations recorded periods.

In all the models the bell-towers are moved from one of the principal modes, indeed, in all the cases, they showed cracks after the earthquakes. The two long churches, San Venanzio and Santa Maria Annuziata, have as other vulnerable elements the longitudinal walls, instead, the façade is a vulnerable element for the Santa Maria in via church, in effect it has two long cracks on both sides.

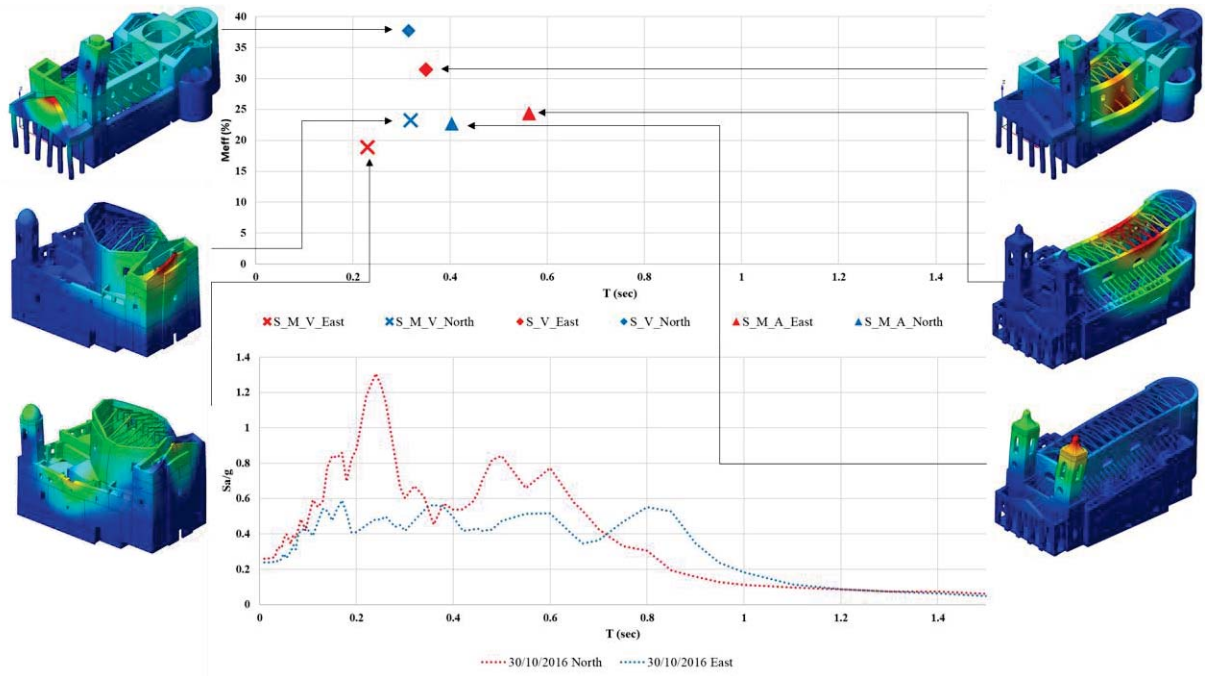

Figure 7 Distribution of principal modal shapes in the North and East directions and comparison with the pseudo-acceleration response spectra of the main shock of Central Italy 2016-2017 seismic sequence.

3.2 Nonlinear static analysis

Subsequently, the models were used to carry out the non-linear static analyses, following the guidelines of the Italian Code [16,21] two different force distributions were used, one proportional to the modal shapes (PushMode) and the other masses proportional (PushMass).

To perform the PushMode the models were subjected to response spectrum analysis using as input the Limit State of Significant Damage (SLSD or SLV in Italian) spectrums considering "Class II" and ordinary structures. The nodal forces were obtained combining with the CQC algorithm the responses in each direction, considering the number of modes necessary to move the 85% of the total mass.

The analyses were performed using the arch-length iteration, using 0.1 as initial load, 1000 as maximum number of iteration and a 10^{-3} as convergence limit.

From these analyses, the capacity curves of each church were obtained for different control nodes. The curves show different behaviors and resistances for both in the directions and control nodes chosen, due to the geometry complexity. In Figure 8 are reported the capacity curves of one control node for each church obtain by PushMass analysis in +X-Direction and +Y-Direction.

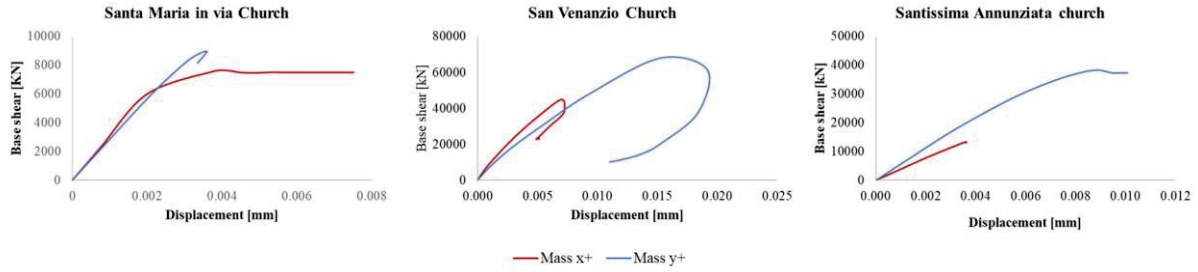

Figure 8 Examples of PushMass curves in +X-Direction and +Y-Direction of a control node for each church

Comparing the numerical cracks with the real damages it is possible to confirm the readability of the numerical models **Figure 9**.

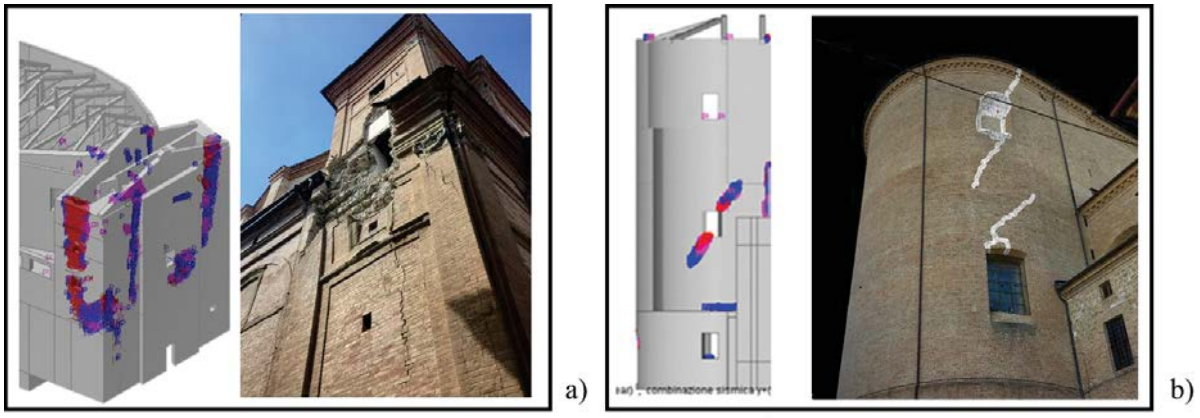

Figure 9 Correspondence between numerical and real cracks for a) Santa Maria in Via; b) Santa Maria Annunziata

4 CONCLUSIONS

The paper presents an accurate study of three churches, Santa Maria in Via, San Venanzio and Santissima Annunziata, located in the crater area of 2016 Central Italy Earthquake, precisely in Camerino, a village in the hinterland of Marche Region. The churches, seriously damaged, were studied with FEM using linear and nonlinear analysis. The nonlinear static analyses show as this type of analysis is able, with a good approximation, to reproduce the real cracks occurred, even if it overestimates the seismic capacity, since it doesn't include the change of frequencies produced by the damage evolution.

AUTOMATIC ASSESSMENT OF PARTIAL FAILURE MECHANISMS IN RETROFITTED HISTORICAL MASONRY AGGREGATES THROUGH ADAPTIVE NURBS LIMIT ANALYSIS

Nicola Grillanda[1], **Marco Valente**[1] **and Gabriele Milani**[1]

[1]Department of Architecture, Built Environment and Construction Engineering (ABC), Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133, Milan, Italy. nicola.grillanda@polimi.it, marco.valente@polimi.it, gabriele.milani@polimi.it

Keywords: Historical masonry aggregates, local mechanisms, NURBS, adaptive limit analysis.

Abstract. *The aim of this work is to propose a new automatic procedure for the seismic assessment of partial failure mechanisms in historical masonry aggregates. Starting from the geometrical survey, a three-dimensional model of the whole aggregate is derived. The model is discretized through few NURBS surfaces (Non-Uniform Rational Bezier Spline) and imported into the MATLAB environment. A procedure of kinematic limit analysis is applied to a pre-selected part of the construction. The walls selected are subdivided into few elements, each one is a portion of the initial NURBS surface and is assumed as a rigid body. Rigid-plastic interfaces are defined on the boundary of each element. As a result, the kinematic limit analysis provides a local mechanism involving the selected walls and an associated kinematic multiplier. An optimization procedure, here conducted by using a Genetic Algorithm, is applied with the aim of finding the collapse multiplier. The procedure can take into account the most spread reinforcement techniques adopted in historical constructions, such as tie-rods and FRP strips, which maintain a local response to horizontal loads. An application to a historical masonry aggregate, located in the center of Arsita (Teramo, Italy), is finally presented.*

1 INTRODUCTION

Historical centers are often the final result of a high number of masonry construction built adjacent to each other. The seismic response of masonry constructions aggregates is affected by several factors, such as geometrical irregularities, uncertainties on connections between walls, difficulties on the identification of masonry mechanical parameters, lack of design details, and pre-existent damage, resulting quite difficult to predict. Seismic events occurred during last years (L'Aquila 2009, Emilia Romagna 2012, Central Italy 2016) damaged severely a huge number of masonry historical constructions [1–4], including residential building aggregates. Therefore, the implementation of an efficient numerical method for the correct prediction of the seismic response of historical masonry aggregates before and after the application of the most typical retrofitting interventions is a very actual problem.

Several numerical methods are available. Focusing the attention on masonry building aggregates, the typical approaches include index-based methods [5,6], local failures analyses through limit analysis techniques [7], Equivalent Frame-based methods [8–10], and Finite Element-based static and dynamic nonlinear analyses [11–14]. However, considering the typical lack of global behavior of this structural typology (see also the huge number of local collapses observed during the last earthquakes [15]), local analyses cannot be neglected in the evaluation of the seismic vulnerability [16–18]. Moreover, the application of a thorough number of local analyses is also recommended by the Italian code [19] for masonry buildings in general.

The typical retrofitting strategies on masonry aggregates are aimed at achieving the global response of the structure under horizontal loads. However, it has to be pointed out that this result usually requires too invasive interventions that are not allowed for historical constructions, for which the original construction cannot be subjected to strong modifications for reasons of cultural heritage preservation. As regards historical constructions, local interventions are usually preferred, such as the application of steel or timber ties [20,21], FRP strips, TRM or FRCM [22,23]. These interventions are aimed at avoiding the most critical out-of-plane mechanisms. As a result, the structural response is still local, but the collapse takes place through a different local mechanism to which a higher horizontal load multiplier is associated. Therefore, the seismic vulnerability evaluation still requires local analyses, allowing studies through limit analysis techniques.

The theory of limit analysis for historical masonry constructions was originally developed by Heyman [24], who proposed to treat masonry as a no-tension material. However, more accurate modelling strategies can be followed to take into account crushing and shear failures. Some recent homogenized limit analysis techniques have been presented [25–27]. In order to decrease the required computational effort, deriving from the reproduction of the correct collapse mechanisms by using refined mesh, a novel limit analysis approach has been presented by some of the Authors [28]. In this procedure, an upper bound formulation is applied on a masonry structure discretized through a reduced number of NURBS surfaces (Non-Uniform Rational B-Spline, [29]). NURBS objects are parametric functions commonly adopted in the CAD modelling that allow representing curved geometries with few surfaces. NURBS surfaces are adopted to represent walls and vaults and are idealized as rigid elements with internal dissipation allowed only along edges. Since the method is based on a reduced number of rigid elements, a mesh adaptation procedure is applied to minimize the kinematic load multiplier and determine the real collapse mechanism. A Genetic Algorithm (GA) [30] is usually applied, even if different meta-heuristic algorithms can be adopted [31]. The method has been adopted to study several typologies of historical masonry structures [32–35], sometimes considering the presence of reinforcement [36–39]. In this work, the adaptive NURBS limit analysis is adopted to study a complex case of historical masonry aggregate located in the center of Arsi-

ta (Abruzzo region) [40,41]. A disposition of tie-rods has been hypothesized on the constructions, and the local mechanisms are compared with those found in the unreinforced case.

2 ADAPTIVE NURBS-BASED LIMIT ANALYSIS

This novel limit analysis approach for historical masonry aggregates is based on a discretization of the whole construction through NURBS (Non-Uniform Rational B-Spline [29]) surfaces. The geometrical representation via NURBS allows representing each wall by using a single surface (even in presence of openings), resulting in a very reduced number of overall elements. Moreover, curved structural elements, such as arches and vaults, can be reproduced through very few surfaces. For sake of simplicity, we refer to [29] for a complete theoretical dissertation on the NURBS geometrical entities and the main algorithms involved.
The NURBS model is imported into the MATLAB environment, where each surface is converted into a 3D macro-element once thickness and offset properties are assigned. Each surface can be subdivided into few elements, each one deriving by a trimmed NURBS surface which is a partition of the initial one.
The assumption of infinitely rigid elements is here followed. Non-linearities are included in the computation by defining rigid-plastic interfaces at the contacts between rigid elements. A simple kinematic limit analysis can be defined in this model. The kinematic of each rigid element is defined through the six degrees of freedom of its gravity center. Relative velocities can occur at interfaces only. In order to properly evaluate the amount of plastic dissipation related to velocity jumps at interfaces, each one is discretized through points in which a local reference system ($\mathbf{n}$, $\mathbf{s}$, $\mathbf{t}$) (Figure 1(a)) is defined, and a three-dimensional failure surfaces (typically a Mohr-Coulomb domain with tension cut-off and linear cap in compression, Figure 1(b)) is assigned. A classic associative plastic flow rule is adopted.

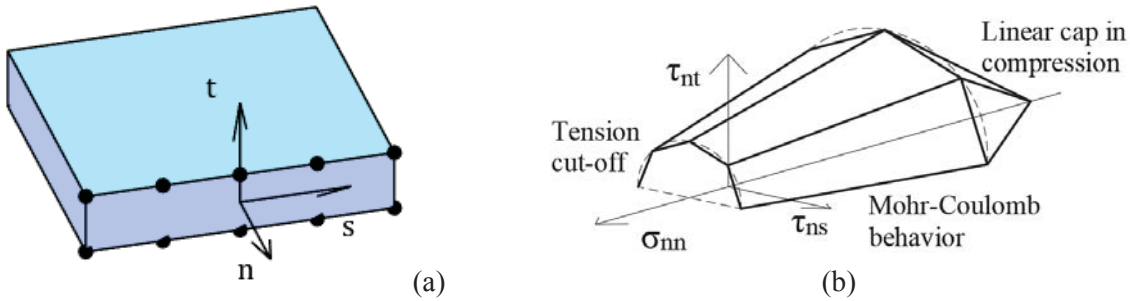

Figure 1. (a) Discretization of interfaces and local reference system, (b) three-dimensional failure surface.

Therefore, interfaces assume the meaning of possible fracture lines. A configuration of dead- and live-load (respectively $\mathbf{F}_0$ and $\boldsymbol{\Gamma}$) is defined. The live-load multiplier Γ is found by applying the Principle of Virtual Powers. The procedure can be summarized in form of standard linear programming problem:

$$\min\left\{\Gamma = \sum_i P_{\text{int}}^i - P_{\mathbf{F}_0}\right\} \text{ such that } \begin{cases}\mathbf{A}_{eq}\mathbf{x} = \mathbf{b}_{eq} \\ \dot{\boldsymbol{\lambda}} \geq 0\end{cases} \tag{1}$$

where:

$\sum_i P_{\text{int}}^i$ is the total amount of internal dissipated power;

$P_{\mathbf{F}_0} + P_{\boldsymbol{\Gamma}}$ is the power dissipated by the external loads;

$\mathbf{x}$ is the vector of unknowns, which include the velocity components of each element and the non-negative plastic multipliers $\dot{\boldsymbol{\lambda}}$;

$\mathbf{A}_{eq}$, $\mathbf{b}_{eq}$ are respectively the overall equality constraints matrix (containing geometric constraints, plastic compatibility, and normalization condition of live loads power) and the corresponding right-hand side vector.

The solution of the presented linear programming problem allows defining a horizontal load multiplier α_0 and a mechanism. The mechanism will depend on the assumed position of fracture lines and, in agreement with the kinematic theorem of limit analysis, the associated horizontal load multiplier will be an upper bound of the collapse multiplier. Therefore, the initial mesh must be adjusted to find the real position of fracture lines. A Genetic Algorithm (GA) is here applied for the mesh adaptation procedure [30]. In this way, a good estimation of the horizontal load multiplier and the correct collapse mechanism is automatically provided.

3 APPLICATION TO HISTORICAL MASONRY AGGREGATES

When local mechanisms in historical masonry aggregates are investigated, dead loads represent self-weights and masses applied on each wall, whereas live loads are constituted by a distribution of horizontal loads proportional to masses (as recommended by the Italian code [19]). In other words, the vector of the power dissipated by the dead loads can be written as follows:

$$P_{\mathbf{F}_0} = \sum_{i=1}^{N_E} \left(W_i \cdot \dot{u}_z^i + F_i^P \cdot \dot{u}_z^P \right) = \mathbf{F}_0^T \cdot \mathbf{x} \tag{2}$$

where:

N_E is the number of elements adopted;

W_i is the weight if the i-th element;

F_i^P is the vertical load given by the non-structural mass applied to the point P;

$\dot{u}_z^i$, $\dot{u}_z^P$ are the vertical components of the velocity vectors respectively of the gravity center and the point P.

The power dissipated by live loads can be derived directly from $P_{\mathbf{F}_0}$:

$$P_\Gamma = \sum_{i=1}^{N_E} \left(\Gamma W_i \cdot \dot{u}_h^i + \Gamma F_i^P \cdot \dot{u}_h^P \right) = \mathbf{\Gamma}^T \cdot \mathbf{x} \tag{3}$$

where:

$\dot{u}_h^i$, $\dot{u}_h^P$ are the horizontal components of the velocity vectors;

Γ is the horizontal load multiplier (which is named α_0 in the Italian code [19]).

This procedure can be applied to evaluate the horizontal load multiplier of complex local mechanisms in historical masonry aggregates. It has to be pointed out that masonry aggregates can present very complex structures, with coexistence of different levels of interlockings that make their structural response quite difficult to predict. Therefore, the proposed code allows performing local analyses on a pre-selected number of walls belonging to the same structural unit. The pre-selected walls are those supposed to be involved in the local failure. Different levels of interlockings can be taken into account by assigning different values of resistance parameters to interfaces located at the corners. In addition to this, the procedure can take into account the most spread retrofitting interventions for these constructions. It is worth noting that the common use of FRP strips or tie-rods maintains still local the structural response under horizontal load, since the aim of these interventions is mainly to avoid the most critical local mechanisms. This allows to easily take into account the contribution of these retrofitting techniques by using local analyses. In the adaptive NURBS limit analysis, the presence of tie-rods can be included by using simple kinematic conditions. Considering the i-th tie-rods applied between the points P and Q (located on different walls), an additional equa-

tion is assigned as a geometrical constraint. The constraint given by the presence of tie-rods is described as follows:

$$\dot{u}_k^P - \dot{u}_k^Q = 0 \tag{4}$$

where:

k is the direction defined by the tie-rod;

$\dot{u}_k^P, \dot{u}_k^Q$ are the velocities along the direction k respectively of the points P and Q.

4 CASE STUDY

A masonry aggregate located in the historical center of Arsita has been adopted for the analyses. Arsita is a small village in the center of Italy that was hit by the 2009 earthquake. As a consequence of this event, 17 masonry aggregates have been inspected by a scientific team set up by ENEA (Italian National Agency for New Technologies, Energy and Sustainable Economic Development), resulting in the publication of the Post-Earthquake Reconstruction Plan for the Arsita Municipality [40,41]. The masonry aggregate here presented is the first one among those studied by ENEA (see Figure 2). This construction is composed of three structural units, here named A, B and C. A and B are residential buildings, whereas C constitutes the Church of Santa Vittoria. The whole construction is approximately 47 m long and 15 m wide. The maximum height is about 15 m in correspondence to the bell tower. The construction is characterized by thick walls. An average value of 70 cm has been observed in units A and B. The church is characterized by thicker walls, with an average value of 90 cm and a maximum of 200 cm in the façade. Several vaulted elements (mainly semicircular barrel vaults) can be found within the central nave of the church and on the first floor of unit B. According to [40,41], the masonry is composed of irregular stones and bad quality mortar.

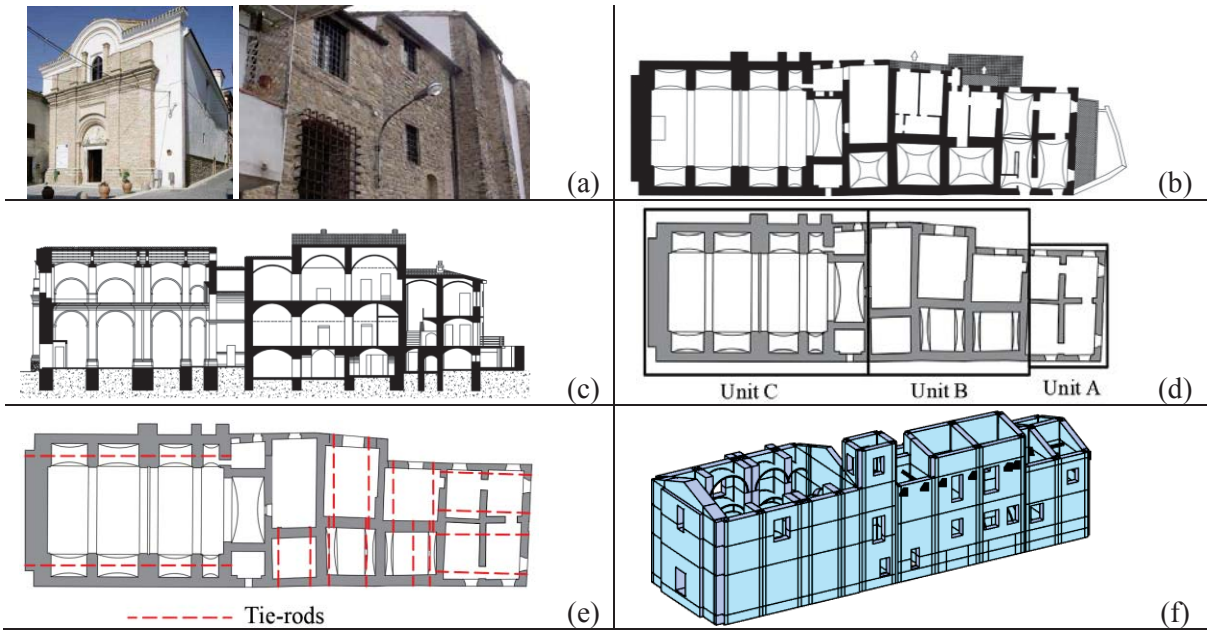

Figure 2. Aggregate "Il Corso": (a) some photos of the aggregate (pictures taken from [40]), (b) plan view, (c) section along the longitudinal direction, (d) identification of the structural units, (e) hypothesized position of tie-rods and (f) 3D NURBS model.

Since this masonry aggregate does not have tie-rods or concrete edgings, the first study has been performed on the unreinforced case [35]. After that, a disposition of tie-rods has been hypothesized to increase the horizontal load multiplier associated with the obtained collapse

mechanisms. The disposition of the tie-rods here assumed is reported in Figure 2(e). Therefore, the adaptive NURBS-based limit analysis has been re-applied to this case study to show how local failures are affected by the application of such retrofitting interventions. As in the unreinforced case [35], good interlocking has been assumed between walls belonging to the same structural unit, whereas the different structural units have been hypothesized as disconnected from each other. Considering the presence of not regular masonry texture, an isotropic Mohr-Coulomb behavior has been assigned [42]. The tensile stress is assumed equal to 0.05 MPa for walls and 0.1 MPa for vaulted elements. As shown in [43], a not null tensile stress is usually needed for slender barrel vaults in churches, since these elements are often too slender to sustain their self-weight in comparison with what is recommended in the classical Heyman's theory [44]. The ultimate compression strength has been assumed equal to 2 MPa, whereas cohesion and friction angle are supposed 0.035 MPa and 22°, respectively.

The new results in terms of local failures, horizontal load multipliers, and spectral accelerations (a_0*), are depicted in Figure 3, together with failure mechanisms of the unreinforced case. In general, the presence of tie-rods allows a notable increase in the values of horizontal load multipliers. Values higher than 1 are mainly related to the presence of thick walls. In two cases, the initial overturning mechanisms convert into vertical flexure mechanisms with participation of the transversal walls (see Figure 3(b) and Figure 3(f)). Then, the other walls belonging to structural unit B (Figure 3(c)) collapse through the partial overturning of the top part in the reinforced case (Figure 3(d)). Finally, the horizontal response of the vaults within the central nave is still the most critical failure mechanism, even if its horizontal load multiplier increases from 0.106 to 0.225. This is mainly due to the high slenderness of the barrel vaults, which cannot counteract the rotation of the supporting walls. As it can be observed in Figure 3(g, h), the collapse occurs initially through the overturning of walls that supports the vaults, whereas a partial overturning takes place once tie-rods have been applied at the quote of the barrel vaults first row. It is clear that higher values of horizontal load multiplier could be found by applying some tie-rods at different quotes, in order to avoid the partial overturning failures of the walls located within the central nave.

It is worth noting that the use of NURBS has been particularly useful in the study of this construction, where there is a high number of curved structural elements that affect its horizontal structural capacity. Finally, this code allows to reproduce several structural conditions, in terms of loads applied and representation of interlocking conditions. However, it is clear that a thorough knowledge of the real structural details is needed in order to correctly estimate the structural behavior under horizontal loads.

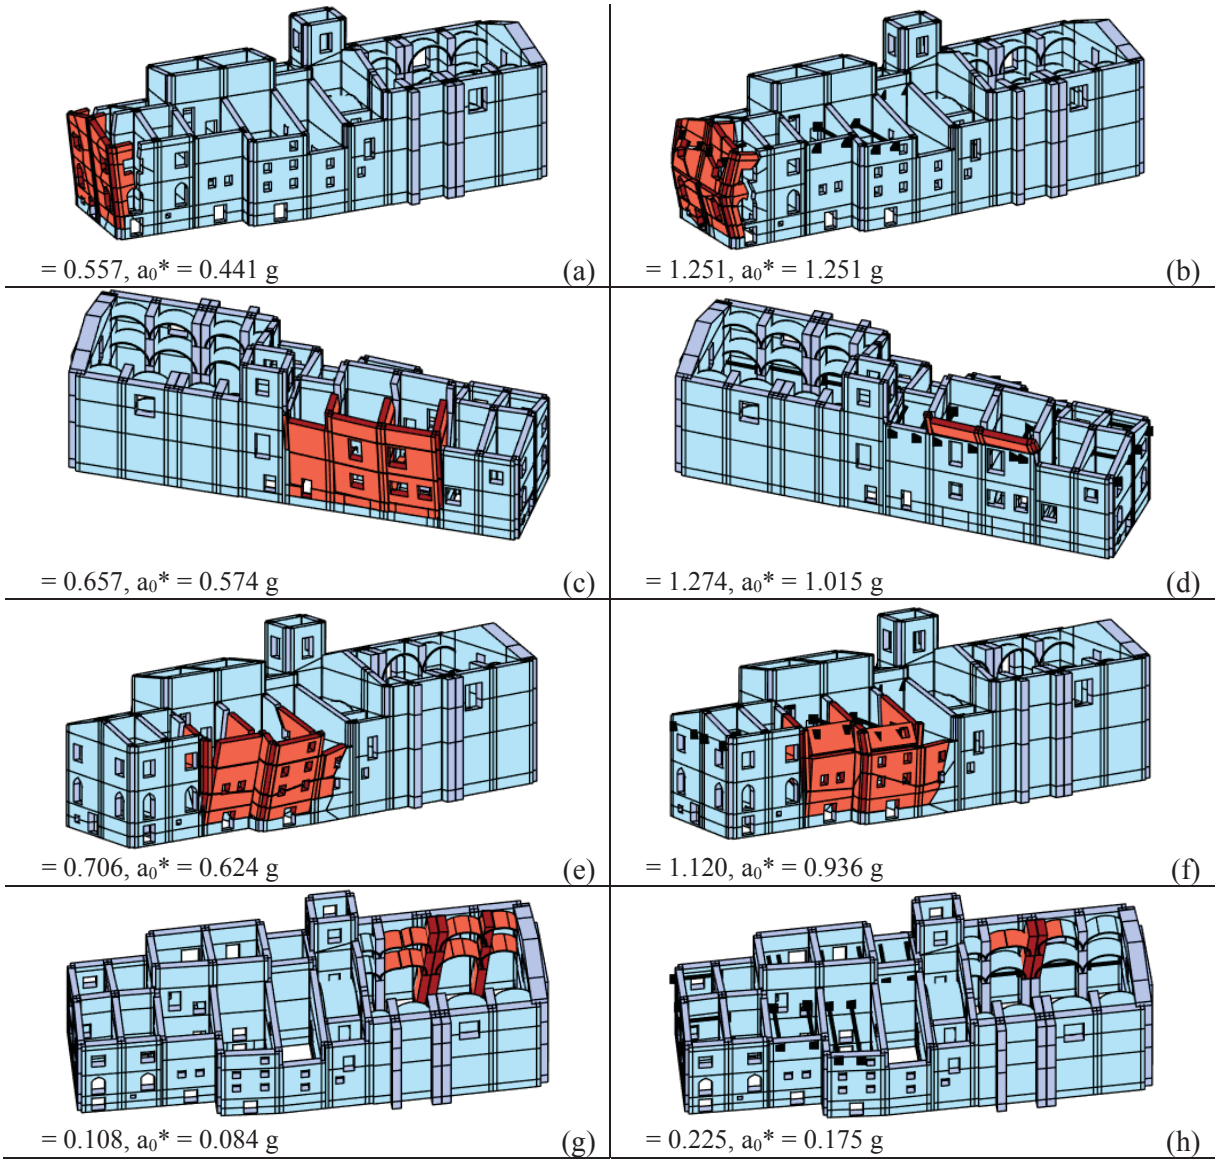

Figure 3. Local failures in the unreinforced (on the left column) and the reinforced case (on the right column): (a, b) unit A, (c-f) unit B, (g, h) unit C.

5 CONCLUSIONS

A novel computational procedure for the assessment of partial failure mechanisms in historical masonry aggregates has been presented. The procedure uses a NURBS discretization of the geometry of the whole structure, allowing to easily represent curved elements and, more in general, the complex geometries typical of historical constructions. A kinematic limit analysis with mesh adaptation governed by Genetic Algorithm is applied. In this way, both standard and non-standard local mechanisms in masonry aggregates, i.e. deriving from the interaction between different structural elements, can be predicted with good precision and the associated horizontal load multiplier is correctly estimated. The procedure allowed to take into account, in an easy way, the effects of the most common retrofitting strategies, such as the application of tie-rods, which maintains a local structural response but affects the shape of the local mechanisms, avoiding the occurrence of the most critical ones. Finally, the use of few NURBS rigid elements maintains a low computational effort. The reliability of this method

has been demonstrated through the application on a complex historical masonry aggregate in both unreinforced and reinforced cases.

Abstract. *Failure mechanisms in masonry walls are commonly due to the low tensile strength of masonry that could cause overturning or pounding due to the interaction with transverse walls. In this paper, the influence of dissipative devices easing the dynamic stability of rocking blocks is studied considering the main parameters affecting the response. Normalized rotation time-histories are obtained for six geometrical configurations under several acceleration records in order to analyse possible resonant effects and beneficial reductions due to the presence of a damper, accounted for in the equation of motion of the one-sided restrained rocking block. Rocking response spectra obtained for undamped systems show that possible beat phenomena may arise for certain geometrical configurations and restraint stiffness values. A design equation for the damping coefficient is proposed for the anti-seismic device and its influence on restrained façade walls under real strong motions is analysed.*

1 INTRODUCTION

Recent seismic events demonstrated that out-of-plane mechanisms are commonly developed in historical constructions causing relevant cracks and sometimes leading to catastrophic collapses. This can be due to not proper wall-to-diaphragm connections [1] or to slender walls as those of church façades [2, 3, 4, 5]. Portions of the building can tilt as rigid blocks around plastic hinges developed during earthquakes, even of low entity, involving complex phenomena of friction, impact, sliding and possible overturning [6, 7]. The most significant way to treat these problems, due to the many uncertainties that affect them, is a probabilistic approach considering univariate and bivariate fragility curves [8].

Kinematic approach is considered one of the most valid tools for the assessment of local modes, based on the assumption of the "most probable" mechanisms that can be developed during a seismic event. This method is widely used worldwide and the Italian national code [9] suggests this approach as a valid preliminary verification for successive global assessment. Besides more complex models can account for horizontal restraints or frictions, the method is based on the pseudo-static application of virtual work principle and collapse mechanisms have to be assumed, thus setting the limit of the approach.

Recent developments were done on rocking analysis, capable of assessing the dynamic stability of rigid restrained blocks and suitable to understand the behavior of tilting objects during seismic motion [2, 10, 11]. Newly published national Italian standards [9, 12] allows the assessment of local mechanisms through the use of nonlinear dynamic analysis of rigid bodies. During the oscillation of rocking structures, the seismic energy is dissipated through the impacts and this can be accounted for in the equation of motion through a cofficient of restitution, whose experimental estimation is of crucial relevance [13]. The rocking block can be free-standing, namely without restraints [14] or with vertical [15] or horizontal [16] elastic restraints. If a further source of energy dissipation is desired, to control the stability of the rocking wall, the restraint could be characterized by a viscous damper.

In this contribution, a damper device is intended to be designed in order to control possible damages occurring on out-of-plane masonry walls. This paper aims at understanding the influence of damping and stiffness of anti-seismic devices through rocking analysis.

2 EQUATION OF MOTION AND RESONANCE CONDITION

The full equation of motion of a damped restrained rocking block in one-sided vibrations under seismic force reads:

$$I_0\ddot{\theta} + sign(\theta)mgR\sin A_\theta + T_K + T_{K'} + T_D = m\ddot{u}_g R\cos A_\theta, \tag{1}$$

where I_0 is the polar moment of inertia of the block with mass m oscillating about the pivot points O and O' of an angle θ (Figure 1), R is the semi diagonal of the block and $A_\theta = \alpha - sign(\theta)\theta$, in which α is the angle between the direction of R and the vertical, being also the inverse of the slenderness of the block ($\alpha = \tan^{-1}(s/h) \simeq s/h = 1/\lambda$). The term T_K relates to the contribution of a horizontal spring, referring to the elastic stiffness of the damper or to separate restraints (steel ties). For the scope of this work the pre-tensioning and yielding are not considered, being the spring indefinitely linear elastic characterized by particular axial stiffness, K, whose term reads

$$T_K = sign(\theta)KR_t^2 cos(A_t)(sin\alpha_r - sinA_t), \tag{2}$$

where $A_t = \alpha_t - sign(\theta)\theta$ and geometrical parameters, R_t and α_t define the position of the spring. $T_{K'}$ is the term given by horizontal bed springs, simulating eventual lateral transversal

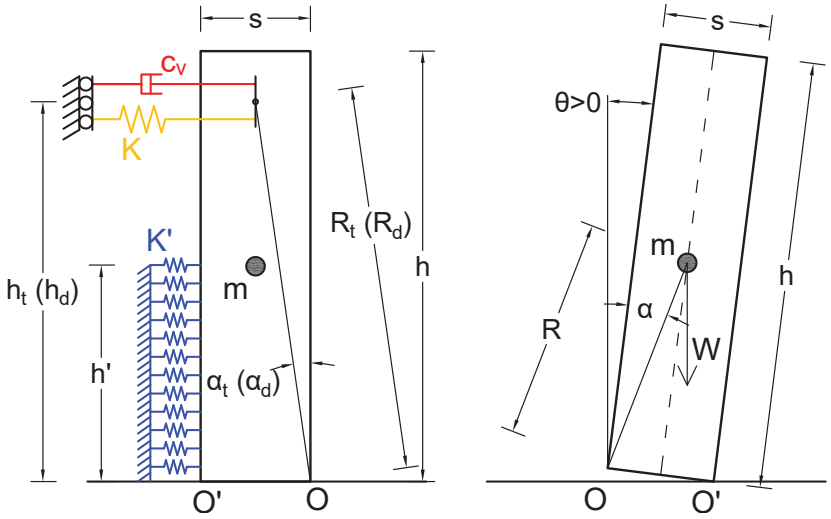

Figure 1: Rocking block model restrained by damper in one-sided motion: geometry and definition of positive rotation.

walls of stiffness (per unit length), K'. Assuming,

$$A = sign(\theta)s^2\, sin\theta\, cos\theta(1 - cos\theta) \tag{3}$$

$$B = sin^2\theta\, cos\theta - cos^3\theta + cos^2\theta \tag{4}$$

$$C = sign(\theta)\, sin\theta\, cos^2\theta \tag{5}$$

the spring bed term can be defined as follows:

$$T_{K'} = sign(\theta)K'h'\left(A + \frac{Bh'}{2} + \frac{Ch'^2}{3}\right) \tag{6}$$

where, h' is the effective height of the spring bed (Figure 1). The term T_d depends upon the damping, c, and the relative velocity between the damper ends, $\dot{u}_d$, function of $\dot{\theta}$, in this specific case, and reads

$$T_d = cR_d^2 cos^2 A_d\dot{\theta}, \tag{7}$$

where $A_d = \alpha_d - sign(\theta)\theta$ and, at the same way of horizontal spring term, R_d and α_d define the position of the damper (Figure 1). For the specific case of damper and elastic spring at the same position, $\alpha_d = \alpha_t$, and $R_d = R_t$. It can be noted that the sign of damping term is directly given by the sign of rotational velocity, $\dot{\theta}$, thus no $sign$ function is necessary in this case.

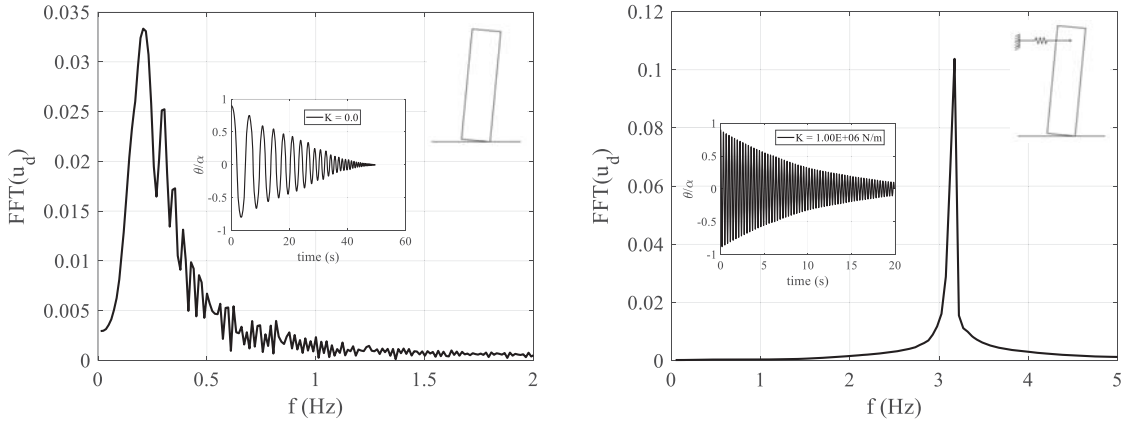
Previous studies demonstrated that amplified response can be achieved in certain circumstances associated with resonance conditions [16]. Depending on the direction of motion, two rocking systems can be defined, one referring to clockwise rotation (single spring in tension) and the other to anticlockwise direction (spring bed in compression). Thus, calling the frequency ratio $p = \sqrt{mgR/I_0}$, resonance frequencies can be computed for both systems,

$$\omega_r^+ = p\sqrt{\left(\frac{KR_t^2}{mgR} - 1\right)} \tag{8}$$

and

$$\omega_r^- = p\sqrt{\left(\frac{8K'R^2}{3mg} - 1\right)} \tag{9}$$

Even if circular frequency of the rocking system varies during the oscillation, it was seen that the horizontal elastic restraint behaves like a "filter" for the output signal. This aspect is confirmed in Figure 2 showing the comparison between the fast fourier transform (FFT) of the displacement response in restrained and in free-standing configuration, under free vibration. The restrained configuration is defined, here, by the presence of a bidirectional indefinitely linear elastic tie with stiffness equal to $K = 1.0e6$ N/m. The restrained rocking block response



(a) (b)

Figure 2: Fast fourier transform of horizontal displacement read at the level of restraint; (a) free-standing block; (b) restrained block.

is characterized by a reduced frequency content if compared to the free-standing configuration. Ideally, if such a restrained system is forced by excitations with similar frequencies, dangerous amplified responses may arise and should be controlled. Artificial inputs with similar frequency content have been adopted in recent studies in order to cause resonant response [17]. In this paper, possible resonance circumstances are investigated under real ground motion, which are characterized by a complex frequency content but representative of realistic situations.

3 GEOMETRIES AND HYPOTHESIS

Geometries of unit length were selected in order to study two different slenderness ratios ($\lambda = 10, 13$) and three different wall thickness values ($s = 0.3; 0.6$ and 0.9 m), resulting in a total of six geometrical layouts representative of common masonry wall façades. The masonry weight density was assumed equal to 21 kN/m^3 for all blocks. The analysis of damped restrained rocking blocks requires the definition of horizontal restraint elastic stiffness, representing a possible steel tie rod placed at a certain height of the wall. Moreover, for the definition of the elastic impact with transverse walls, a value of stiffness (per unit length) needs to be set. A realistic value of K' can be based on transversal walls thickness, t, and effective with, L_{eff}, with equivalent lateral elastic modulus, E_x,

$$K' = E_x t / L_{eff}. \tag{10}$$

label	λ [-]	s [m]	h [m]	m [kg]	R [m]	I_0 [kg m^2]
block1	10	0.3	3.0	1926	1.51	5837
block2	10	0.6	6.0	7706	3.01	93401
block3	10	0.9	9.0	17339	4.52	472847
block4	13	0.3	3.9	2505	1.96	12773
block5	13	0.6	7.8	10018	3.91	204374
block6	13	0.9	11.7	22541	5.87	1034645

Table 1: Geometrical parameters of selected blocks.

However, if the system global stiffness in the positive direction equates the one in negative direction [16], the spring bed stiffness becomes a function of horizontal restraint stiffness:

$$K_{sys} = K'_{sys} \rightarrow K' = K\frac{3}{8}\frac{R_t^2}{R^3 cos\alpha}. \tag{11}$$

A reference value of tie stiffness, K_d, can be calculated starting from a design value of steel tie rod diameter, ϕ_d, based on simple equilibrium criterium (Equation 12) assuming the seismic action as a horizontal equivalent static force acting at the center of gravity of the block. The length of the tie rod is assumed $10\,$m.

$$T_d h_t + Ws/2 = \mu W h/2, \tag{12}$$

where $T_d = \sigma_d \frac{\pi \phi_d^2}{4}$ is the force given by the tie, applied at height h_t, computed considering a *S275* steel, a design stress value, $\sigma_d = \frac{0.7 f_{u,k}}{1.05}$. W is the self weight of the block and $\mu = 0.2$ is the collapse multiplier.

Even if it is hard to define a critical damping for rocking blocks (appropriate for single-degree-of-freedom oscillators), mainly because of the non-constant value of eigenfrequency [18], a reference value of damping can be defined starting from the capacity curve of the free-standing block. The damping becomes function of the solely geometry of the block and a characteristic event time, δ_t [17],

$$c_d = \frac{F_0}{v} = \frac{\mu W}{\delta_u/\delta_t} = 2mg\delta_t/h \tag{13}$$

The viscous-elastic damper, which is ruled by a stiffness, K and a coefficient of damping c, is located at the top of the wall. Furthermore, dampers are ideally bilinear.

It is worth noting that the yielding of the steel tie rod was not considered, as outer the scope of the study.

4 ANALYSIS AND RESULTS

The influence of the wall geometries and of the viscous-elastic damper on the dynamic stability of the rocking walls are studied under free and forced vibration in one-sided motion. For the latter analyses, a selection of several (> 40) real accelerograms was done in order to consider a wide range of frequency content and intensity levels. Strong motion accelerations are selected among recent seismic events that stroke Central Italy during 2016-2017 and past events characterized by high level of magnitude (i.e. $M_w > 5.0$) (Table 2). Two limit states are defined for the scope of these analyses as reference values of moderate ($\theta/\alpha = 0.4$) and limited ($\theta/\alpha = 0.1$) rocking.

Table 2: List of selected seismic events.

4.1 Undamped rocking response spectra

The construction of design response spectra is common in civil engineering with the aim of defining the seismic input of a given structure [14]. This method is valid for structures that may be related to classical single degree of freedom systems for which an equivalent period can be defined. Commonly 5% of damping ratio is considered to take into account the capability of the building on dissipating energy.

Even if rocking systems are characterized by an amplitude-dependent eigenfrequency, a rocking spectrum can be defined for a given geometry evaluating the maximum response in terms of normalized rotations under a certain seismic event, for different values of horizontal restraint stiffness. Figures 3 and 4 show the rocking spectra obtained for the undamped restrained rocking block2 in one-sided motion (K' and K calculated according to Equation 11 and 12, respectively, Section 3) under 1995/10/01 - 6.2 M_w and 2016/10/30 - 6.5 M_w - Norcia earthquakes (Table 2). 50 values of K were chosen within the range $0 \leq K \leq K_d$. A limit state of moderate rocking was considered corresponding to $\theta/\alpha = 0.4$ [3]. Amplifications are clearly visible for different values of K where beats and resonant effects develop (Figure 3). This not monotonic trend observed when the stiffness monotonically increases or decreases suggests near-resonant conditions. Response time-histories are shown upon the corresponding spectrum peaks (Figure 5). Although values of K different from zero should correspond to a more stable response (since the block is ideally "more stable"), the peaks on the rocking spectrum demonstrate the opposite. Indeed, as shown in Figure 5(a), even low values of stiffness result in an amplification response up to three times. For the spectrum built for Norcia

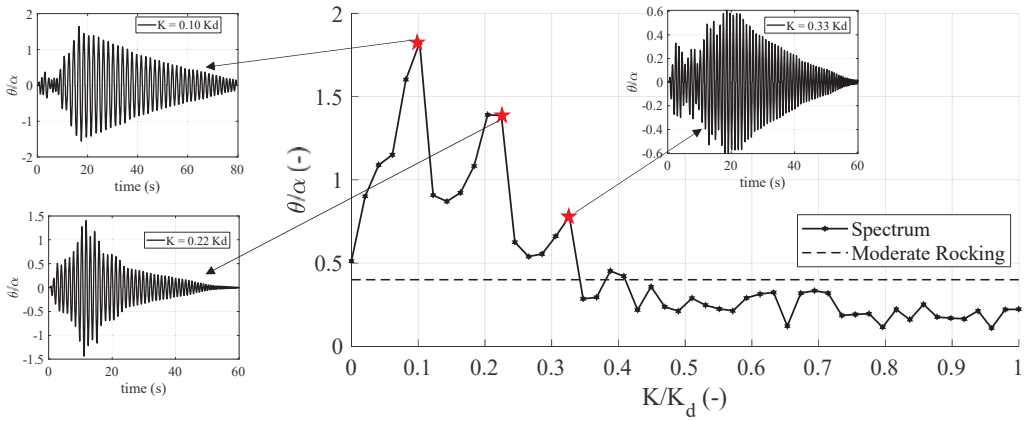

Figure 3: Rocking spectrum obtained for restrained block2 in one-sided motion under 1995/10/01 - 6.2 M_w - Dinar (Turkey) earthquake; resonant-like responses shown for $K/K_d = 0.10$, 0.22 and 0.33.

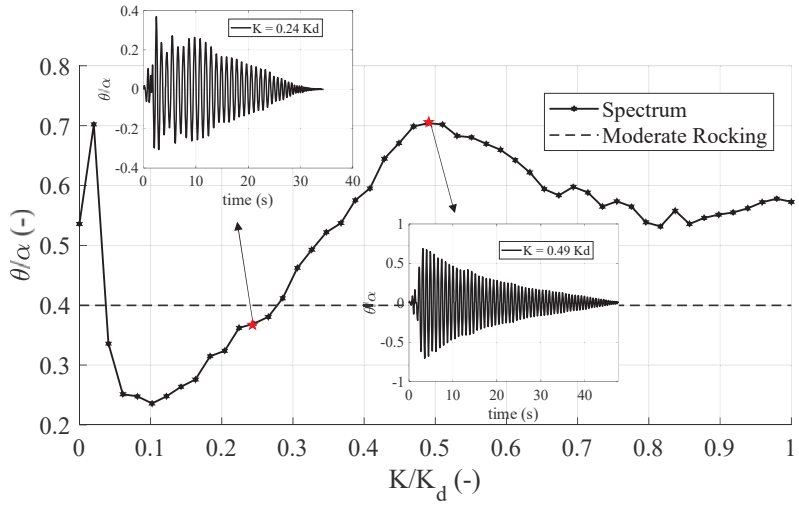

Figure 4: Rocking spectrum obtained for restrained block2 in one-sided motion under 2016/10/30 - 6.5 M_w - Norcia earthquake; resonant-like responses shown for $K/K_d = 0.24$ and 0.49 .

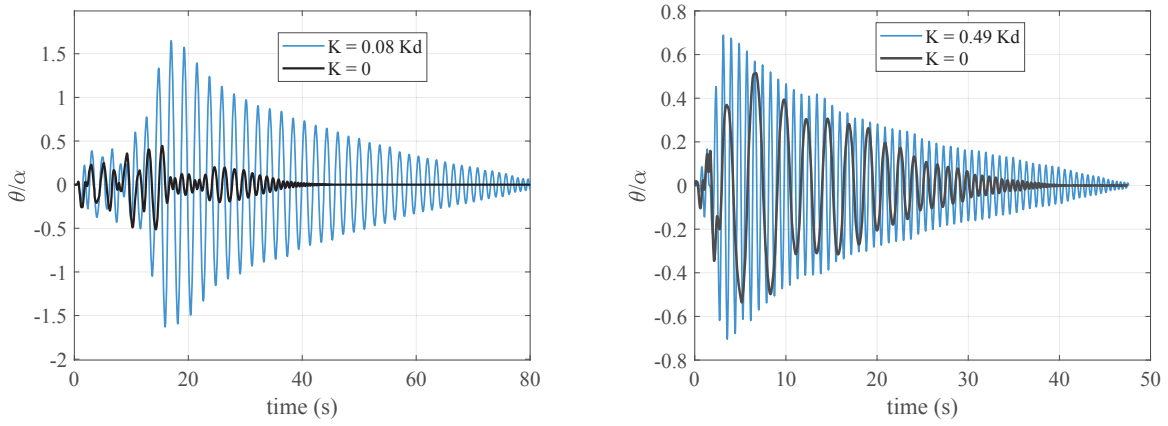
earthquake (Figure 4), maximum rotations are beyond the moderate limit state only for stiffness values ranging between $0.02 < K/K_d < 0.3$, while amplified responses, sometimes overcoming the free-standing peak, are obtained elsewhere (e.g. $K = 0.49\,K_d$, Figure 5(b)).

Among all selected geometries, block2 and block5 ($s = 0.6$ m, see Table 1) are more sensitive to resonant-like effect under strong-motions, while other geometries respond in a stabler manner. Given a certain slenderness, the moment of inertia plays a crucial role in the frequency content of the block (blocks with thickness $s = 0.3$ and 0.9 m show a reduced amplification response).

4.2 Damped free vibration

To better study the influence of damping in the rocking stability of rigid blocks, preliminary analyses are performed on block1 under free vibrations. For this purpose, an initial normalized rotation, $(\theta/\alpha)_0$ is set equal to 0.9, corresponding to the 90% of the ultimate kinematic displacement capacity ($u_G = s/2$), read at the center of gravity. Moreover, in order to isolate



(a) (b)

Figure 5: Comparison between free and restrained rocking block responses; (a) block2 - 1995/10/01 - 6.2 M_w - Dinar earthquake; (b) block2 - 2016/10/30 - 6.5 M_w - Norcia earthquake.

the influence of viscous damping, a unit value of restitution coefficient is set ($e = 1.0$), corresponding to perfectly elastic impacts. Firstly, responses under two-sided motion are computed. Secondly a realistic value of K' is set in order to simulate the presence of transversal walls under both free and restrained configuration ($K = 0.0$, and $K = K_d$, respectively) [16].

Assuming the clockwise direction as the positive rotation (Figure 1), the damping contribution takes the sign of rotational velocity, $\dot{\theta}$, coherent with the self weight term, among the others. The validation of sign and shape of T_d term is shown in Figure 6 for free vibration of block1 in two-sided motion for the particular case of $c = 0.1\%\, c_d$.

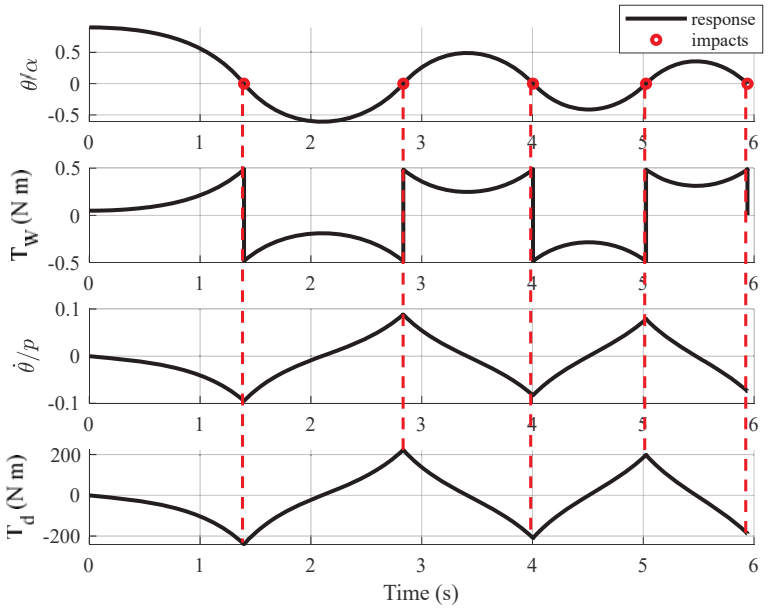


Figure 6: Validation of damping term sign for a simple free vibration time-history analysis of free-standing block1 in two-sided motion ($K = K' = 0.0$); from top to bottom: (i) normalized rotation; (ii) self weight term; (iii) normalized rotational velocity.

Figures 7 shows the influence of four different values of damping ($c = 0.0; 0.1; 1.0;$ and $5.0\%\, c_d$) on the damped free-standing block1 under two- and one-sided motion (i.e. without and with the presence of transversal walls with equivalent spring bed stiffness $K' = 4.5e8$ N/m/m, [16]). The beneficial effect of increased damping coefficient is clearly visible from the Figures. The damping device decreases the successive peaks and delays the first impact time, as evidently demonstrated passing from $c = 1.0\%$ to $c = 5\%\, c_d$.

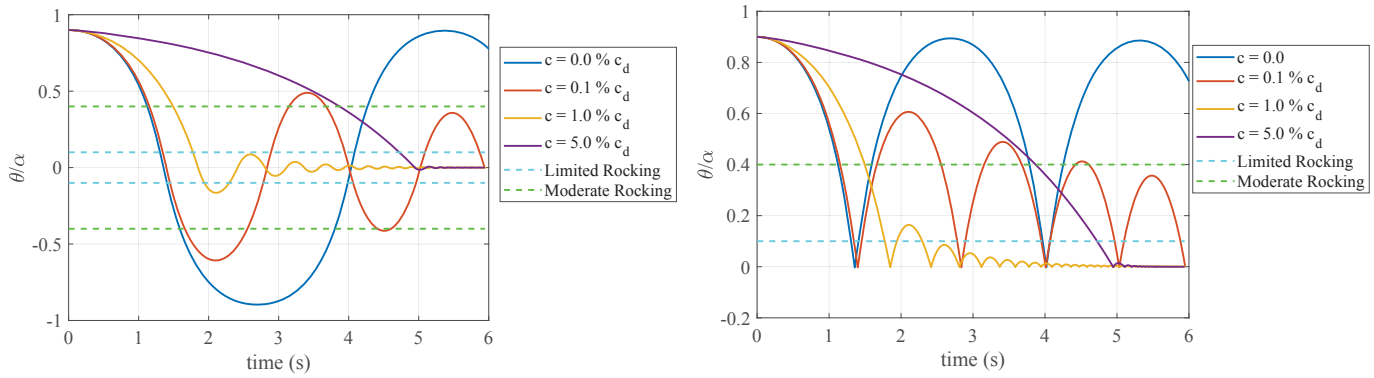

Figure 7: Influence of damping on free-standing rocking block1 under free vibrations; (a) two-sided motion; (b) one-sided motion.

The effect of dampers is also studied for the restrained configuration (that is with K different from zero) in one-sided motion, setting $K = K_d$ as defined in Section 3. The first impact time is strongly reduced by the presence of the tie re-centering the block in its "zero" position (Figure 8). It is visible an increased rotational frequency due to the restrained condition. This aspect could be problematic in terms of repeated cyclic stresses on the transverse walls, where masonry could crush for the attainment of compressive strength. It is interesting to note that, for the same value of damping coefficient, despite the more "regular" response if compared to the free-standing configuration, higher normalized rotations are obtained for the restrained block. Indeed, as confirmed in Figure 9, setting $c = 1.0\%\, c_d$, the peak reduction is gradual for the restrained block, only corresponding to 27% reduction after the first impact, while a reduction of 82% of normalized rotation is obtained for the free-standing block.

4.3 Damped forced vibration

Nonlinear analyses of the restrained ($K = K_d$) blocks with the same geometries are performed under real inputs in order to study the influence of dampers on façade-like walls. The lateral stiffness per unit length is computed according to Equation 11. For the purpose of this work, a value of $E_x = 1.5e9$ N/m/m can be used according to [12]. Moreover, 30 cm thickness and 1.0 m length can be assumed. The analytical value of the coefficient of restitution, $e_H = 1 - \frac{3}{2} sin^2\alpha$, based on [18] is set.

The beneficial effect of damping is clear in Figure 10 where a significant reduction of maximum normalized rotation is obtained for higher values of damping. Amplified response is obtained for the undamped cases characterized by high and longer oscillations probably caused by the bouncing and near resonant effects given by the tie. For higher values of damping, the rotation time-histories shape is similar during the first impacts only, as successive frequency

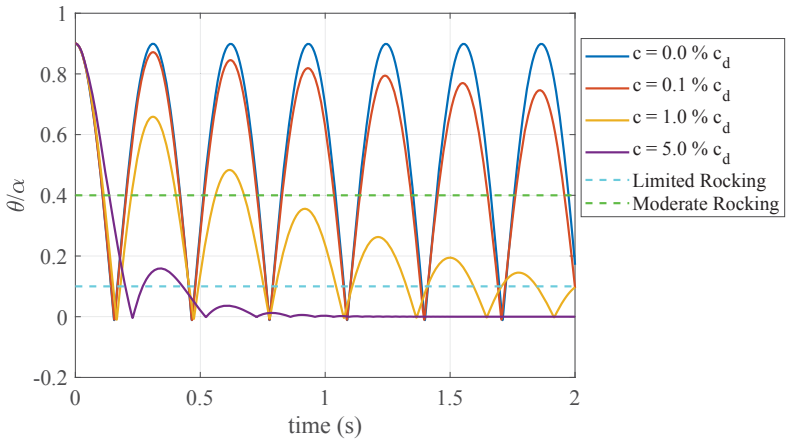

Figure 8: Influence of damping on restrained rocking block1 under free vibration in one-sided motion.

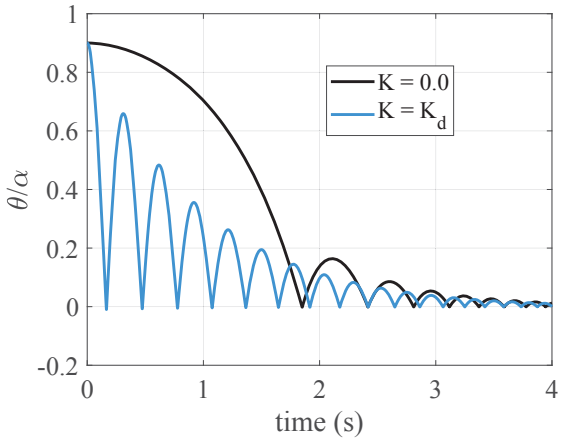

Figure 9: Comparison between free and restrained configuration under free damped vibration in one-sided motion; block1, $c = 1.0\%\, c_d$.

and peaks values are affected by damping force. Besides the response is strongly dependent on the geometry of the block and the type of input, damping values of $c > 10.0\%\, c_d$ should fulfil the limited rocking limit state.

5 CONCLUSIONS

This paper analysed the dynamic response of out-of-plane rocking walls with a viscous-elastic damper at the top under recorded acceleration time histories. Six different geometries were tested to investigate the role of size and slenderness of the rigid block in the dynamic response. From the non-linear analyses outcomes, a not monotonic trend in rocking spectra was observed when the stiffness was monotonically increased or decreased. The rocking spectra are therefore recommended in the design of whatsoever horizontal restraint for rocking walls to avoid such undesired amplifications due to near-resonance conditions. Moreover, the influence of damping was investigated in free and forced vibrations. As for the response in free vibrations, the beneficial effect of a greater damping coefficient was clearly visible, since it caused a reduction of consecutive peaks and delayed the first impact time. The effect of dampers was also

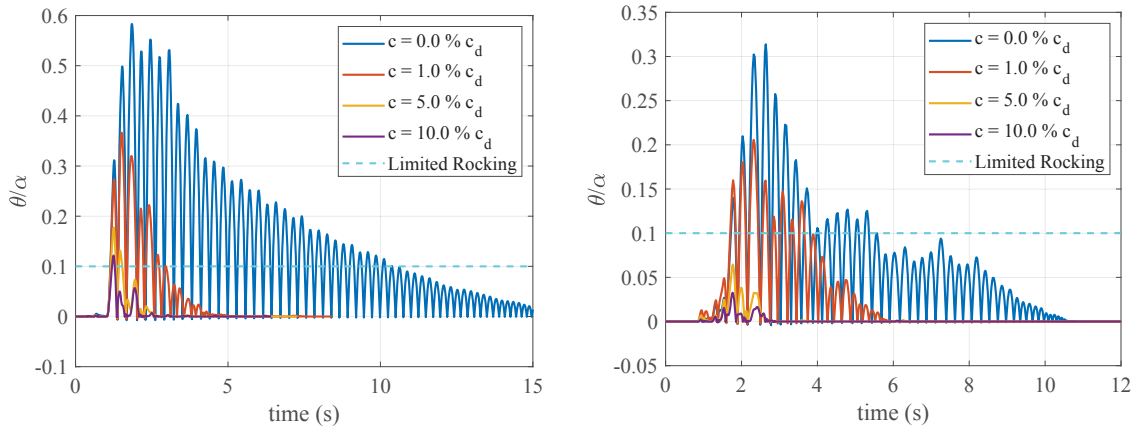

Figure 10: Influence of damping on restrained block1 under real seismic input; (a) 2016/10/26 - 5.4 M_w Castelsantangelo sul Nera earthquake; (b) 2016/08/24 - 6.0 M_w Accumoli earthquake.

studied for the restrained configuration in one-sided motion. The first impact time was strongly reduced by the presence of the tie that re-centered the block in its "zero" position. Moreover, the resulting increased rotational frequency due to the restrained condition could be problematic in terms of repeated cyclic stresses on the transverse walls, where masonry could crush for the attainment of compressive strength. Forced vibrations responses also results in advantageous use of damper devices for the control of rocking motion of walls, considered in a realistic one-sided configuration sensitive to possible resonant behaviors. Not only maximum normalized rotations are strongly reduced by higher values of damping, but responses time-histories present relevant changes in terms of frequency and shape after the first impacts. A value of $c > 10\% \, c_d$ can be evaluated as the corresponding design value for the limited rocking limit state, but further analyses are necessary and intended in order to account for pretensioning and plasticity of the steel and for the possible development of multi-degree-of-freedom mechanisms.

Abstract. *This paper concerns the seismic vulnerability assessment of a historic masonry building by means of the spectral acceleration values detected with several approaches. This comparison is related to the particular geometrical-configuration of the case study, which makes the structure particularly prone to collapse mechanisms. These accelerations are evaluated in the static and dynamic nonlinear framework through the most common Finite Element Method (FEM) strategies employed by the scientific community. In particular, the nonlinear static analysis is performed by using a multi-control point pushover methodology allowing the detection of the most damaged areas in the building in which the nodes are located. The nonlinear dynamic analysis is performed by using an artificial accelerogram, and the damage cracks patterns are compared with the ones provided by the static approach. Afterward, a comparison between the spectral accelerations obtained with the FEM approaches and the limit analysis, according to the kinematic theorem, is proposed. This simplified analysis is used to investigate two of the most relevant out-of-plane failure mechanisms, previously highlighted by the global nonlinear investigations. The results show interesting aspects of the seismic resilience of the building, the San Fili Castle of Stignano, in the province of Reggio Calabria (southern Italy), which is strongly influenced by the absence of the box-like behavior.*

1 INTRODUCTION

The mitigation of seismic vulnerability is an excellent interest task for researchers, especially in seismic prone areas such as southern Italy [1, 2]. Structures that characterize old cities have several uncertainties affecting the geometrical and mechanical features. They are the result of many modifications that happened throughout the centuries. In order to take into account these complexities, different devices, and numerical methodologies have been successfully utilized as a support for the seismic investigation. For these reasons, this study concerns the seismic assessment of a historic masonry building by using both nonlinear static and dynamic analyses.

The case study is the San Fili Castle of Stignano (province of Reggio Calabria, south of Italy, Figure 1), a fortified residential building built in the XVIII century all in rubble masonry [3]. This artifact was taking into account owing to its particular geometrical configuration. A Finite Element (FE) model was developed with ABAQUS software by meshing the 3D geometric model provided by the Digital Photogrammetry [4]. Moreover, the Concrete Damage Plasticity (CDP) model, available in the computer program, was adopted to describe the nonlinear behavior of masonry [5]. Preliminary sensitivity analyses were carried out to calibrate the dimensions of the mesh and test the effect of some simplifications on the geometry [4, 6-8].

The spectral acceleration values obtained with FE Method (FEM) approaches were compared with the ones provided by the limit analysis according to the kinematic method. In particular, this simplified analysis was used to investigate two of the most relevant out-of-plane failure mechanisms, highlighted by the global nonlinear analyses. The results of the nonlinear static analysis were presented in terms of pushover curves related to different control points at the top level, as the center of mass of this level and three vertexes of the prismatic volume of the building, which has a triangular plan. For these points, displacement time-histories derived from the dynamic analysis were also presented together with the time history of the base shear in order to compare these results with those provided by the pushover analysis.

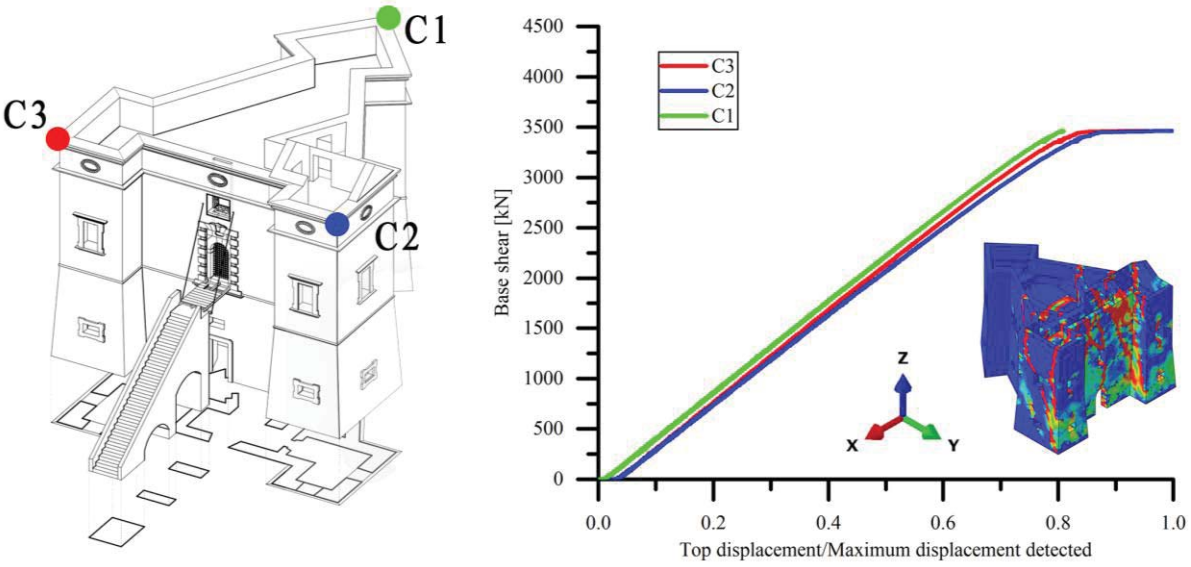
2 NON-LINEAR STATIC AND DYNAMIC ANALYSES

The first step for the seismic assessment is obtaining a proper model of the investigated structure. However, these buildings are complex geometry, which requires simplifications in

order to obtain FE model able to reproduce the structural behavior realistically, as it is studied in the papers by Tiberti *et al.* [9, 10]. In order to reduce the computational burden and obtain a convergent behavior of the solution in all ABAQUS simulations, a sensitivity analysis to set the correct mesh seed is also performed. In the latter, the mesh size is related to the natural frequencies and the participating mass for the three main modes.

Moving on, the nonlinear Pushover Analysis (PA), according to the N2 method adopted by Structural Codes [11, 12], is carried out. Through this method, the seismic vulnerability is evaluated by the conversion of the multi-degree of freedom system (MDOF) into the equivalent system with a single degree of freedom (SDOF) by using the modal participation factor. The PA consists in applying the vertical action including gravity loads and then in considering the seismic forces, acting separately along the positive and negative geometric directions (X and Y) of the analyzed structure [13].

In the simulations, a mass-proportional force distribution pattern is assumed, corresponding to a uniform horizontal acceleration pattern. As a matter of fact, the triangular shape of the building suggests to considerer three Boundary Control Points (BCPs) [14] onto the three vertexes. Their selection plays a very important role in the evaluation of the seismic vulnerability because the three nodes, namely C1, C2, and C3, show different displacement values at the collapse time. In Figure 2, the results of +Y PA are reported.



(a) (b)

Figure 2: (a) Localization of the three BCPs onto the San Fili Castle; (b) Results of PA for +Y direction.

In Table 1, the results of PAs are reported in terms of:

- safety factors F_S, which is the ratio between displacement capacity d^*_C and seismic demand d^*_D of the SDOF system,
- behavior factor q^*, which is the ratio between the elastic forces and the yield ones of the SDOF system, which represents the ductility of the structure,
- and spectral acceleration, which is the ratio between shear force F^* and participating mass m^*,

for the three BCPs.

Subsequently, the validation of PA results has been performed by using the Response History Analysis (RHA) based on the application of an artificial accelerogram along the X or Y directions [15-17]. In these analyses, the same model used in PAs is now subject to gravity loads, in the first phase, and, in the second phase, to an accelerogram applied to the base separately for each direction. With the aid of RHAs, the time histories of base shear, damage variables, and displacements of the control points might be assessed [18]. Figure 3 shows the results of RHA in Y direction.

Load direction	BCP	$F_S=d^*_C/d^*_D$	q^*	$a^*=F^*/m^*$
+X	C1	0.23	2.69	2.56
	C2	0.27	2.32	2.97
	C3	0.38	2.20	3.14
-X	C1	0.31	2.17	3.18
	C2	0.38	2.15	3.20
	C3	0.35	2.38	2.89
+Y	C1	0.19	2.86	2.40
	C2	0.23	2.66	2.59
	C3	0.22	2.68	2.57
-Y	C1	0.34	2.03	3.39
	C2	0.28	2.02	3.41
	C3	0.26	2.17	3.17

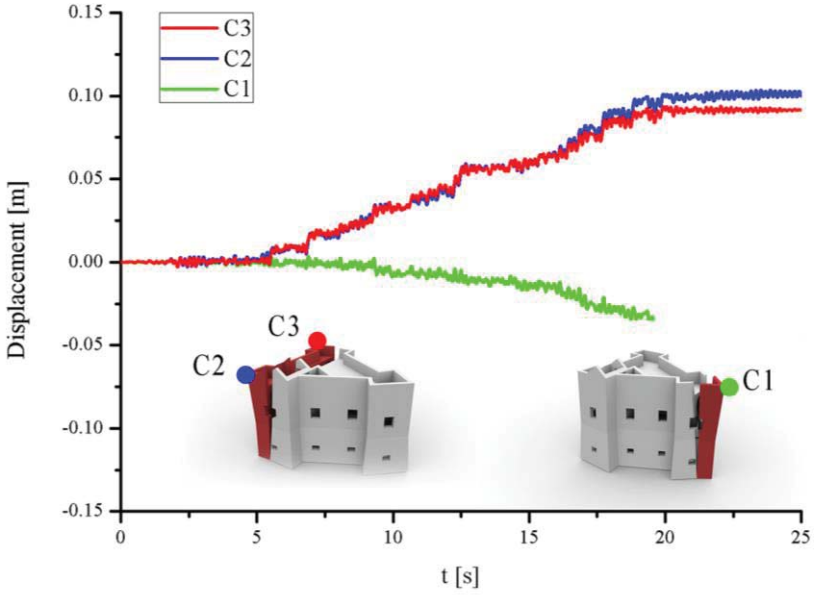

Figure 3: Results of RHA for Y direction in terms of top displacements of BCPs.

3 LIMIT ANALYSIS WITH KINEMATIC APPROACH

The previous seismic analyses highlighted the onset of out-of-plane mechanisms, which occur on the perimeter walls denoting the lack of box-like-behavior. In order to compare the

spectral acceleration provided by the different approaches (PAs, RHAs, and KAs), two out-of-plane mechanisms were analyzed: Simple Overturning (SO) and Vertical Overturning with 2 side wings (VO) (Figure 4). These mechanisms refer to the rocking west tower of the north front which collapses firstly in the +Y PA and reaches higher displacements than all other simulations. The BCP C2 is placed above this structural element, and the detrimental effect of the static thrust of a masonry vault was considered. At the first stage, two linear kinematic analyses were carried out in order to evaluate the corresponding multiplier at collapse α_0 by using the Virtual Work Theorem (VWT) [2, 19]. In the calculation, masonry walls are considered as an assemblage of macro-elements made of a no-tension material with an infinite compressive strength. In the next stage, according to NTC 2018, the nonlinear kinematic analysis was used in order to calculate the spectral acceleration values a^* of the SDOF system.

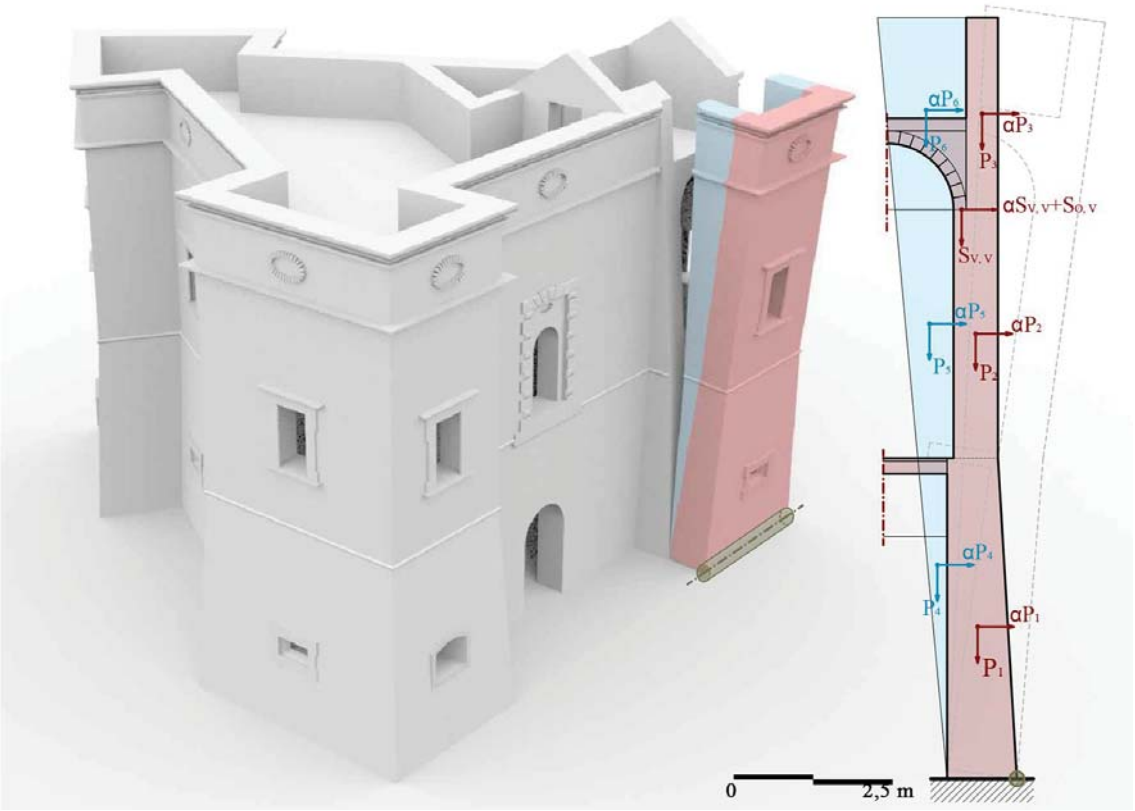

Figure 4: KAs calculation scheme.

4 COMPARISON OF SPECTRAL ACCELERATION VALUES

With regard to the spectral acceleration, a comparison among all types of analyses is reported in Table 2. In numerical analyses, the values concerning node C2 are taken into account along the +Y load direction in PAs as well as the Y direction in RHAs. In the case of KAs, the spectral accelerations are calculated on the ultimate displacement configuration of the SDOF equivalent system. As evidenced by the reported results, the seismic response obtained through the different numerical approaches is comparable. The RHA provides higher spectral accelerations than the PA, but the values are quite comparable in terms of magnitude. This confirms the difficulty in the numerical modeling of very complex structures, especially in the case of nonlinear dynamic analysis which represent the best investigation tool. Regarding the analytical approach, there is a discrepancy with the results of the numerical insight. The lowest values obtained for the KA are mainly due to the non-refinement of the simplified method, which is more conservative since the accelerations obtained are calculated on a single

failure mechanism. On the contrary, the numerical calculation involving the entire structure and a* values are assessed as the ratio of Base-shear to participating mass. However, KA is a quick tool for the seismic analysis of masonry walls. Even today, the design of localized interventions, such as the insertion of tie-rods for achievement of the box-like behavior, takes place through simplified approaches [20].

Pushover Analysis +**Y**: a_{PA}^* [m/s^2]	Response History Analysis **Y**: a_{RHA}^* [m/s^2]		Kinematic Analysis: a_{KA}^* [m/s^2]	
BCP: C2	Positive values	Negative values	SO	VO
2.59	2.90	2.75	0.89	1.10

Table 2: Spectral acceleration values obtained with the different approaches.

5 CONCLUSIONS

The nonlinear static analysis is performed with the purpose of highlighting the seismic vulnerability of the case study. Owing to the triangular plan of the building, a multi-control point approach is used. The dynamic simulations allowed the seismic capacity of the San Fili Castle to be drawn clearly. The results, in terms of both damage and seismic resilience, are quite in agreement with those provided by pushover analysis. Also, it is noteworthy that the kinematic approaches lead to lower spectral acceleration values. However, these simplified investigations might be useful to improve the connection conditions between macro-elements by using traditional techniques such as steel tie-roads. In addition, this first study of the problem in question could be applied to the implementation of the Internet of Things paradigm to a structural health monitoring system of the building in order to conduct real-time analyses with data acquired using accelerometers [21, 22].

Keywords: Fragility functions, Masonry, Local failure mechanisms, Seismic vulnerability.

Abstract. *Damage observations from strong earthquakes show that unreinforced masonry buildings have exhibited recurrent local failure mechanisms and constitute a serious life-safety hazard. This contribution is aimed at evaluating the fragility functions for unreinforced masonry walls in the presence of local failure mechanisms induced by out-of-plane loading. The out-of-plane response consists of the overturning of the entire or a part of the wall insufficiently connected to the rest of the structure. The wall can be idealized as a number of rigid bodies undergoing rocking motion. They are assumed to undergo one-sided rocking or vertical spanning strip wall displacing as an assembly of a coupled rigid body. In this study, we use a set of 44 ground motions from earthquake events that occurred in Italy from 1972 to 2017. For any given wall undergoing a specific collapse mechanism, the probability of collapse is evaluated through a Multiple Stripe Analysis (MSA). Then, a fragility curve is fitted to the MSA data points. The procedure outlined may be extended to obtain typological fragility functions as a combination of the fragility curves corresponding to the various mechanisms analyzed. A preliminary application of the procedure to the historical centre of Ferrara, Italy, is described.*

1 INTRODUCTION

The out-of-plane behavior of UnReinforced Masonry (in the following, URM) structures subjected to ground motion excitations has been widely investigated. Recent seismic events have shown that overturning of entire or parts of walls represents one of the most serious life hazards [1]. Ancient buildings not conceived with specific design criteria against earthquake actions are generally more vulnerable than new buildings, because of the inadequacy of connections of walls to transverse stabilizing walls and floor structures.

In Italy, the seismic analysis of masonry structures based on the study of local collapse mechanisms starts with Giuffrè [2] and a design method based on kinematic analysis is currently reported by the Italian building code [3]. Another approach, often more accurate, makes use of the motion equations of rocking rigid blocks subjected to a given acceleration time history. In this context, the study of rocking oscillators starts with the seminal paper by Housner [4], which derives the out-of-plane response of a parapet wall considered as a single degree of freedom (SDOF) system. Following Housner, the research focuses on the dynamic response of rigid blocks subjected to pulse or earthquakes excitations [5]. In particular, it is shown that this response is characterized by strong nonlinearity and dynamic instability.

Later, other models are developed to approximate the rocking response of complex multi-block systems with an equivalent SDOF system [6]. In particular, a useful SDOF idealization for the displacement-based analysis of the out-of-plane bending of URM walls is proposed in [7].

The increasing interest in a probabilistic approach that allows taking account of uncertainties, vulnerabilities and risk in earthquake engineering provides a description of the structural response by means of dynamic analyses. In PEER-PBEE framework [8], the fragility curve represents one of the main key tools. Several studies provide fragility curves for rocking blocks as a function of various intensity measures [9, 10].

The aim of the present study is to propose a dynamic approach using rigid block modeling to derive fragility curves for two types of very frequent local failure mechanisms. In particular, we analyze one-sided rocking and one-way vertical spanning strip walls (VSSW) displacing as an assembly of two rigid bodies. Section 2 reviews the mechanical models used to reproduce the out-of-plane behavior. Section 3 presents the procedure for evaluating the fragility curves and reports some results. As a case study, a preliminary application to the historical centre of Ferrara (Figure 1), Italy, is presented.

2 MECHANICAL MODELS REVIEWS

This section presents the equations of motion for the one-sided rocking and two-block rocking mechanisms. The dynamic response of the rigid blocks to prescribed acceleration time histories is obtained from a specifically suited MATLAB code that numerically solves the nonlinear equations with a 4^{th}-5^{th} order Runge-Kutta integration technique.

2.1 One-sided rocking

A rectangular block resting on a horizontal plane and presenting a vertical one-sided restraint is considered (Figure 2). The friction coefficient is assumed large enough to avoid sliding between the block and the plane.

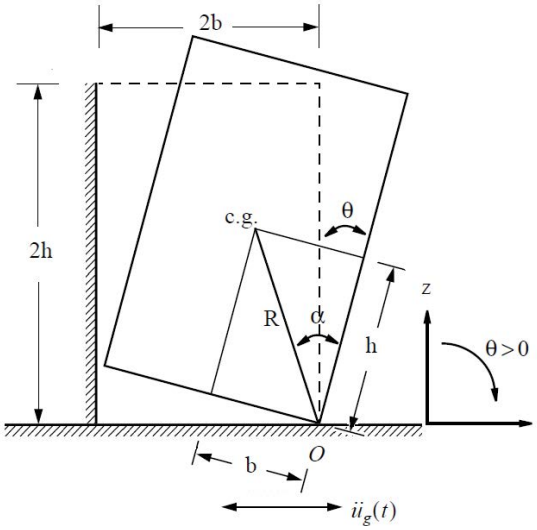

Figure 2: One-sided rocking under ground motion.

The equation of motion that governs the one-sided rocking response can be written as follows:

$$I_0\ddot{\theta} + gM_bR\sin(\alpha-\theta) = -M_bR\ddot{u}_g\cos(\alpha-\theta) \tag{1}$$

with R being the distance between block centroid and rotation centre O, θ the angular rotation, I_0 the polar second moment of area, α the angle between R and the vertical edge of the block, M_b the block mass of the block and g the gravity. The presence of a vertical restraint makes rotation θ remain positive.

In this paper, a coefficient of restitution is accounted for to estimate the energy dissipation. This coefficient, defined as the ratio between angular velocities after ($\dot{\theta}^+$) and before ($\dot{\theta}^-$) the generic impact, takes the following form [11]:

$$\eta_{1s} = \left(1-\frac{3}{2}\sin^2\alpha\right)^2\left(1-\frac{3}{2}\cos^2\alpha\right) \tag{2}$$

2.2 Two-block mechanism

A wall with a deformed shape corresponding to the formation of pivot interfaces at the top, the bottom, and an intermediate height is now considered (Figure 3). The main parameters that describe the mechanism are angles α_1 and α_2, defining the slenderness of the two blocks; M_{b1} and M_{b2} represent the masses of the blocks and I_{01} and I_{02} their polar second moments of area.

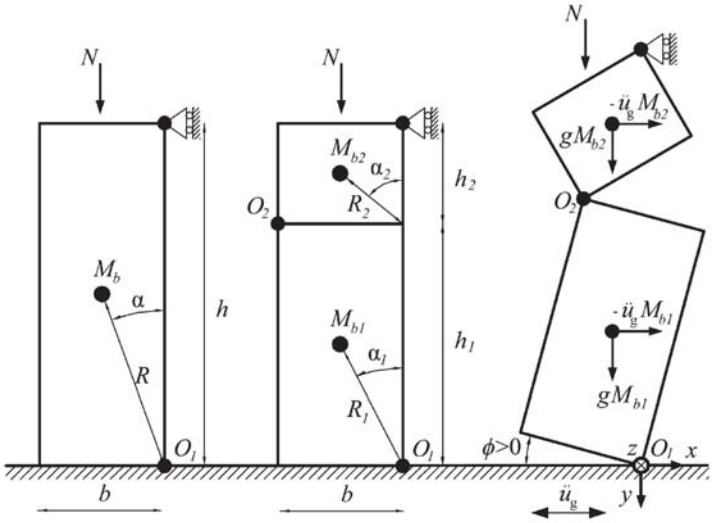

Figure 3: two block mechanism under ground motion

The equation of motion can now be written in the following form (the interested reader is referred to [12] for more details):

$$\left(I_{01}+B_1 I_{02}+B_2 M_{b2} R_2^2\right)\ddot{\phi}+\left(C_1 I_{02}+C_2 M_{b2} R_2^2\right)\dot{\phi}^2+gAR_2\left[M_{b1}+M_{b2}\left(1+\frac{B_2}{4A^2}\right)\right]= \\ -A\left(M_{b1}+M_{b2}\right)R_2\cot\left(\alpha_1-\phi\right)\ddot{u}_g+Q \tag{3}$$

The coefficient of restitution for this mechanism, depending of the block slendernesses, is defined as [12]:

$$\eta_{tb}=\frac{M_{b1}R_1^2+I_{01}\dfrac{\tan\alpha_2}{\tan\alpha_1}-2M_{b1}R_1^2\sin^2\alpha_1+M_{b2}R_1^2\left[2+\dfrac{\sin\alpha_1\cos\alpha_1}{\tan\alpha_2}-\sin^2\alpha_1\left(4+\dfrac{\tan\alpha_2}{\tan\alpha_1}\right)\right]}{M_{b1}R_1^2+I_{01}-I_{02}\dfrac{\tan\alpha_2}{\tan\alpha_1}+M_{b2}R_1^2\left[2+\sin\alpha_1\cos\alpha_{11}\left(\dfrac{1}{\tan\alpha_2}+\tan\alpha_2\right)\right]} \tag{4}$$

This coefficient decreases with wall slenderness and elevation of the intermediate hinge. The experimental evidence shows that the coefficient of restitution ranges between 0.84 and 0.90 of the predicted value [13].

3 FRAGILITY ANALYSIS

The fragility curve is defined as a conditional probability of failure.

$$P\left(C\middle|IM=x\right)=\Phi\left(\frac{\ln\left(x/\theta\right)}{\beta}\right) \tag{5}$$

where x is the median value of the selected Engineering Demand Parameter (EDP), while θ is the capacity related with the collapse damage state. Coefficient β is the logarithmic standard deviation of the demand conditioned on the Intensity Measure (*IM*). Fragility parameters may be estimated from an Incremental Dynamic Analysis (IDA) or a Multiple Stripe Analysis (MSA). In this contribution, the second approach is chosen.

3.1 Ground motion selection

A set of 44 natural ground motions from the ITACA [14] is used. The ground motion set collects the horizontal components of acceleration time histories recorded in Italy during 23 earthquake events occurred from 1972 to 2016. The ground motions are selected with a large range of peak ground acceleration (PGA) and peak ground velocity (PGV). The intensity measure used for the fragility curves is the PGA, which is the key strong motion parameter for seismic design in Italy [3].

3.2 Engineering Demand Parameter

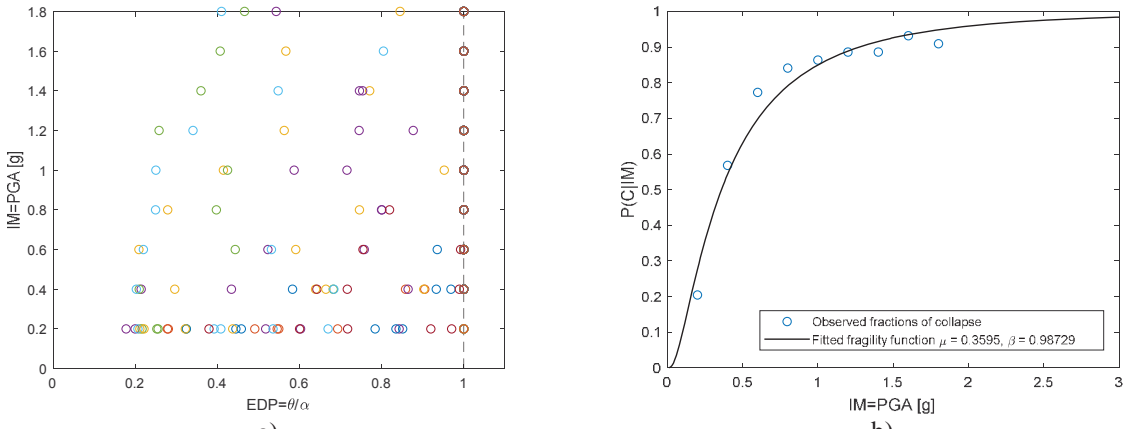
An appropriate choice of the EDPs is necessary for the fragility analysis. The EDP for an overturning block may be chosen as the ratio between block rotation θ and slenderness angle α (see Figure 1):

$$EDP = \theta/\alpha \tag{6}$$

Values of the EDP larger than zero imply that the structure starts to rock. When the EDP exceeds 1, the overturning occurs. This definition of the overturning condition is a simplification on the safe side. In fact, a rocking block might exhibit a higher EDP without overturning [15].

3.3 Multiple Stripe Analysis (MSA)

This type of analysis consists of a series of time history analyses for a specified set of *IM* levels [16]. Compared with the IDA, the MSA offers the advantage of a reduced computational effort. The maximum likelihood criterion is then used to fit the computed fragilities with suitable analytical functions (Figure 4).

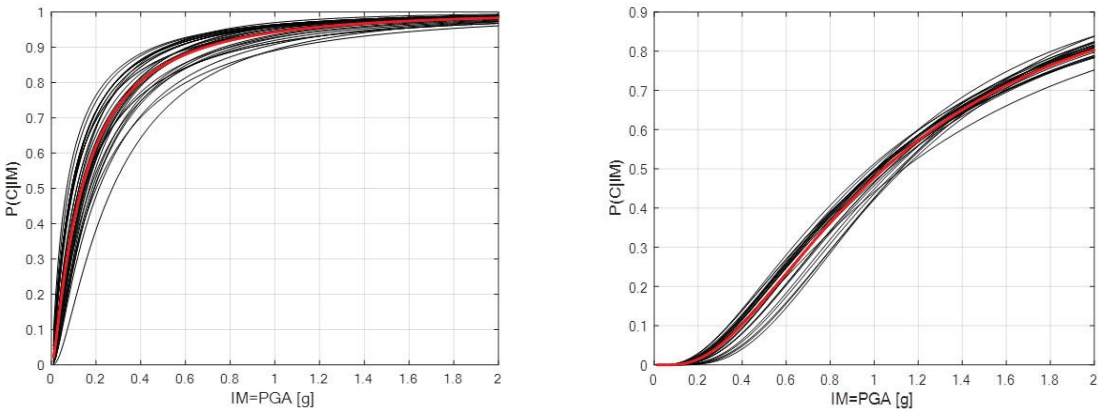


a) b)

Figure 4: a) example of MSA results. b) collapse probability as a function of IM and estimated fragility curve.

3.4 Fragility curves

A survey of an aggregate of buildings in the historic centre of Ferrara, Italy, has been preliminary carried out to form a "population" of masonry walls. The probability of occurrence of the one-sided rocking and two-block mechanism is estimated based on peculiar characteristics of the the surveyed buildings. The corresponding fragility curves are evaluated (Figure 5). These curves describe the vulnerability of the aggregate according with the analyzed mechanisms. It is worth noting that the rocking mechanism is more vulnerable than the two-block mechanism. This greater vulnerability relies upon the nature of the rocking mechanism, which has a trigger acceleration lower than that of the two-blocks mechanism.



a) b)

Figure 5: a) one-sided rocking fragility curves; b) two block mechanism fragility curves. (the red line represents the average curve)

4 CONCLUSIONS

The paper presents a procedure for evaluating the analytical fragility curves of out-of-plane loaded URM walls with a non-linear dynamic approach.

In a future research, a suitable combination of the obtained fragility curves taking account of the probability of occurrence of the various collapse mechanisms could allow to define typological fragility curves for classes of URM buildings.

5 ACKNOWLEDGEMENTS

The present research was carried out within the activities of the (Italian) University Network of Seismic Engineering Laboratories–ReLUIS in the research program funded by the (Italian) National Civil Protection – Progetto Esecutivo 2019/21 – WP2.

Keywords: Cultural Heritage, Masonry churches, Seismic vulnerability, Damage index, Risk analysis

Abstract. *In this paper, seismic vulnerability and risk assessment of two churches samples, located in Teramo and Ischia island in the Naples gulf, both affected by the most recent earthquakes occurred in Italy, are presented. An overview of some simplified methods particularly suitable for seismic evaluations at a territorial scale of ancient churches is presented. In particular, the damage index provided by the post-earthquake usability form adopted by the Italian Civil Protection Department, the vulnerability and risk analysis method implemented in a recent work and defined LV0, and the LV1 method contemplated in the Italian Guidelines for Cultural Heritage have been calculated for the examined samples of churches. These methods have an increasing precision level and they may be applied as well in sequence at a different scale for screening and identifying the present priorities and, consequently, for designing the required interventions. The obtained results have been compared to each other in order to evaluate, starting from the most precise Italian Guidelines method, if the other simplified analysis techniques are more or less effective in predicting the large scale seismic behaviour of churches. Finally, the comparison among the achieved indexes allows for the evaluation of the health state of inspected churches, so to both plan additional in-depth evaluations and program a priority scale in performing future retrofitting interventions.*

1 INTRODUCTION

Seismic vulnerability represents the building attitude to suffer damages related to an assigned earthquake. In order to assess vulnerability of buildings, it is sufficient to detect the damages caused from seismic events, associating them with the shock intensity. A building can show structural damages to load-bearing elements and/or non-structural ones. Damage typologies depend on structure geometry, age, materials, construction site, proximity to other buildings and placement of non-structural elements, as well as on the earthquake duration and intensity. In order to reduce structural damages and the loss of life, buildings need to be secured. Current Italian standards and guidelines [1-3] require that structures should have certain seismic criteria in order to exhibit a ductile response during a seismic event.
Seismic vulnerability assessment of historic buildings represents an enormous applicative relevance problem and constitutes an important preliminary step in masonry heritage safeguarding. A common monumental building typology exposed at seismic risk is represented by masonry churches. In fact, in many cases churches, due to their singular geometry, have shown a vulnerability greater than that of other historical masonry building types. In particular, the presence of large halls without intermediate walls, usual poor masonry mechanical properties, large walls having high slenderness, pushing roof elements, colonnades, decorative elements not effectively constrained to the walls and lack of intermediate floors give an extremely variable seismic response of churches [4-9].
The systematic observation of the typical damage scenarios reported by churches following earthquakes has also highlighted how the seismic response is attributable to local collapse mechanisms connected to the loss of balance and the consequent transformation into a kinematic motion of one or more portions of the construction, which detach from it due to crack occurrence [10-19]. These observations led to the classification of 28 collapse mechanisms developed by the Italian Department of Civil Protection [8, 20]. The possible kinematic mechanisms assessment is not an easy solution problem: detailed structural analyses carried out using software or finite element methods [21-24], have high computational costs, so to make very difficult their application for a territorial scale analysis, and, therefore, simplified methodologies can be preferred [25-31].
For this reason, in this paper three simplified methodologies are investigated in order to assess seismic vulnerability of churches placed in two zones affected by last Italian earthquakes. In particular, the damage indexes detected after seismic events have been evaluated and compared to those deriving from application of both Italian Guidelines on Cultural Heritage and a method developed by a research group of the University of Basilicata (UniBas) defined as *LV0*, with the final goal to evaluate the more or less reliability of these latter two methodologies to predict the large scale seismic behaviour of examined churches.

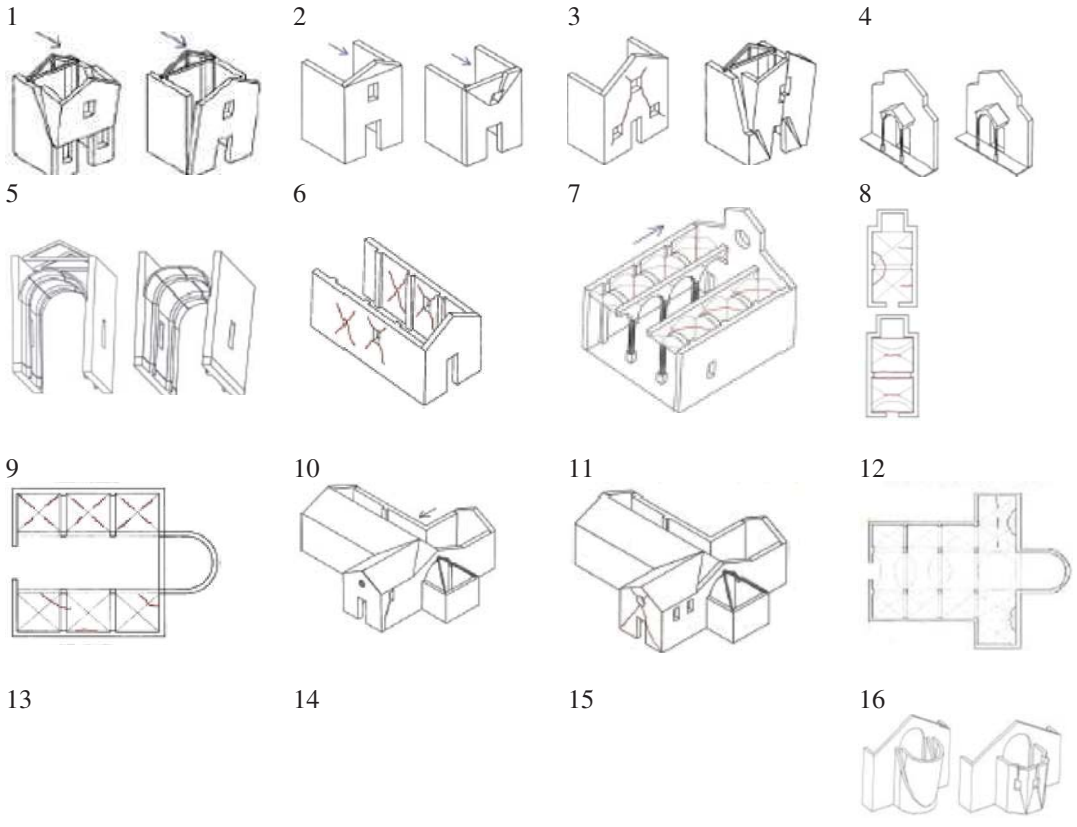
2 LARGE SCALE ASSESSMENT METHODOLOGIES

2.1 The church form (A-DC model – Italian Civil Protection Department)

The proposed methodology, developed by the Italian Civil Protection Department [20], is based on the evaluation of a damage index (i_d) calculated through the observation of 28 potential local collapse mechanisms that could be activated during a seismic event.
Local mechanisms are (Figure 1):

1. Façade overturning
2. Top overturning
3. In-plane damages

4. Narthex
5. Transverse response of the hall
6. Shear mechanism into lateral walls
7. Longitudinal response of the colonnade
8. Hall or central aisle vaults
9. Lateral aisles vaults
10. Transept wall overturning
11. Shear mechanism into transept walls
12. Transept vault
13. Triumphal arches
14. Dome
15. Lantern
16. Apse overturning
17. Apse shear mechanism
18. Presbytery or apse vaults
19. Roof elements: hall
20. Roof elements: transept
21. Roof elements: apse
22. Chapel overturning
23. Shear mechanism into chapel walls
24. Chapel vaults
25. Interaction due to irregularities
26. Projections
27. Bell tower
28. Belfry



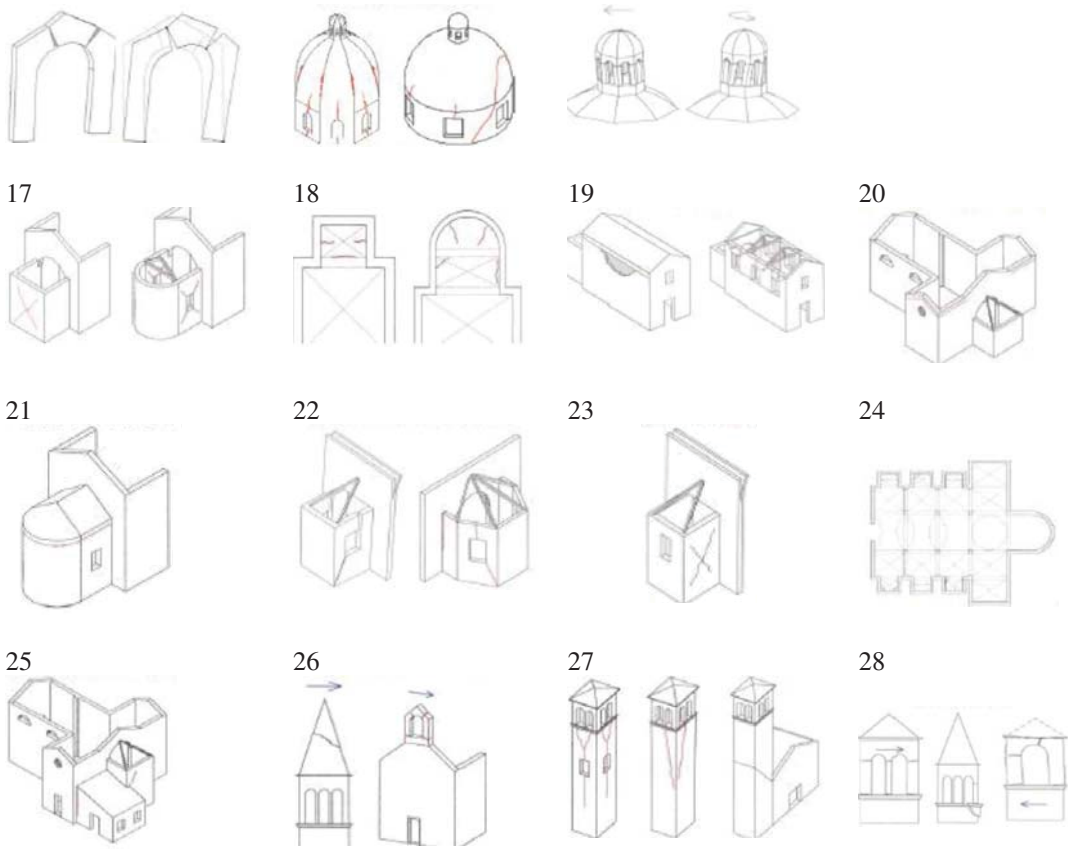


Figure 1: Local mechanisms of churches

For each possible mechanism, a damage value d_k between 0 (no damage) and 5 (collapse) may been assigned, and the resulting global damage index i_d is calculated as the ratio of the sum of the detected damage values d_k to the potential mechanisms number n (<=28) multiplied by 5 according to the following relationship:

$$i_d = \Sigma d_k / 5n \quad (1)$$

The application of the above formula provides damage index values i_d ranging from 0 (no damage) to 1 (total collapse of the church examined).

2.2 Vulnerability and risk analysis method (UniBas)

In this methodology, developed by a research group of University of Basilicata (UniBas), the resulting seismic risk of churches at a territorial scale is based on the evaluation of the following three tools, which an independent score is assigned to [25, 30, 32]:

- *Tool 1*: attention priority on actions related to the buildings according to their exposure value (*E*);
- *Tool 2*: description, classification and mapping of seismic hazard (*H*);
- *Tool 3*: evaluation and quantification of the seismic vulnerability level (*V*).

The seismic risk score is assessed through a correlation among exposure (*E*), threats (*H*) and seismic vulnerability (V) according to the following relationship [33, 34]:

$$R = E \times H \times V \quad (2)$$

In particular, *Tool 1* considers socio-cultural values, i.e. antiquity, historical, symbolic and

aesthetic factors, and economic values, i.e. use, financial and scientific factors.
Tool 2 provides the *H* score through the analysis of threats, which are classified into sporadic events and continuous processes (depending on their occurrence probability), as shown in Table 1. Every threats have a score according to the damage severity, namely absent, medium and catastrophic. The seismic hazard index (*H*) is obtained by summing these scores and assumes values between 0 and 2,15.

	Parameters	Damage gravity		
		Absence	**Average**	**Catastrophic**
Sporadic Events	earthquake and tsunami threat	0	0,20	0,40
	landslides	0	0,15	0,25
	volcanic threat	0	0,20	0,40
	hydro-methodological threat	0	0,15	0,25
	chemical-technological threat	0	0,15	0,25
	forest fires	0	0,15	0,25
Continuous Events	erosion threat	0	0,05	0,10
	physical stress of threat	0	0,05	0,10
	air pollution	0	0,01	0,05
	socio-organizational threat	0	0,01	0,05
	demographic decline	0	0,01	0,05

Table 1: Scenarios description and classification of threats according to the damage severity.

Finally, the *Tool 3* provides the *V* score, that is the seismic vulnerability. This tool is based on the assessment of 13 parameters (see Table 2), of which 10 are derived from the Italian 2nd level GNDT vulnerability datasheet [35]. Each parameter is characterised by 4 classes having an assigned score and the vulnerability index is defined through the following relation:

$$IV=\sum^{n}_{i=1} v_i \cdot p_i \quad (2)$$

where:
v_i is the parameter class score, depending from building properties;
p_i is weight correlated to the parameter importance.
Depending on the vulnerability index obtained, it is possible to define three different vulnerability levels as follows:

- *low*: $0 < IV \leq 10.81$;
- *medium*: $10.81 < IV \leq 55.52$;
- *high*: $55.52 < IV \leq 100$.

Total seismic risk (R) is obtained by applying the following relation [32]:

$$R=IV\times(H+1) \quad (3)$$

	Parameters	Classes				Weight
		A	B	C	D	
1	Position of the building and foundations	0	1,35	6,73	12,12	0,75
2	In-plane configuration	0	1,35	6,73	12,12	0,50
3	In-elevation configuration	0	1,35	6,73	12,12	1,00
4	Distance among walls	0	1,35	6,73	12,12	0,25
5	Non-structural elements	0	0	6,73	12,12	0,25
6	Resistant system type and organization	0	1,35	6,73	12,12	1,50
7	Resistant system quality	0	1,35	6,73	12,12	0,25
8	Floors	0	1,35	6,73	12,12	1,00
9	Roofs	0	1,35	6,73	12,12	1,00
10	Conservation state	0	1,35	6,73	12,12	1,00
11	Environmental alterations	0	1,35	6,73	12,12	0,25
12	Construction system negative alterations	0	1,35	6,73	12,12	0,25
13	Fire vulnerability	0	1,35	6,73	12,12	0,25

Table 2: The UniBas form for seismic vulnerability evaluation of churches.

2.3 The LV1 Method (Italian Guidelines on Cultural Heritage)

The Italian LV1 method provides a statistical-based method to assess the vulnerability of masonry churches [8]. This methodology is based on 28 mechanisms defined in Section 2.1 and the vulnerability index i_v, framed in the range [0÷1], is assessed through vulnerability indicators and seismic upgrading devices according to the following formula:

$$i_v = \frac{1}{6}\frac{\sum_{k=1}^{28}\rho_k\left(v_{ki}-v_{kp}\right)}{\sum_{k=1}^{28}\rho_k}+\frac{1}{2} \tag{4}$$

where:

i_v is the vulnerability index;
k represents the 28 collapse mechanisms potentially activated;
ρ_k is the mechanism weight;
v_{ki} is the vulnerability score related to the k-*th* mechanism;
v_{kp} is the score connected to the upgrading device related to the k-*th* mechanism.

The inactive collapse mechanisms have ρ_k=0; instead the activated mechanisms n. 4 and 15 have ρ_k = 0.5, those with numbers 10, 11, 12, 18, 20, 22, 23, 24, 25 and 26 have a value between 0.5 and 1 in relation to their importance and the remaining activated ones have ρ_k=1.
For each mechanism, the possible seismic protection devices and vulnerability indicators are suggested in [8] and a score depending from effectiveness or severity degree variable between 1 and 3 must be defined. Table 3 shows the vulnerability issues and seismic upgrading devices for the most commonly detected local collapse mechanism, namely the façade overturning.

Through Table 4 it is possible to calculate the indicators v_{ki} and v_{kp} related to vulnerability parameters and anti-seismic devices, respectively.

01 – Façade overturning			
Possibility of activation of collapse mechanism: YES [ ] NO[ ]			
YES	NO	Seismic protection devices	Importance
[ ]	[ ]	Presence of metal tie road	[ ] [ ] [ ]
[ ]	[ ]	Presence of constraining elements	[ ] [ ] [ ]
[ ]	[ ]	Connection systems at angles of walls	[ ] [ ] [ ]
YES	NO	Vulnerability issues	Importance
[ ]	[ ]	Presence of pushing elements (arches, vaults, beams)	[ ] [ ] [ ]
[ ]	[ ]	Presence of big windows	[ ] [ ] [ ]

Table 3: Seismic protection devices and vulnerability issues suggested in [8] for façade overturning mechanism.

Number of vulnerability parameters or seismic protection devices	Importance	Score (v_k)
at least 1	3	3
at least 2	2	
1	2	2
at least 2	1	
1	1	1
None	0	0

Table 4: v_k scores assigned to vulnerability factors and seismic protection devices.

Starting from vulnerability index i_v (eq. 4), it is possible to define an ultimate limit state (ULS) seismic acceleration:

$$a^*_{g(SLU)} = 0.025 \cdot 1.8^{5.1-3.44 \cdot i_v} \tag{5}$$

For safety check, it is required to evaluate the return period corresponding to the ULS as follows:

$$T_{ULS} = T_{R1} \cdot 10^{\log(\frac{T_{R2}}{T_{R1}}) \cdot \log(\frac{a_{ULS} S}{F_C a_1 S_1}) / \log(\frac{a_2 S_2}{a_1 S_1})} \tag{6}$$

where T_{R1} and T_{R2} are the return periods of the seismic hazard and represent the limits of the interval where T_{ULS} is located, a_1S_1 and a_2S_2 are the corresponding peak acceleration values on rigid ground taking into account the topographical conditions and FC is the confidence factor.

The safety index referred to the ULS is the ratio between the capacity return period at the ultimate limit state T_{ULS} and the corresponding reference (demand) return period $T_{R,ULS}$:

$$I_{S,ULS} = T_{ULS}/T_{R,ULS} \tag{7}$$

$I_{S,ULS}$ value greater than or equal to one means that the building is in safe conditions, while values lower than the unit show that the building needs seismic upgrading interventions.

3 THE CASE STUDIES

3.1 Teramo's churches

Teramo is the provincial capital of the homonymous province, located in the Italian Abruzzo region. The 12 investigated churches in the current study, depicted in Figure 2 [22], are:

1. Saint John church. Hall: 16.50x14.30m, average height 10.00m. There are no apse and bell tower.
2. Saint Anastasio church. Hall: 14.70x7.20m, average height 6.70m. Apse: 7.50x3.50m, average height 7.15m. There is a bell tower.
3. Holy Mary of Carmine church. Hall: 11.30x6.20m, average height 7.20m. Apse: 6.45x5.00m, average height 7.00m. There is a bell tower.
4. Saint Nicola church. Hall: 11.00x4,60m, average height 3.50m. There are no apse and bell tower.
5. Saint Catherine of Alexandria church. Hall: 13.40x6.50m, average height 7.50m. There are no apse and bell tower.
6. Saint Luca church. Hall: 8.00x4.00m, average height 6.00m. There are no apse and bell tower.
7. Saint Mary de Praediis church. Hall: 14.50x9.00m, average height 5.00m. Apse: 3.00x1.50m, average height 5.00m. There is not a bell tower.
8. Saint Michael Archangel church. Hall: 16.50x14.30m, average height 10.00m. There are no apse and bell tower.
9. Saint Francis of Assisi church. Hall: 11.40x7.00m, average height 7.80m. Apse: 5.85x5.80m, average height 6.00m. There is a bell tower.
10. Saint John in Pergulis church. Hall: 14.90x9.30m, average height 8.00m. There are no apse and bell tower.
11. Holy Salvatore church. Hall: 10.70x7.20m, average height 8.00m. There are no apse and bell tower.
12. Saint Stephen church. Hall: 14.40x5.25m, average height 5.85m. Apse: 5.25x3.40m, average height 3.50m. There is a bell tower.

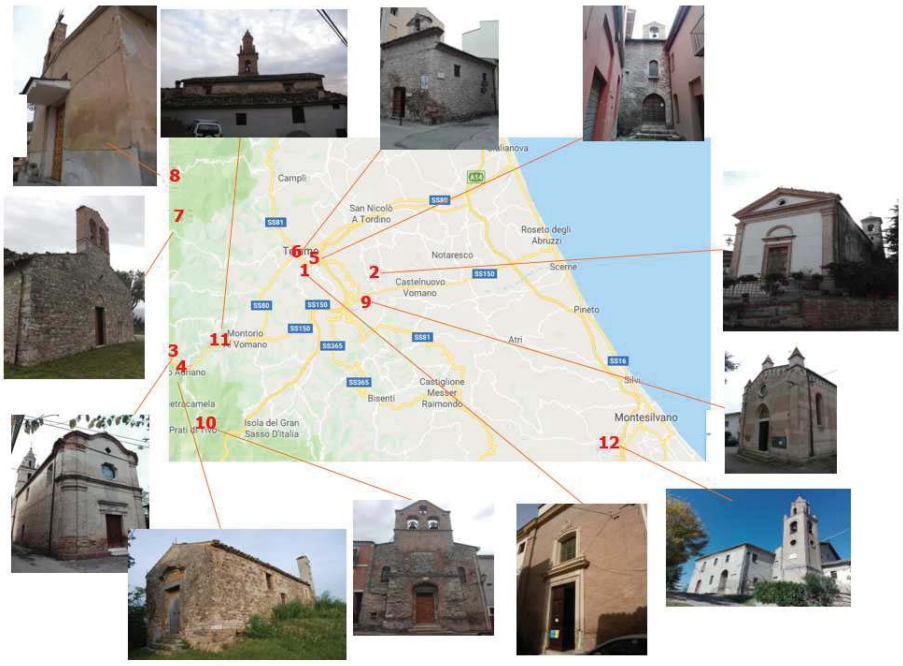

Figure 2: Location of the 12 churches investigated in the city of Teramo.

3.2 Ischia's churches

Ischia is an Italian island belonging to the Phlegrean islands archipelago located in the northern area of the Gulf of Naples. The 10 investigated churches showed in Figure 3 [22] are:

1. Saint Francis of Paola church. Hall: 19.50x3.30m, average height 7.00m. Apse: 3.40x3.30m, average height 8.50m. There is a bell tower.
2. Saint Vito church. Hall: 22.00x4.80m, average height 7.10m. Apse: 4.80x2.80m, average height 10.00m. There is a bell tower.
3. Most Holy Annunciation church. Hall: 6.50x3.90m, average height 6.55m. Apse: 4.80x4.00m, average height 6.55m. There is not a bell tower.
4. Saint Sebastiano church. Hall: 17.30x6.30m, average height 12.30m. Apse: 6.30x4.60m, average height 8.00m. There is a bell tower.
5. Saint Michael Archangel church. Hall: 8.60x5.20m, average height 8.00m. Apse: 5.20x4.70m, average height 8.00m. There is not a bell tower.
6. Saint Mary of Loreto church. Hall: 30.00x5.80m, average height 11.00m. Apse: 8.15x5.80m, average height 10.00m. There is a bell tower.
7. Saint Francis of Assisi church. Hall: 21.00x8.40m, average height 10.00m. Apse: 9.00x6.80m, average height 12.00m. There is not a bell tower.
8. Most Holy Annunciation coven. Hall: 11.00x5.60m, average height 7.00m. Apse: 6.00x5.50m, average height 7.40m. There is a bell tower.
9. Saint Mary of Soccorso church. Hall: 14.80x6.80m, average height 7.50m. Apse: 4.60x4.10m, average height 8.50m. There is a bell tower.
10. Saint Gaetano church. Hall: 17.00x5.80m, average height 13.70m. Apse: 4.70x1.70m, average height 7.15m. There is not a bell tower.

4 APPLICATION OF THE METHODOLOGIES

4.1 Teramo's churches

Collapse mechanisms and damage indices of churches calculated according to the form delivered by the Italian Civil Protection Department are reported in the Tables from 5 to 16.

For each mechanism, a different colour for each damage value between 0 (no damage) and 5 (collapse) is assigned, as shown in Figure 4.

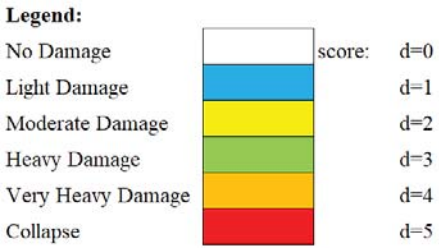

Figure 4: Colours assigned to damage scores

Activated mechanisms	Seismic Damage
Facade overturning	
In-plane damages	
Transverse response of the hall	
Shear mechanism into lateral walls	
Longitudinal response of the colonnade	
Hall or central aisle vaults	
Lateral aisles vaults	
Roof elements: hall

Table 16: St. Stephan Church's activated mechanisms.

The filling of the previous forms for all of the investigated churches has lead towards the evaluation of the following damage index i_d:

- St. John Church (Table 5): i_d =(1/40)= 0,02
- St. Anastasio Church (Table 6): i_d = (19/75) = 0.25
- Most Holy Annunciation Church (Table 7): i_d = (11/75)= 0,15
- Saint Nicola Church (Table 8): i_d= (3/35)= 0,08.
- Saint Catherine of Alessandria Church (Table 9): i_d= (5/20)= 0,25
- Saint Luca Church (Table 10): i_d= (10/35)= 0,29
- Saint Mary de Praediis Church (Table 11): i_d= (16/60)= 0,27
- Saint Michael Archangel Church (Table 12): i_d= (8/35)= 0,23
- Saint Francis of Assisi Church (Table 13): i_d= (4/70) = 0,06
- Saint John in Pergulis Church (Table 14): i_d= (4/35)= 0,11
- Most Holy Salvatore Church (Table 15): i_d= (5/65)= 0,08

- Saint Stephan Church (Table 16): i_d= (13/50)= 0,26

The results obtained from applying the *LV0* method to the churches inspected in Teramo are shown in Table 17.

Churches	Vulnerability Index
St. John	21,22
St. Anastasio	51,52
Holy Mary of Carmine	31,32
St. Nicola	53,18
St. Catherine of Alexandria	66,32
St. Luca	22,23
St. Mary de Praediis	39,06
St. Michael Archangel	37,37
St. Francis of Assisi	22,23
St. John in Pergulis	28,96
Most Holy Salvatore	45,44
St. Stephen	30,64

Table 17: Vulnerability indexes of Teramo's churches using vulnerabily method implemented by the University of Basilicata (UniBas).

Table 18 shows vulnerability indexes and results of the ULS safety checks achieved from the *LV1* method developed in the Italian Guidelines for Cultural Heritage described in Section 2.3.

Churches	Vulnerability Index	Safety Index
St. John	0,23	1,41
St. Anastasio	0,39	0,57
Holy Mary of Carmine	0,32	0,81
St. Nicola	0,31	0,85
St. Catherine of Alexandria	0,32	0,66

Table 28: St. Gaetano Church's activated mechanisms.

The damage indexes of the inspected churches have been calculated on the basis of the previous tables, leading to the following results:

- St. Francis of Paola church (Table 19): i_d =(7/80)= 0,09
- Saint Vito church (Table 20): i_d= (6/80)= 0,08
- Most Holy Annunciation church (Table 21): i_d= (12/65)= 0,16
- Saint Sebastiano church (Table 22): i_d= (17/80)= 0,19
- Saint Michael Archangel church (Table 23): i_d= (23/70)= 0,33
- Saint Mary of Loreto church (Table 24): i_d= (16/85)= 0,18
- Saint Francis of Assisi church (Table 25): i_d= (8/80)= 0,10
- Most Holy Annunciation Coven church (Table 26): i_d= (4/70)= 0,06
- Saint Mary of Soccorso church (Table 27): i_d= (8/80)= 0,10
- Saint Gaetano church (Table 28): i_d= (4/75)= 0,05

The application of the *LV0* method (developed by a reserach group pf the University of Basilicata) has led to the results depicted in Table 29. Finally, Table 30 shows vulnerability index

values and ULS safety checks obtained through *LV1* method developed by the Italian Guidelines for Cultural Heritage as described in Section2.3.

Churches	Vulnerability Index
St. Francis of Paola	25,93
St. Vito	25,93
Most Holy Annunciation	38,64
St. Sebastiano	34,33
St. Michael Archangel	46,46
St. Mary of Loreto	32,66
St. Francis of Assisi	24,25
Most Holy Annunciation coven	21,56
St. Mary of Soccorso	23,24
St. Gaetano	32,33

Table 29: Vulnerability indexes of Ischia's churches using the LV0 method.

Churches	Vulnerability Index	Safety Index
St. Francis of Paola	0,36	1,16
St. Vito	0,36	1,18
Most Holy Annunciation	0,42	0,85
St. Sebastiano	0,43	0,78
St. Michael Archangel	0,48	0,66
St. Mary of Loreto	0,43	0,78
St. Francis of Assisi	0,40	0,93
Most Holy Annunciation coven	0,40	0,93
St. Mary of Soccorso	0,34	1,30
St. Gaetano	0,36	1,21

Table 30: Vulnerability indexes and ULS safety checks for Ischia's churches using LV1 method.

4.3 Comparison of results

All results from examined methodologies are grouped in Tables 31 and 32, respectively, for Teramo's churches and Ischia's ones. In the first column of Tables 31 and 32 the ranking is reported in descending order (from the worst church to the best one) in terms of vulnerability indexes (I_v) defined according to the *LV1* method developed in the Italian Guidelines for Cultural Heritage. In the subsequent columns of the above mentioned tables, the safety indexes (I_s) of the *LV1* method, the vulnerability indexes calculated on the basis of the *LV0* method, indicating the method proposed by a UniBas research group and expressed in percentage terms and the damage indexes i_d resulting from filling the "A-DC model" form, developed by

the Italian Civil Protection Department, after the post-earthquake emergency phase have been reported too.

Church	I_v (LV1 method)	I_s (LV1 method)	I_v (LV0 method)	i_d (A-DC form)
St. Luca	0,435	0,44	0,22	0,30
St. Michael Archangel	0,414	0,495	0,37	0,27
St. Mary of Praediis	0,388	0,57	0,39	0,27
St. Anastasio	0,388	0,57	0,52	0,25
St. Stephan	0,38	0,573	0,31	0,26
St. Catherine of Alessandria	0,322	0,664	0,66	0,20
St. Mary of Carmine	0,322	0,813	0,32	0,15
St. Nicola	0,315	0,848	0,53	0,08
St. John in Pergulis	0,309	0,88	0,29	0,11
St. Salvatore	0,255	1,21	0,45	0,08
St. Francis of Assisi	0,244	1,29	0,22	0,05
St. John	0,229	1,41	0,21	0,02

Table 31: Comparison between al examined methodologies for Teramo's churches

Church	i_v (LV1 method)	I_s (LV1 method)	I_v (LV0 method)	i_d (A-DC form)
St. Michael Archangel	0,48	0,659	0,46	0,33
St. Sebastiano	0,43	0,779	0,34	0,19
St. Mary of Loreto	0,43	0,782	0,33	0,18
Most Holy Annunciation	0,42	0,85	0,24	0,10
St. Francis of Assisi	0,40	0,93	0,39	0,16
Most holy Annunciation Coven	0,36	1,05	0,26	0,08
St. Francis of Paola	0,36	1,165	0,26	0,09
St. Vito	0,36	1,18	0,22	0,06
St. Gaetano	0,36	1,21	0,32	0,05
St. Mary of Soccorso	0,34	1,3	0,23	0,07

Table 32: Comparison between al examined methodologies for Ischia's churches

For comparison purpose, it is believed that damage indexes provided by the Italian Civil Protection Department form represent the reference values, since they have been proposed starting from damages occurred after last Italian earthquakes. From comparison in term of vulnerability index, it has been detected that the *LV0* method provides very frequently lower

values (82% of the cases examined). In particular, this always occurs for the Ischia's churches, while for the Teramo's ones the *LV0* indexes are greater than damage indexes only in four cases. These results allow to say that the *LV0* method, even if it provides a ranking similar to that of the A-DC form, is not on the safe side in predicting the vulnerability of examined churches. On the other hand, it seems that the *LV1* method is good in predicting the vulnerability ranking and indexes of churches under investigation.
Finally, from A-DC form values, it has been revealed that churches usable only after prompt interventions are those characterised by indexes in the range between 0,2 and 0,3, while the worst conditions that carry out the church unusable are obtained for a damage index higher than 0,3. This limit value could be reached for vulnerability indexes greater than 0,32 and 0,40, respectively, in the areas of Teramo and Ischia. This is due to the fact that Teramo belongs to a territory with seismicity greater than that of Ischia.

5 CONCLUSIONS

In the context of the cultural heritage conservation and protection it is essential to have an adequate knowledge of the existing constructions, which allows to well identify the structural element for a reliable seismic safety assessment and the choice of the intervention strategies for improving their structural performance. To this purpose, it is preferable to perform analyses with sophisticated finite element programs. However, the use of such programs for vulnerability assessment at a territorial scale is not suitable, since it would take too long time. For these reasons expeditious methodologies are preferred. In this paper three different quick vulnerability analysis methods, namely the *LV1* Italian Guidelines method, the "Church form –A-DC model" developed by the Italian Civil Protection and the *LV0* methodology developed by a research group of the University of Basilicata, have been proposed and applied to two samples of churches located in Teramo and in the Ischia island, both affected by the last Italian earthquakes. The churches of these two areas have in common many features, but there are also some structural differences which have modified the values of their vulnerability index. A comparative seismic risk and vulnerability analysis considering the above three methods has been conducted at a territorial level for both areas considered.
From the analyses carried out, it can be revealed that the damage indexes provided by the Italian Civil Protection Department A-DC form represent the reference values, since they have been calculated on the basis of the damages really occurred after last earthquakes. In particular, churches usable only after prompt interventions are those characterised by indexes in the range between 0,2 and 0,3, while unusable church have damage index higher than 0,3. This limit value could be reached for vulnerability indexes greater than 0,32 and 0,40, respectively, in the areas of Teramo and Ischia. This occurred since Teramo belongs to a territory with seismicity greater than that of Ischia. Starting from this evidence, it has been detected that the LV1 method provides, in the cases analysed, more conservative results with respect to LV0 method, even if providing, similarly to the A-DC form, a macro-element approach is followed in evaluating the vulnerability index.

Keywords: Non-destructive tests, modal analysis, geophysical prospections, dynamic behavior, seismic assessment, archaeological structures, discrete element method

Abstract. *The knowledge path applied to the conservation of archaeological sites represents a crucial phase with the aim of qualifying materials and structural features, as well as identifying vulnerabilities for the selection of possible interventions. The use of non-destructive testing (NDT) techniques can significantly contribute to understand the overall structural behavior and correctly simulate the response through suitably calibrated numerical models. Archeological ruins often show several vulnerabilities due to the presence of incomplete structures, discontinuities, deterioration, and cumulated damages. In this framework, the paper describes a multidisciplinary approach for the structural assessment and conservation of some incomplete structures in the archeological site of Hierapolis of Phrygia (TR). The region is still nowadays characterized by high seismicity. This study is part of a bigger project consisting of the development of an archaeo-seismic park in Hierapolis. On this site, preserved and visible seismic effects on structures and soils making an educational function for valorization, prevention, and conservation purposes. The applied methodology consists of the execution of structural and geophysical inspections on selected structures (e.g,. Roman Bath complex, Nymphaeum) to experimentally define their dynamic response and characterize soil properties for an accurate simulation of the seismic behavior. Dynamic identification test on structures (with the support of other NDTs), ground penetrating radar (GPR), electrical resistivity tomography (ERT) and seismic prospection methods on soils were applied. The outcomes are used to calibrate and validate numerical models, mainly based on the discrete element method (DEM), able to simulate the dynamic behavior of structures composed by large stone blocks with thin mortar layers or massive multi-leaves freestanding walls, which represent the main structural types in Hierapolis. The study has been used to define an appropriate methodology to choose practical and reliable solutions for inspections and the correct selection of numerical tools for structural analyses and simulations.*

1 INTRODUCTION

Archaeological sites reveal important signs of our culture and history. Nowadays, the structure of ancient buildings appears often incomplete, e.g., lacking of bearing walls and piers, of horizontal components (floor and roofs, vaults and domes), and of mutual connections. Moreover, some monuments with peculiar functions in the past (e.g., amphitheater, nymphaea, temples) were built as relevant massive constructions, whose stability is also jeopardized by local failures, despite their thick sections. All those structures require particular care for their conservation in the current environmental conditions, and present high vulnerability to dynamic actions [1].

In such a context, the archaeological site of Hierapolis of Phrygia (Turkey) is paradigmatic, because: a) it includes a large variability of remains belonging to constructions that had various functions from its foundation as Greco-Roman city (around 3rd century B.C.) up to its abandonment (about the 14th century); b) it extends on a wide area (over 40 hectares) having high seismicity (expected peak ground acceleration PGA=0.4g) [2]. The site has been studied for over seven decades from the Italian Archaeological Mission in Hierapolis (MAIER) [3], that contributed to the excavations and restoration works for its valorization and use. The final aim is to complete the recovering of the whole site to make an archaeo-seismic park, i.e., a site where visitors can appreciate the ruins also in terms of their important seismic history.

In this paper, the results of an integrated multi-disciplinary approach aimed at analyzing the current structural conditions of typical remains in the area are discussed. The research involved the geophysical investigation of soil to identify the current seismic parameters, which integrated a series of structural investigations. They were based on dynamic tests used for the calibration of numerical models able to evaluate the seismic vulnerability and simulate the mechanical behavior under the expected earthquake.

Two categories of constructions were analyzed: (i) massive large travertine block remains (as for the Roman Baths and Latrines); (ii) multi-layer thick masonry structures (as for the Nymphaeum of Apollo and the Martyrion of St. Philip) [4][5][5].

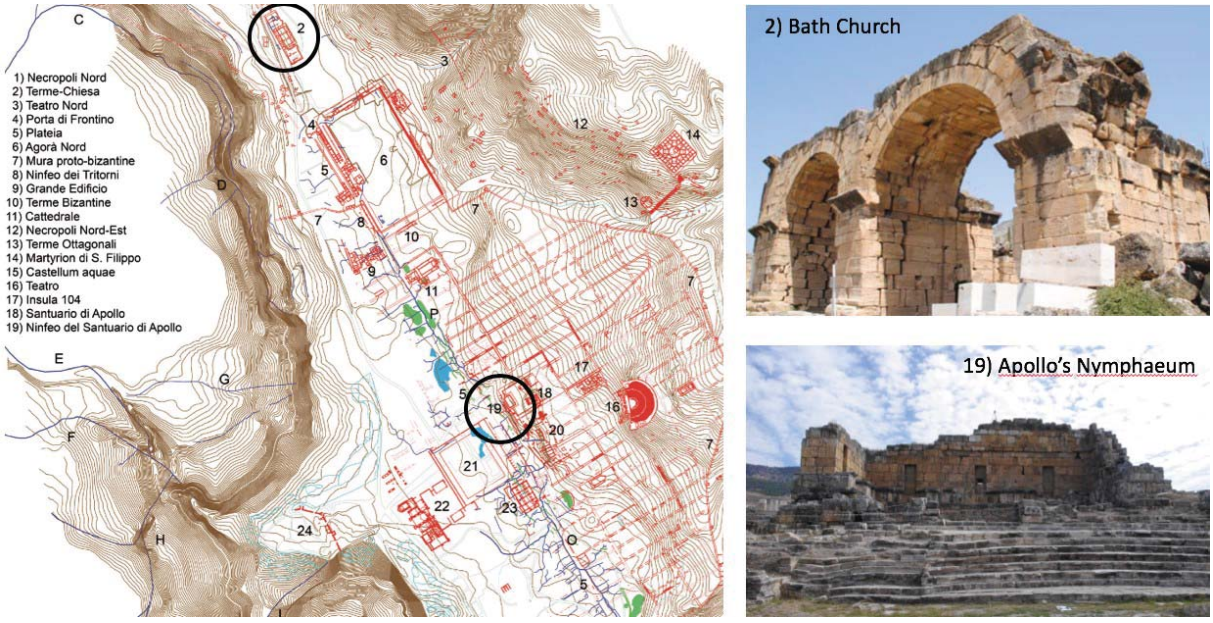

Figure 1: Archaeological chart of Hierapolis (after [7]) with location of two investigated monuments.

2 MATERIALS AND METHODS

Two extensive on-site investigation campaigns were performed by the authors in 2015 and 2018. Structural inspections and geophysical prospections were combined and integrated to assess the quality of building materials and their conservation condition, and to characterize the soil properties of some emblematic monuments in the archaeological site. Onsite testing on structures included visual inspections, critical and structural surveys, dynamic identification tests, sonic pulse velocity test, ground penetrating radar (GPR) applications, and video-endoscopy. Prospections on ground were performed through MASW (multichannel analysis of surface waves) and HVSR (horizontal to vertical spectral ratio) methods, to characterize the seismic properties of soils and identify the possible local amplification of the response during earthquakes. ERT (electrical resistivity tomography) measurements were also performed to support the seismic characterization of soil in its laterally and in-depth variation.

2.1 Geophysical prospections

The use of geophysical measurements in the characterization of soils and in the structure analysis supports since decades geological and engineering studies [8][9][10][11]. In the framework of this multidisciplinary project controlled source seismic refraction, surface wave, passive seismic measurements, as well as ERT and GPR data were collected across the Roman Bath and the Nymphaeum area in front of the Apollo temple, to characterize the shallow soil system. Seismic acquisitions were performed using vertical geophones (4.5 Hz natural frequency) and a Geode system digital seismograph, covering a maximum total array length of 94 m. Table 1 shows the acquisition parameters for the seismic controlled source measurements.

Controlled source seismic prospection	
Instrument	N. 2 Geode digital seismographs
Source	5 kg Sledgehammer on steel plate
Trigger system	Electric circuit
Receivers	24-48 vertical geophones
Receiver spacing	1 - 2 m
Survey length	47 - 94 m
Record length	2 s
Sampling	0.25 ms
Electrical resistivity tomography (ERT)	
Instrument	Iris Syscal Pro 72
Power source	External battery
Electrodes	48
Electrode spacing	1 - 2 m
Survey lenght	47 - 94 m
Stacks	3-6
Time	250 ms
Ground penetrating radar (GPR)	
Instrument	PulseEkko Pro (500 MHz antenna) IDS Ris Hi-Mod Dual frequency (200-600 MHz)

Table 1: Details of controlled-source seismic measurements at Hierapolis.

2.2 Structural investigations

The combination of modal analysis using ambient vibrations on the upper structures and seismometers on the ground demonstrated to be very useful to define the fundamental frequencies and assess possible resonance, local amplification phenomena and soil-structure interactions.

The outcomes of onsite inspections were used to create and calibrate engineering models, i.e. numerical (Finite Element, FE [12][13]) and Discrete Element, DE [14][15]) methods and kinematic limit analyses [16][17], able to assess the global and local seismic vulnerability of the structures.

Ambient vibrations tests (AVT) and output-only identification techniques were performed to identify modal parameters (natural frequencies, damping ratios and mode shapes) of Roman Bath and Apollo's Nymphaeum monuments. A network of accelerometers connected to an acquisition unit was installed in specific points of the two buildings. A preliminary FE model was constructed to analyze mode shapes and select the optimum sensor locations. Tests consisted in acquiring data implementing several setups, over a predetermined period, at a specific sampling rate. Time series acquired at a sampling frequency of 100 Hz were composed by 131'072 points with an overall signal recording duration of 21'51''.

3 RESULTS

The results of geophysical prospections were combined and integrated with ones of the structural investigations. Moreover, the outcomes of inspections on structures were used to calibrate and validate analytical and numerical models, able to simulate the dynamic response and assess the seismic vulnerability of the site monuments. A selection of the analysis carried out for the archaeological remains of Hierapolis are reported hereinafter.

3.1 Soil characterization

Controlled-source seismic surveys were used for both refraction seismic method [18] and surface wave method. The refraction method was used to estimate the 2D structure of the subsoil beneath the monuments and evaluate the velocity of compressional seismic velocities (Vp). The surface method was indeed used to estimate the shear velocities (Vs) characteristic of the first subsoil and the Vs_{30} seismic soil classification for a seismic design (according to Eurocode 8 [19]). The shear seismic wave velocity (Vs) is the most critical parameter for the seismic response analysis [20][19] and it was estimated onsite by the MASW technique [21]. 2D seismic surveys enhanced the lateral variation complexity of the studied subsoil, while Vs surveys showed a progressive improvement of mechanical behaviour of the subsoil in deep, thus highlighting the presence of a shallow thin layer of loose sediment overlying a deep fractured rock. In term of seismic soil characterization, being Vs_{30} = 760 m/s, the site is classifiable as soil B, according to ('Deposits of very dense sand, gravel or very stiff clay, at least several tens of m in thickness, characterized by a gradual increase of mechanical properties with depth') [19]. The passive seismic method allowed evaluating the possible soil resonance frequency behaviour: the results of HVSR [22] analysis were consistent with the previous surveys, indicating a resonance frequency peak of 16 Hz, to be related to a main seismic impedance contrast at 6 m depth. Moreover, the combination of ERT and seismic methods outside the eastern part of the Roman Bath with the GPR measurements provided new information about the fractured system of the soil.

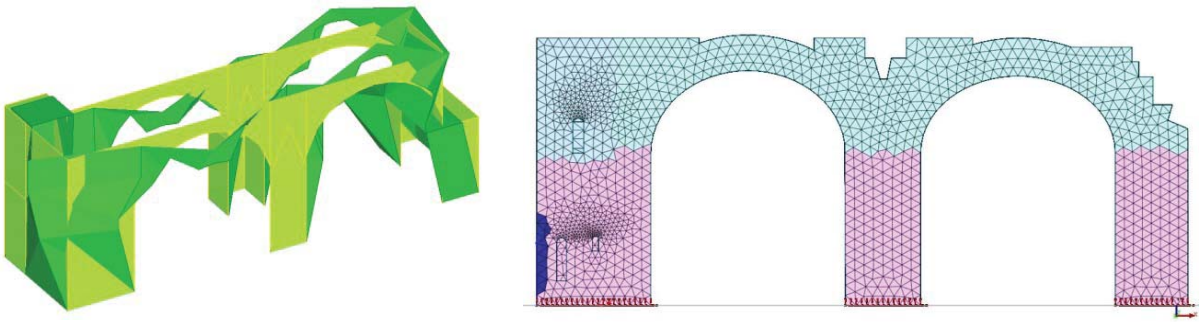
All geophysical methods confirmed the presence of multistep normal faults in the shallow layers around the Roman Bath and the Nymphaeum of Apollo. These information supported the structural analysis with seismic soil classification and geometrical description of the faults system, which is responsible for the structural damage of the buildings still standing in the site.

3.2 Dynamic and structural characterization

Ambient vibration data collected through dynamic identification tests were pre-processed applying a high-pass filter with cut-off frequency of 1 Hz and a decimation of 2 (Nyquist frequency of 25 Hz), with segment length of 1024 points and 66.67% window overlap. System identification was performed using a modal analysis software, implementing a non-parametric frequency domain techniques, i.e., Enhanced Frequency Domain Decomposition (EFDD) [23]. Peaks in the frequency domain related to structural frequencies were selected and the corresponding mode shapes and damping ratios identified.

In the case of the Roman Bath complex, it was rather difficult to excite the structure through ambient vibrations; therefore, an additional external input was necessary. Modal analysis results demonstrated that the structure, despite the high level of damage, is able to show a unitary dynamic response with clear mode shapes (Figure 2). On the contrary, in the case of Apollo's Nymphaeum, it was very difficult to identify a global dynamic response, due to the stiff and rigid walls that composed the building. In this case, the predominant effect of out-of-plane failure of blocks was detected.

All the performed inspections (both visual and instrumental) were used to construct and validate structural models, later used for the seismic assessment.



a) b)

Figure 2: Characterization of dynamic response through modal analysis (a) and creation of FEM model (b) of Roman Bath complex.

3.3 Structural and seismic assessment

The structural and seismic assessment of the investigated structures was performed through a combination of local and global analyses, able to simulate their seismic response. Outcomes of in-situ surveys were implemented to validate the adopted behavioral models.

The assessment procedure was performed according to the Italian [24] and European [19] codes. Target spectrum was calculated according to FEMA-368 guidelines, with PGA of 0.33g, average return period Tr=475 years, damping 5%, magnitude Mmin=6.0 and Mmax=7.0, and minimum and maximum distance from the epicenter of 0 and 25 km respectively.

DEM has proven to be an effective tool to simulate the response of structures composed by large blocks of stone connected through thin mortar layers. Blocks can be considered rigid

and displacements lumped at joint interfaces, while seismic behavior is ruled by rocking phenomena rather than structural resistance. The Nymphaeum of Apollo is an extraordinary example of this type of archaeologic remain, made of huge travertine blocks and average 4 m thick wings. Structural survey was limited to external accessible leaves, but allowed to validate previous data and detect some thickness values of top travertine blocks. On this basis, a statistical analysis on unit dimensions was performed [25].

The DE model was generated in 3DEC environment [26] (Figure 3.a). The structure was discretized by means of rigid block through the automatic generation of joints tool, on the basis of the statistical distribution, assuming that inner infill has a composition similar to external leaves. Linear and nonlinear properties were lumped at the interfaces, characterized according to [27], on the basis of calibration results of a preliminary FE model [28].

Nonlinear dynamic time-histories analyses were performed. Artificial time-histories of 25 s length were generated from the elastic spectrum, according to [19], and final deformed configurations were observed at progressive levels of PGA. Results showed that up to about 0.5g no significant damage occur (Figure 3.b). At about 0.75g, some blocks shift from the original positions, leaving small gaps in the interfaces (Figure 3.c); this is best observable in the intersection of North and East walls. The simulation at extremely high PGA levels (e.g., from 1g to 1.25g) show the partial collapse of the outward portion of North wing and of the end of West one (Figure 3.d, e). This provided a qualitative approximation of possible failure modes. Major response is due to out-of-plane mechanism, as detected by experimental mode shapes.

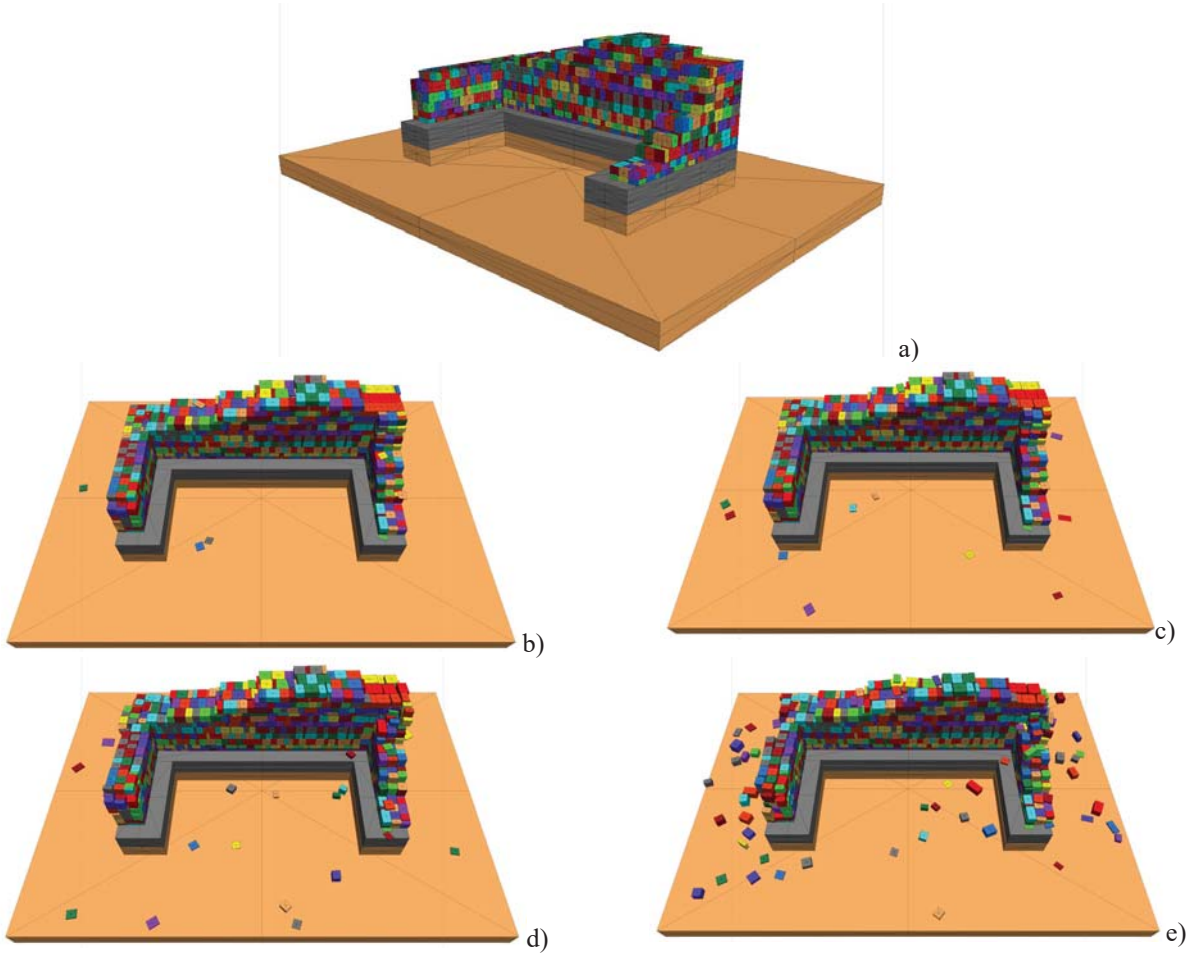


Figure 3: DE model of Nymphaeum of Apollo (a) and final configuration of time-histories analyses for increasing PGAs: 0.50g (b), 0.75g (c), 1.00g (d), 1.25g (e).

4 CONCLUSIONS

The paper presented an integrated methodology for the assessment of archaeological structures in Hierapolis of Phrygia (Tukey). Structural inspections and geophysical prospections on selected structures were used to experimentally define the dynamic response and characterize the soil properties for a reliable simulation of their seismic behavior. On one hand, dynamic tests were able to identify modal parameters and assess the response (thus determining whether or not the buildings show a unitary behavior, despite the high level of damage). On the other hand, indirect information on soil properties and foundations supported the structural analysis with seismic soil classification and geometrical description of the shallow faults system.

Test results were implemented to calibrate and validate numerical models, i.e., a combined modeling approach involving FE and DE methods. DEM was particularly suitable to perform dynamic simulations, as the typical monumental structures in the site are made of large stone blocks with thin mortar layers or massive multi-leaves freestanding walls.

This study could represent a basis to define appropriate procedures to choose practical and reliable solutions for inspections and the correct selection of numerical tools for structural analyses and simulations of incomplete structures in archaeological sites.

Keywords: Glued-Laminated-Timber (Glulam) truss, slotted-in steel plates and dowels connection, experimental and numerical modal analysis, stiffness, damping, induced vibrations in timber structure.

Abstract. *The dynamic response to time varying loads, e.g. wind loads or earthquakes, is in many cases decisive when designing a tall timber building. The structural parameters governing the dynamic behaviour are the mass, the damping and the stiffness. The last two parameters are not well-known at serviceability levels for timber structures in general and for timber connections specifically. Results from forced vibration tests on single components and on a full-scale truss for an eight-storey residential building have been analyzed. In parallel, a detailed Finite Element (FE) model of a large Glulam truss with slotted-in steel plates and dowels connections has been developed and simulations have been made. The damping caused by the structural components, the embedment of fasteners and friction of mating surfaces of components in the selected connection types is quantified experimentally. The materials' stiffness values in the model were evaluated. The results from this study bring knowledge on the structural dynamic properties of large timber structures with mechanical connections and will facilitate the performance prediction of new tall timber buildings for better comfort at higher levels in environmentally friendly expansions of our cities.*

1 INTRODUCTION

Tall timber buildings are becoming more common due to their environmental benefits and low weights. Large engineered wood products such as Glulam members or Cross-Laminated-Timber plates are often used. For instance, the largest column of the 18-storey Mjøstårnet in Norway, is made of glued spruce lumbers and has a cross sectional area equal to 625 x 1485 mm^2. To assemble the structural elements, slotted-in steel plates and dowels are used [1]. This connection technique has traditionally been used in long-span bridges and roof structures. Moreover, the density and the modulus of elasticity of the wood material are well known; they are lower than the corresponding values for steel and concrete. When the height of timber buildings rises in cities around the world, new types of challenges appear for structural designers. One of them is wind-induced vibrations which appears to be annoying for the occupants at lower heights for buildings made of timber than for traditional high-rise buildings [2]. Mass, stiffness and damping matrices (denoted M, K and C) need to be fairly well known to accurately predict responses of structures subjected to time varying excitations. For tall timber buildings, it is relevant to analyze the accuracy of the mass and stiffness matrices used by structural designers in FE-analysis for serviceability load levels. Unfortunately, some dynamical properties of large timber structures are not well known [2]. The damping is the least known dynamical property and recently started research projects aim to close the knowledge gap through ambient vibration tests [3, 4, 5] and forced vibration tests of tall timber buildings [6].

The load distribution in timber structures depends on the stiffness of the structural elements and the stiffness of the connections. Glulam structures are usually modeled as beam elements with well-known stiffness but the load distribution in connections with multiple fasteners is uncertain. The joints are often modelled either with constrains in displacement and rotation, i.e. clamped, or only with constrains in displacement, i.e. pinned [1]. Most connections in Glulam structures consist of many steel dowels and several slotted-in steel plates in parallel. However, most of the experimental and numerical studies have been performed on single dowel connections. Building design codes for timber structures propose simple parameters to evaluate the slip of single connections, e.g. [7] and [8] but better slip models for connections with multiple fasteners and several shear planes are needed [9]. Wood is a complex material to model: high orthotropy, inhomogeneities at different scales and large variability, and this must be considered when predicting the embedment between timber and steel [10]. Phenomenological models for embedment have recently been developed based on the beam on foundation approach [11], with elastic and plastic foundation modulus [12]. Such material models are suitable for beam element models to predict deformations and load capacity. Constitutive models with non-linear material stiffness and embedment stiffness with criteria for yielding and softening [13, 14, 15] have also been developed recently and they are applicable to solid FE-models mainly to predict load capacity but not focusing on the deformations at serviceability levels.

Damping in timber structures has mainly been studied experimentally through cyclic tests, representing seismic load histories, on single components or large structures [16], but not much through vibrational tests to assess the damping at serviceability levels [17]. Standard values of the critical viscous damping ratio are set to 1 % and 1.5 % for timber bridges without respectively with mechanical connections when designed for pedestrian induced vibrations [18].

2 FORCED VIBRATION TESTS ON A LARGE TIMBER TRUSS

2.1 The Glulam truss

A truss made of Glulam members assembled with slotted-in steel plates and dowels connections has been vibrational tested in the factory where it was manufactured, in Töreboda, Sweden. It has 14 Glulam members of quality GL30c according to [19], an overall height of 18.5 m and a width of 4.3 m. It is now part of the lateral stabilizing timber structure of a six-storey residential building and it stands up on a concrete foundation to prevent the building from collapse in case of strong winds. The short elements, diagonals and beams have a rectangular cross-section of 215 x 360 mm. The first column has a rectangular cross-section of 215 x 540 mm. The second column is composed of a similar cross-section glued with 90 x 215 members on each side to form a T-shaped cross-section. Holes, cutting and details for the Glulam members were made with a CNC-machine. The steel plates and the dowels are made of S355JO steel quality. The plates are 8 mm thick and weight between 8 and 37 kg. The dowels are 12 mm in diameter and have a length of 210 mm. Each connection has two steel plates and 8 to 45 dowels hammered in each timber member. In total there are 650 dowels and 28 steel plates in the truss. Heavy steel feet with welded 8 mm plates, weighting 88 and 106 kg, are mounted with dowels at the end of both columns. The overall weight of the Glulam truss including the steel elements is 4280 kg and the densities of the timber members have been measured and the mean density was evaluated to 426.8 kg/m^3.

2.2 The vibration test

When the truss was assembled, forced vibrations tests (FVT) were made at the factory. With overhead cranes, the truss was lifted from the ground with lift straps placed close to the center of gravity of the truss, see figure 1. Excitations were made in different directions on and close to the steel foot of the lower column (bottom end) with a short-sledge impulse hammer. During the tests, fourteen tri-axial piezo electrical accelerometers at the center of each truss connection and twelve single axial accelerometers on the middle of the short Glulam elements were used. The accelerometers, with a sensitivity of 100 mV/g ($\pm$ 10 %), were glued on one side of the Glulam members. The data were recorded with an LMS data acquisition system with 56 input channels that measured 50 accelerations in the X- Y- or Z-directions, see figure 1, and the excitation force from the impulse hammer.

Further information on the Glulam truss properties and details of the vibration test performed are available in paper [20].

3 A NUMERICAL MODEL OF THE LARGE TIMBER TRUSS

3.1 The 3D FE-model with solid elements

The Glulam truss has been modeled, as an FE-model, to numerically evaluate the structural dynamic properties and compare them with the experimental results. The model was developed using the pre- and post-processor MSC Simxpert and analyzed with the FE-solver MSC Nastran. The model consists of 1 726 778 eight-noded solid elements (CHEXA) and 523 961 six-noded solid elements (CPENTA) with a total of 2 715 641 nodes. Different element sizes have been used with densified meshes around details such as the holes for the dowels in the timber members and the steel parts and coarser meshes in areas without complexity, see figure 2. To ensure continuity between solid elements from the same part but with non-congruent meshes, contact constraints paired and permanently glued slaves contact bodies to masters contact bod-

Table 1: The material properties used in the FE-models of the Glulam members.

ies with non-congruent meshes. Permanent glue contacts constrained parts of different material together, i.e. timber member to dowel and dowel to steel plates. The MSC Nastran node-to-segment contact method has been used and it created multi-point constraint equations among the nodes from a slave body which met the surface of a master body. Then, the augmented Lagrange multiplier method was used to embed constraints into the modal analysis.

Steel parts were modeled using an isotropic material model with a Young's modulus of 210 GPa, a Poisson's ratio of 0.3 and a density of 7850 kg/m^3. The Glulam members were modeled using an orthotropic material model with the six stiffness parameters presented in Table 1.

Two spring elements representing the hoisting loops were attached to the ground and to several points of the upper timber column with an interpolation constraint element (RBE3). The RBE3 elements defined the motion at a reference grid point as the weighted average of the motions at a set of other grid points. The axial stiffness of the springs was calibrated to match the natural frequency of the global bouncing mode in the Y-direction from the experimental results.

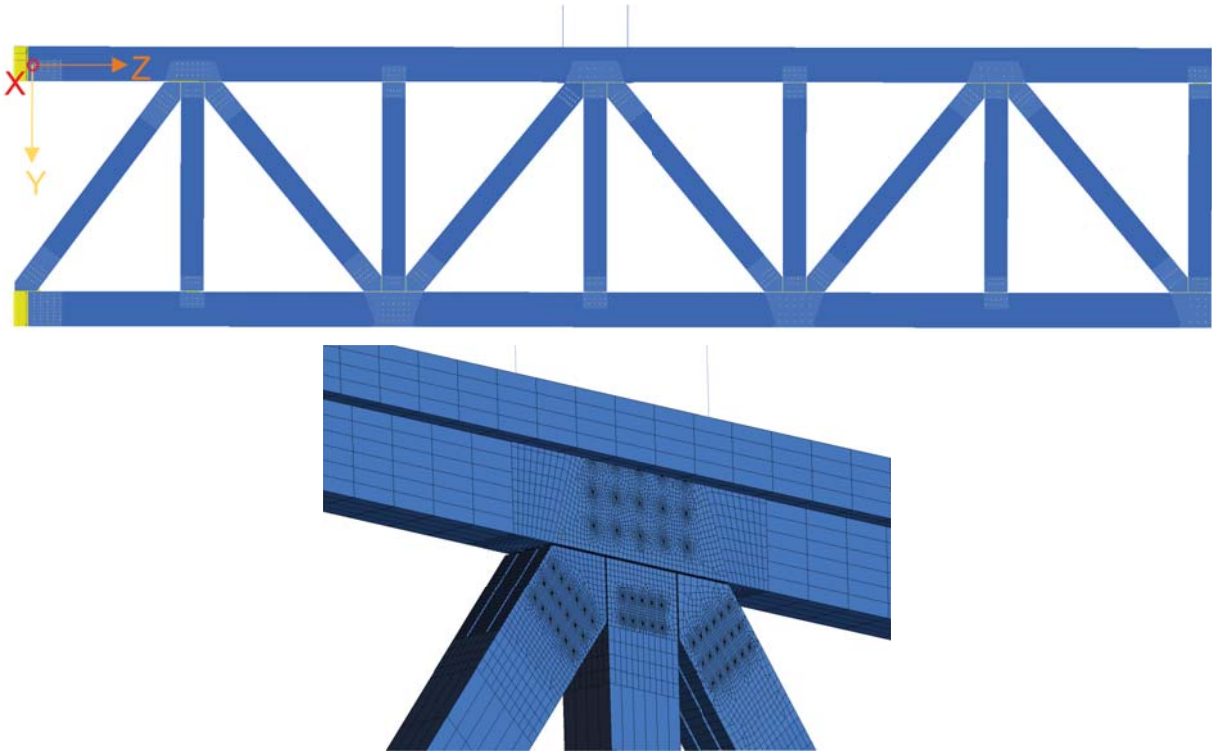

Figure 2: a) the FE-model representing the truss and b) the meshing details of the top-middle connection.

3.2 The numerical analysis

In a structural dynamic system without damping, the vectors of displacement, u, and acceleration, $\ddot{u}$, are related to the mass matrix $[M]$, the stiffness matrix $[K]$ and the excitation force vector, p, according to the equation of motion:

$$[M]\ddot{u} + [K]u = p \tag{1}$$

The eigenfrequencies and eigenmode shapes of the model were extracted using the normal mode analysis in MSC Nastran implementing the block shifted Lanczos eigenvalue extraction method. The numerical mode shapes with very low displacement out of the plane of the truss, which is the structurally operational plane, and with eigenfrequencies between 5 and 130 Hz were investigated.

4 COMPARISON AND DISCUSSION

During the FVT, five eigenmodes corresponding to motion in the plane of the truss and with eigenfrequencies between 5 Hz and 100 Hz were identified and their corresponding mode shapes and damping values were extracted. From the numerical analysis, 23 in-plane eigenmodes were calculated. Modal Assurance Criterion (MAC) values comparing the experimental modes shapes Φ_r^X, stemming from modal testing, to the analytical mode shapes Φ_s^A, stemming from the FE-analysis, are calculated according to equation 2 and are presented in the matrix in figure 3.

$$MAC_{r,s} = \frac{(\Phi_r^{X^T} \Phi_s^A)^2}{\Phi_r^{X^T} \Phi_r^X \Phi_s^{A^T} \Phi_s^A} \tag{2}$$

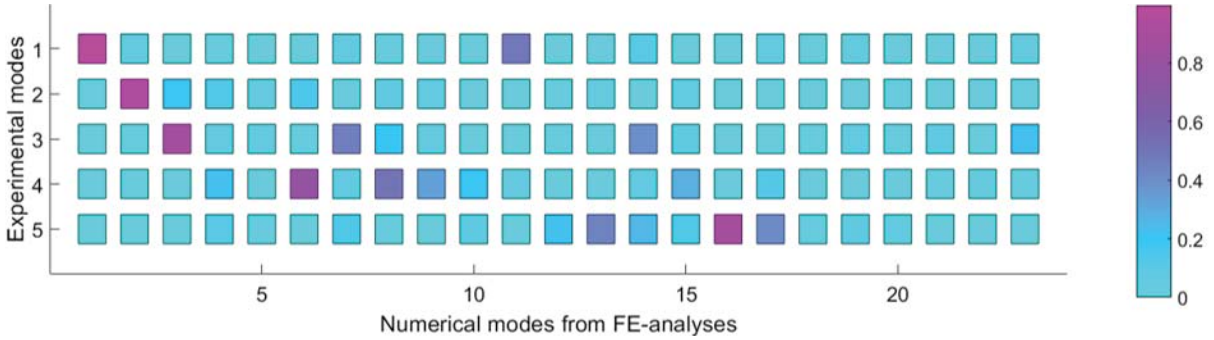

Figure 3: A representation of the MAC matrix comparing experimental mode shapes to numerical mode shapes.

According to the MAC values, five numerical modes (mode 1, 2, 3, 6 and 16) have high consistency with the five experimental modes ; their MAC values are between 0.88 and 0.99. Table 2 presents graphical representations of the mode shapes, the eigenfrequencies, the experimental damping and the MAC values of the paired eigenmodes. The numerical eigenmode 2 corresponds to a local motion of the end of the pillar and matches in both eigenfrequency and shape the paired experimental eigenmode 2. The numerical eigenmodes 3, 6 and 16 are stiffer and have eigenfrequencies 10 % higher than their experimental counterparts. These modes are global bending vibration modes and are of interest when investigating structural timber trusses aimed for stabilization against lateral forces e.g. wind loads. The total mass of the glulam and the stiffness of the single elements are correct at a global scale. At a smaller scale, slightly lower than the diameter of the dowels, timber presents large variability in the density and in the orthotropic stiffnesses [22]. At this lower scale, the embedment stiffness between timber and dowels is sensitive to the local variations of the modulus of elasticity and the shear modulus. Higher frequencies in the numerical models can signify that this embedment stiffness in the FE-model is overestimated. Linear material model for timber with standard elastic modulus stemming from clear wood testing might not be suitable. Bi-linear material models with a yield criterion for timber friction and gaps between timber and dowels should be considered in FE-models made of solid element to predict the dynamic properties of timber structures. The damping ratios (relative to the critical viscous damping) from the test data of the experimental modes 2, 3, 4 and 5 vary between 0.6 % and 1.0 %. They are lower than the damping ratios of timber floors tested in lab [17] and the standard values for timber bridges [18].

Experimental results	Numerical results
	Exp. 1: 8.97 Hz and ζ_1 = 1.7 %	Num. 1: 8.97 Hz (0%) and $\mathrm{MAC}_{1,1} = 0.99$
	Exp. 2: 25.25 Hz and ζ_2 = 0.9 %	Num. 2: 26.9 Hz (+6%) and $\mathrm{MAC}_{2,2} = 0.99$

	Exp. 3: 42.65 Hz and ζ_3 = 1.0 %	Num. 3: 47.5 Hz (+11%) and $\text{MAC}_{3,3} = 0.97$
	Exp. 4: 61.57 Hz and ζ_4 = 0.6 %	Num. 6: 67.7 Hz (+10%) and $\text{MAC}_{4,6} = 0.88$
	Exp. 5: 92.78 Hz and ζ_5 = 0.7 %	Num. 16: 103 Hz (+11%) and $\text{MAC}_{5,16} = 0.9$

Table 2: Experimental and numerical eigenmodes and their MAC values.

5 CONCLUSIONS

There is still limited knowledge on the stiffness and damping of real timber connections for dynamic loads. This study, comparing modal data measured on a real large structure and modal data from a detailed 3D FE-model, shows the suitability of modal analysis methods. Non-linear embedment stiffness between timber and the dowels is likely to be important and further studies on damping properties in timber structures must be performed to better evaluate the dissipation of energy. The FE-model presented in this article will be further developed and reduced in coming investigations.

6 ACKNOWLEDGEMENT

We would like to express our thanks to Moelven Töreboda AB for the opportunity and the help to measure in their factory while manufacturing had to run with a tight schedule for the building project. The authors gratefully acknowledge the funding for the project “Tall Timber Buildings – concept studies” from Formas the Swedish Research Council for Environment, Agricultural Science and Spatial Planning [Dnr: 942-2015-115].

Keywords: Conservation engineering, Shear walls, Retrofit, Composite materials

Abstract. *The use of new composite materials for reinforcement of heritage masonry structures, especially in seismic prone areas, is of interest structural engineers and conservators. However, the need to increase the structural performance of masonry structures is often in contrast with the principles of conservation in terms of reversibility, limited visual impact, compatibility of new materials with masonry. With the aim at striking a balance between structural safety and heritage protection, this paper investigates strengthening stone and brickwork masonry walls using glass-fiber reinforced polymer (GFRP) meshes embedded into a coating of lime or cement mortar. An experimental research program was undertaken in the laboratory on large-scale wall panels. Both clay brick and stone work specimens were tested, with and without strengthening. Single-sided and double-sided strengthenings were considered, as it is often not practicable to apply the reinforcement to both sides of a wall. Static tests were carried out on twelve masonry panels, under in-plane diagonal shear loading. The mechanisms by which load was carried were observed, varying from the initial, uncracked state, to the final, fully cracked state. The results demonstrate that a significant increase of the in-plane shear capacity of masonry can be achieved by using the proposed retrofitting technique. The experimental data were used to assess the effectiveness of the strengthening, and a finite element (FE) numerical model is discussed and calibrated against experimental results. The FE model was used to investigate further aspects of the reinforced masonry under shear-loading.*

1 INTRODUCTION

The performance of historic and heritage masonry buildings during previous earthquakes in Italy and other parts of Europe has demonstrated that many structural failures could be attributed to inadequate shear capacity of their wall panels [1, 2, 3]. This was particularly serious not only for very old ashlar stone masonry buildings, but also for those buildings, often more recently built, made of brickwork masonry [4]. The use of very weak lime mortar in construction and inadequate construction methods, not fulfilling the so-called "rules of the art" as defined in historic manuals and recent studies constitute the primary reasons for poor performance.

While it is not socially and economically acceptable to demolish these unsafe buildings, it is possible to retrofit them. A large portion of its programmed economic stimulus in Italy is associated with upgrading the building stock through, for instance schemes for improvement of structural safety of old masonry buildings against the seismic loading (Fig. 1). The anticipated cost benefit of lightweight composite reinforcements that can be easily transported and applied without interfering with the use of the buildings, against the conventional steel/concrete, are presented in Table 1. This table also reports the grade of reversibility and compatibility for different traditional and innovative retrofitting methods for shear walls [5, 6].

Reinforcement method	Brickwork masonry	Stone work masonry	Grade of structural efficiency	Reversibility of intervention	Compatibility with masonry
Lime grout injections	Unsuitable	Suitable/ Unsuitable*	High	Low	Good
Deep repointing of mortar joints with lime new mortar	Suitable/ Unsuitable*	Suitable/ Unsuitable*	Low to Medium	High	Very Good
Epoxy-bonded FRP jacketing	Suitable	Suitable	High	Low	Very Low
Reinforced Concrete Jacketing	Suitable	Suitable	Very High	Low	Very Low
FRCM Jacketing	Suitable	Suitable	Medium to High	High	Good

* highly depends on the masonry type, dimensions the mortar joints, if there are internal voids in the shear walls

Table 1: Reinforcement of shear walls: commercially available methods.

During the past two decades applications of Fiber Reinforced Polymer (FRP) products have increased significantly, most notably for seismic retrofitting. Among many beneficial characteristics of FRP materials are light weight, ease of installation, high tensile strength, and immunity to corrosion [7, 8, 9].

With regard to shear walls, it is well known that FRP jackets can provide additional shear capacity, confinement and clamping force within wall leaves, enhancing wall performance especially when stressed by the action of an earthquake. However, serious limitations remain for the use of epoxy adhesives. These resins are typically employed to fix the composite reinforcements to masonry. Their long term behavior, as well their "compatibility" with masonry materials and the limited "reversibility" of these interventions are object of debate in the scientific community [10]. Conservation bodies often do not authorize the use of epoxy-bonded

FRPs on listed masonry buildings and different retrofitting solutions have been recently proposed.

Figure 1: Examples of different methods to retrofit shear walls: a. Epoxy-bonded Carbon FRP, b. Steel mesh reinforced concrete jacketing, c. Grout Injection in the internal core of multi-leaf stone walls.

The most important Italian Conservation Body (*Soprintendenza Archeologia, Belle Arti e Paesaggio*) supervises around 9.66 M heritage items (archeological sites, heritage buildings and museum assets) with a density of about 33.3 items/100 km^2. In Italy, the density of this enormous quantity of assets is much higher in seismic prone areas (Tuscany, Campania, Marche and Umbria have a density of 40, 41, 49 and 53 items/100 km^2, respectively). In this situation, to overcome the limitations of the use of epoxy-bonded reinforcement, the use of inorganic, i.e. lime or cement based, coatings reinforced with composites meshes has been proposed. The final result is a Fiber Reinforced Cementitious Mortar (FRCM) [11, 12, 13]: this can be easily used to create a jacket, to apply to one or both surfaces of the shear walls. Low fire resistance of FRPs is an issue that can be resolved by using FRCMs: composite materials are embedded in the mortar jacketing and this can also protect the reinforcement.

To verify the effectiveness of FRCM reinforcement with respect to real-scale laterally loaded wall panels, to study the structural behaviour of FRCM reinforced members and to investigate some specific aspects of the modelling of shear walls, shear tests on large-scale panels reinforced with FRCM have been performed. The variables considered in this test program included masonry type, single-side and double-side reinforcement, and method of application of the reinforcement (preventive method, i.e. reinforcement applied to un-cracked walls, or repair method, i.e. reinforcement used to repair damaged or cracked shear walls). Combined experimental and analytical research is underway at the Structures Laboratory of the University of Perugia to investigate the effectiveness of FRCM jackets on the seismic performance of shear walls. Some preliminary results on shear walls tested under simulated seismic loading are presented in the paper. Analytical research, leading to a seismic design approach is also presented. Design performance levels are compared with experimentally obtained drift capacities, verifying the applicability of the design procedure.

2 EXPERIMENTAL VALIDATION

2.1 Wall geometry and test method

The specimens in this study are twelve full-scale shear walls, made of solid bricks or ashlar stone blocks. The walls are 1200 x 1200 mm. The nominal thickness of the brick and stone walls was 240 mm. Thus, all the test specimens had been constructed at once by an expert mason at the Structures Laboratory (Lastru) of the University of Perugia, located in Terni, Italy.

a. b.

Figure 2:Realization of full-scale shear walls: a. Solid bricks test specimens, b. shear test setup.

Figure 2 shows the test setup: the shear wall panel is subjected to a diagonal, compressive, in-plane loading and fails by a diagonal shear crack, typically originating from the panel's centroid where the stresses are maximum. A highly strained region is assumed to form in the panel's centre at the crack location.

Hence for a linear elastic membrane under in-plane loading, the plane-stress components σ_{xx}, σ_{xy} and σ_{yy} at the panel's centroid are given by:

$$\sigma_{xx} = \sigma_{yy} = -0.56\frac{F}{A_n}$$
$$\sigma_{xy} = \sigma_{yx} = 1.05\frac{F}{A_n}$$

where F is the diagonal force and A_n is the wall horizontal cross section.

The principal stresses σ_I and σ_{II} are:

$$\sigma_I = 0.50\frac{F}{A_n}$$
$$\sigma_{II} = -1.62\frac{F}{A_n} \quad (2)$$

According to the interpretation provided by the RILEM guidelines (Fig. 3), at failure ($F=F_{max}$), σ_I is equal to the masonry tensile strength f_t:

$$f_t = \sigma_I = 0.50 \frac{F_{max}}{A_n} \tag{3}$$

The masonry shear strength, τ_0, at failure, is then given by:

$$\tau_0 = \frac{f_t}{1.5} \tag{4}$$

The two sides of each wall panel have been labelled with letters A and B. Contact instrumentation (LVDT: Linear Variable Differential Transformers) was used to measure the deformation of the panels along the unloaded (in tension) and loaded (in compression) wall's diagonals. The change in length of the wall's diagonal in compression (Δl_{CSA} and Δl_{CSB} for side A and B of the wall panel, respectively) and in tension (Δl_{TSA} and Δl_{TSB}), are giving the compressive and tension strains as:

$$\begin{aligned} \varepsilon_{CSA} &= \frac{\Delta l_{CSA}}{l_{CSA}} \qquad & \varepsilon_{TSA} &= \frac{\Delta l_{TSA}}{l_{TSA}} \\ \varepsilon_{CSB} &= \frac{\Delta l_{CSB}}{l_{CSB}} \qquad & \varepsilon_{TSA} &= \frac{\Delta l_{TSA}}{l_{TSA}} \end{aligned} \tag{5}$$

where l_{CSA} and l_{CSB} are the gage lengths of the LVDTs applied along the compressed diagonals on side A and B, respectively. Similarly, l_{TSA} and l_{TSB} are the gage lengths for the stretched wall diagonals. Hence, the compressive and tensile axial strains, ε_c and ε_t, and the shear strain, γ, are given by

$$\varepsilon_C = \frac{\varepsilon_{CSA} + \varepsilon_{CSB}}{2} \tag{6}$$

$$\varepsilon_T = \frac{\varepsilon_{TSA} + \varepsilon_{TSB}}{2}$$

$$\gamma = \left|\varepsilon_C\right| + \varepsilon_T \tag{7}$$

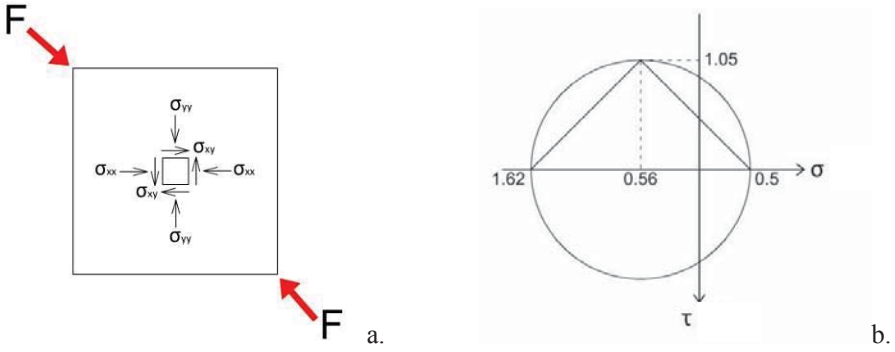

Figure 3: : a. Components of plane stress at panel centroid,
b. Graphical interpretation: Mohr's circle (tangential stress (τ), normal stress (σ)) (units in MPa).

A value of the shear stiffness modulus (G), representative of the cracked condition of the masonry, was calculated starting from the tangential stress (τ) versus angular strain (γ) curve. This was obtained by taking into account the envelope curve of the loading and unloading cycles and by constructing a bilinear curve, with a subtended equivalent-area to the tangential

stress (τ) versus angular strain (γ) curve. The equivalent bilinear curve is made of a horizontal and an inclined lines. The bilinear was calculated using the following procedure:
- The horizontal line of the bilinear was determined starting from the ultimate tension (τ_u) of the load test and ends at the ultimate angular strain (γ_u)
- By imposing energy equality, i.e. the equality between the area (A) underlying the diagram of the envelope curve and that of the bilinear equivalent, the value of the average angular deformation of the panel at the end of the inclined section of the bilinear (γ_y)

$$\gamma_y = 2\left(\gamma_u - \frac{A}{\tau_u}\right) \tag{8}$$

- The slope of the inclined line was thus obtained represents the value of the modulus of shear stiffness G (Fig. 4)

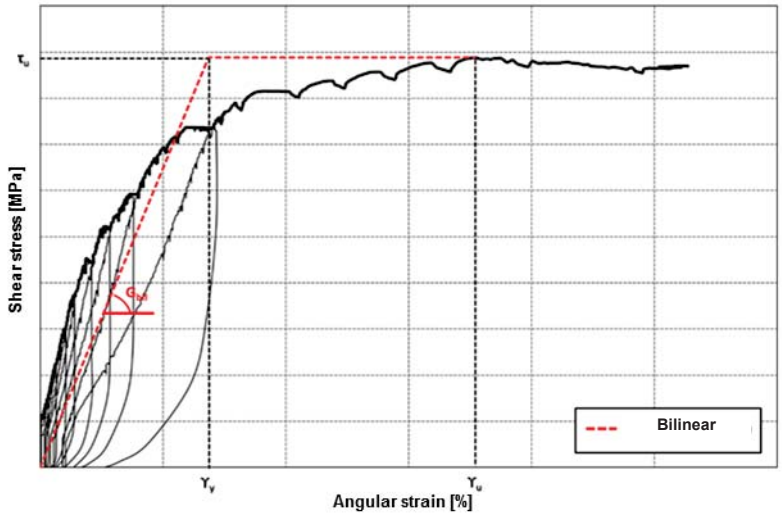

Figure 4: Determination of the shear modulus (G).

	Type of Masonry	Single- or Double side Reinforcement	Mesh Type	Coating Material

PIE-05-S		Single	2	Basic M15

Table 2: Reinforcement of shear walls: test matrix.

Table 2 shows the test matrix: it can be noted that a total of twelve full-scale wall panels were tested: seven walls were made of solid bricks (MAT-series), while the remaining five (PIE-series) was constituted by ashlar (rubble) calcareous stones. The letter designations U, D and S were used to identify unreinforced, double-sided and single-sided strengthenings, respectively.

2.2 Materials and retrofitting method

A composite grid, made of fiberglass (GFRP), was applied, using an inorganic mortar, to the prepared surface of the wall panels. To connect the two coatings on the wall surfaces, composite connectors were also inserted into holes cut horizontally and transversally into the walls. The composite grids were fully embedded in the mortar coating and were secured in place by fixing them to the composite connectors. The same structural mortar used in the grid application was also employed to fill the holes.

Reinforcement application is not difficult and it can be carried on both uncracked and damaged shear walls. Furthermore, it is worth noting that the proposed retrofitting method can be used as a rapidly deployable emergency repair technique or a long-term and permanent strengthening procedure suitable for seismic protection of heritage buildings. Different methods of applying FRCM composite strengthening systems to the walls were investigated.

		Type 1	Type 2
Mesh	Material	Fiberglass, AR	Fiberglass, AR
	Weight density (dry fiber) (g/m^2)	235	465
	Weight density (pre-preg) (g/m^2)	335	581
	Mesh size (mm)	50 x 50	35 x 30
	Mesh unit uensile strength (kN/m)	63	110
Single Cord	Young's modulus (GPa)	72	72
	Elongation at Failure (%)	3.5	1.5
	Tensile strength (MPa)	1200	1200

AR = Alkali Resistant

Table 3: Two types of fiberglass mesh used for reinforcement: physical and mechanical properties.

Two types of composite grids have been used for shear reinforcement. The main mechanical properties of the GFRP meshes are listed in Table 3. These values are given in the produced data sheet (Kimia ltd., Perugia, Italy). The superficial weight density, and mesh size of Type 1 are 335 g/m^2 (for impregnated, pre-preg, fibres) and 50 x 50 mm, respectively, while higher values characterized the Type 2. A detail of the GFRP meshes are shown in Figures 5 and 6.

Two types of mortars (*Basic M15* and *Betonfix RCA*) were used for the coating (Tab. 2): Both are ready-to-use mortars, having a special fibre-reinforced composition. *Basic M15* is a lime (hydraulic) mortar and the producer (Kimia ltd.) reports in the data sheet a compressive strength > 15 MPa. On opposite *Betonfix RCA* is a cement mortar with a compressive strength > 25 MPa.

Figure 7 and Table 4 show the masonry units (brick and typical stone) and the main mechanical properties.

	Bending strength (MPa)	3.61
Bedding mortar	Compressive strength (MPa)	2.69
	Bending strength (MPa)	0.76

Table 4: Bricks and mortar properties.

2.3 Test results and analysis

Table 5 shows the results in terms of the maximum load F_{max}, masonry tensile strength f_t and shear modulus. A multi-letter designation MAT has been used for brickwork panels, while this was PIE for stone work specimens. A further letter (U = unreinforced, S = single-sided reinforcement, D = double-sided reinforcement) has been adopted to specify the type of reinforcement. All GFRP-reinforcements have been applied to undamaged, sound, wall panels. Ten wall panels were reinforced (6 single-sided reinforcements, and 4 double-sided) with the GFRP grid, applied using a low-cement mortar. Panel 1 in both brickwork (MAT) and stone (PIE) series was the control panel and unreinforced.

	Wall Thickness (mm)	Single- or Double-side Reinforce-ment	F_{max} (kN)	f_t (MPa)	G (MPa)
MAT-01-U	240	-	67.03	0.077	1080
MAT-02-D	291	Double	205.0	0.236	1490
MAT-03-S	260	Single	100.3	0.117	1052
MAT-04-D	297	Double	199.8	0.233	2512
MAT-05-S	270	Single	113.4	0.133	2703
MAT-06-S	267	Single	120.9	0.141	1624
MAT-07-S	265	Single	120.9	0.138	1834
PIE-01-U	245	-	73.80	0.084	2092
PIE-02-D	303	Double	182.3	0.206	2034
PIE-03-S	285	Single	136.1	0.155	954
PIE-04-D	307	Double	209.6	0.242	876
PIE-05-S	293	Single	138.2	0.160	1902

Table 5: Results of shear tests.

For the brickwork panels, the test results show that the increase in the shear load capacity (F_{max}) is nearly three times, for double-sided reinforcement, that of the load capacity without the GFRP composite. However, for single-sided reinforcement, this increment reduced to about 70%, ranging from 49.5 % (MAT-02-D) to 80.5 % (MAT-06-S). The brickwork specimens showed the largest increase in shear capacity. The shear modulus variations were smaller in percentage and more scattered: for single-sided reinforcement, the stiffness of the wall panels increased in a range between -3.6 % and 150%.

Results from the shear tests on stone work panels are also shown in Table 5; they indicate that the average shear capacity of both single- and double-sided reinforced panels was 84 % and 164% stronger than the unreinforced wall panel.

For both brickwork and stone unreinforced panels, the shear load – angular strain curves show a quasi-elastic behaviour with a weak yield plateau: this was mainly caused by the development of a diagonal cracks along the compressed diagonal. The two unreinforced panels (denoted MAT-01-U and PIE-01-U) presented a brittle, zig-zag shaped failure along the compressed diagonal. Cracking appeared suddenly in the mortar joints and, more rarely, in the bricks, producing the instant failure of the masonry walls.

For the reinforced wall panels, shear load – angular strain curves underline two stages of the global behaviour: a first elastic and a second plastic (Figs. 8 and 9). The elastic phase of

the curves of the reinforced panels are characterized by the steeper slope as those of the unreinforced, regardless to the type of the composite reinforcement (Type 1 or Type 2). The load corresponding to the elastic limit and the ultimate load are much higher than that of unreinforced control panels. The gain in strength is quite significant. Thus, a first consequence of the reinforcement is the increase of the shear capacity of the walls. Moreover, it can be also noted an important increase of the post-elastic deformation capability of the reinforced walls, emphasized by the presence of a relevant post-elastic plateau. Because tests were conducted in load stroke-control (and not displacement-control) this is a pseudo-ductility and reader should be alerted about the limitations of the post-peak test data. Figure 10 shows the typical failure modes on both unreinforced and reinforced wall panels.

3 NUMERICAL SIMULATION

3.1 FE model

The experimental data were implemented numerically, via non-linear constitutive laws, in a commercial FE modelling code. Accounting for the brickwork masonry nonlinear behavior [14, 15, 16], 3D finite element (FE) models were thus adopted. To this end, after defining their geometry with CAD drawings, the panels were discretized by means of iso-parametric solid elements (Solid 65), having 8 nodes with 3 Degrees of Freedom (DOF) at each node. To facilitate the analysis, the periodically repeating patterns of the brick masonry typology was modelled by dividing each periodic unit cell into ten cuboid subcells (ten brick units, three head and one bed joints) characterized by different material properties (Figure 11).

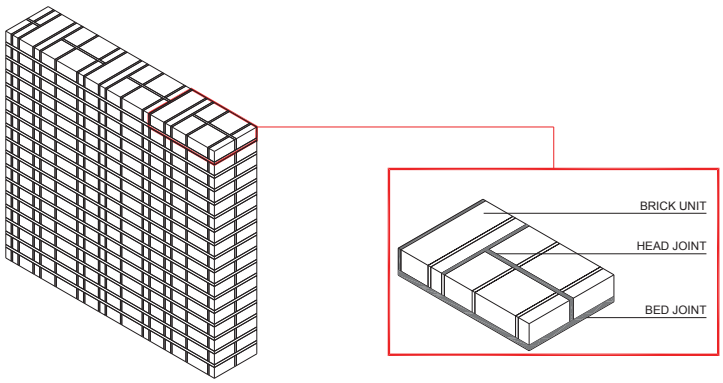

Figure 11: Derivation of periodic unit cell.

Since all units were identically oriented and the masonry layout did not change through the thickness, for convergence checking, each periodic unit cell was then modelled with a sufficient number of elements through the height of each sub-cell. After performing a sensitivity analysis varying the mesh size, the mesh of all FE models was thus refined so as to have three elements (18.33 × 20 × 20 mm) across each brick unit, two elements (18.33 × 20 × 3.33 mm) across each bed joint and a single element (7 × 20 × 20 mm) across each head joint (it is important to remark that in this two latter cases the size of the mesh was dictated by the thickness of the mortar joints).

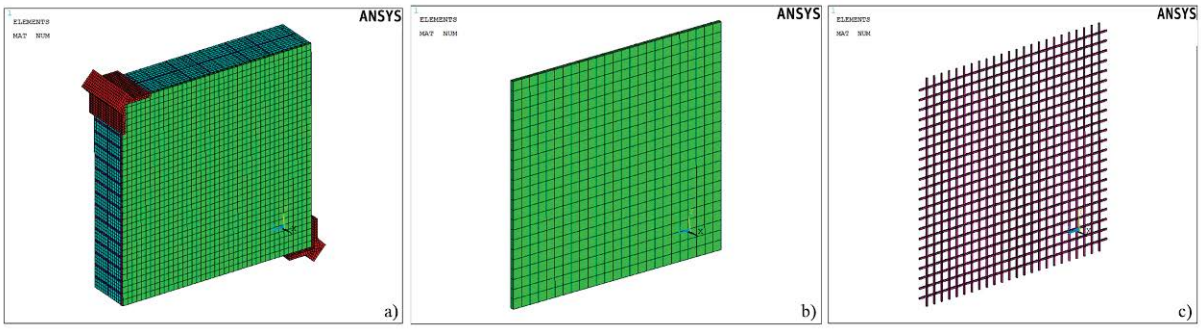

Figure 12: FE model with mesh discretization: a. Reinforced model; b. Mortar coating; c. GFRP mesh.

As for reinforcement, a shared node approach was instead used for simulating the GFRP meshes embedded into the mortar coating. Accordingly, the connection between the mortar matrix and the reinforcement was achieved treating the glass meshes (modelled by means of 2-noded uniaxial tension-compression Link 180 elements) as a slave material, which is merged to the surrounding master material.

This allows to capture the more critical details avoiding distorted meshes as well as shear lock effects. Figure 12 shows the full FE model, which is characterized by 85,642 elements and 90,356 nodes, with 271,068 DOF.

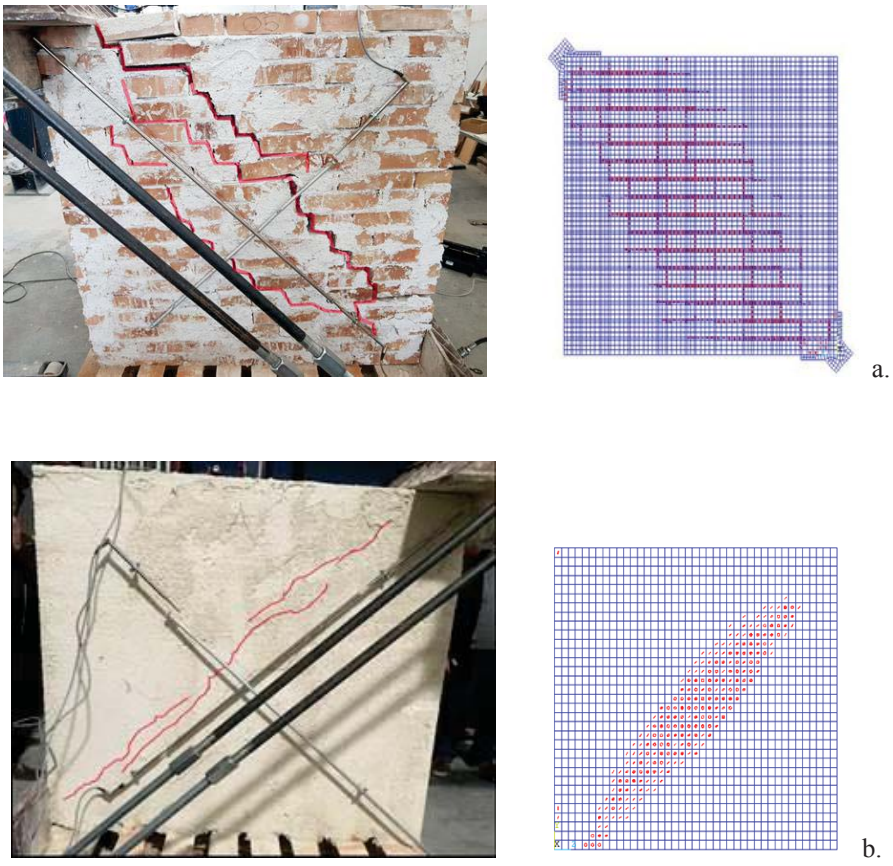

Figure 13. Experimental vs FE model crack pattern: a. Unreinforced face; b. Reinforced face.

To model the behavior of brickwork masonry, a 3d nonlinear analysis was implemented through the use of a damage mechanic approach. Based on this, a tensile cut-off failure criterion was adopted for each masonry component (brick units, bead and head joints). The aforementioned elastic-plastic model, generally used for brittle materials such as concrete, can account for either crushing or cracking failure modes using a smeared model. More specifically, the cracking pattern observed during the damaging process of both bricks and mortar joints was simulated by means of only 2 material parameters (assigned according to the material properties obtained through the experimental tests): compressive (f_c) and tensile (f_t) strength. Moreover, to increase the reliability of the proposed analysis, the simulation of the contacts between the panel and loading plates was performed using unilateral contact interfaces. Accordingly, surface-to-surface contact elements were adopted, determining the contacting properties for the tangent and normal behavior through the use of a trial-and-error procedure. In detail, a Coulomb friction law was used assuming that at each interface sliding may (or may not) occur by introducing a coefficient of friction ($\mu = 0.3$).

3.2 FEA results

According to the aim of simulating the in-plane response of the specimens and therefore providing an interpretation of the detected damage pattern, FE analyses were developed, in which each model was firstly subjected to self-weight, followed by a ramped 9000 N shear load. Figure 13 reports the cracking pattern observed during the FE analysis on the panels. In agreement with the damage observed at the end of the experimental tests, cracking is not present on the whole panel, but mainly on its bed and head joints. More specifically, following predominant horizontal cracking initiated at the specimen mid-height, when the interface bond strength was attained, stepped diagonal cracks spread (through horizontal and vertical joints) along the compressed diagonal.

As shown in Table 6, in order to evaluate the efficiency and accuracy of the proposed FEM, the estimates of the ultimate shear capacity were then compared with laboratory outcomes. Even in this case, it can be emphasized how FE models satisfactorily reproduce the observed ultimate capacities, since in all cases the maximum deviations between predicted and measured response (i.e., error of the model) were found to be no more than 14%.

	Predicted in-plane capacity (kN)	Experimental in-plane capacity (kN)	Error of the model (-)
MAT-01-U	67.5	67.03	1.01
MAT-02-D	176.25	205.0	0.86
MAT-03-S	112.5	100.3	1.12
MAT-04-D	172.5	199.8	0.86
MAT-05-S	112.5	113.4	0.99
MAT-06-S	135	120.9	1.12
MAT-07-S	135	120.9	1.12

Table 6. Experimental vs predicted shear load capacities.

4 CONCLUSIONS

This research has investigated the shear behavior of stone and brickwork masonry walls, strengthened using GFRP meshes embedded into a mortar coating. Full-scale shear tests and numerical simulations were performed to determine the strength capacity of wall panels reinforced with the proposed retrofitting method.

The following conclusions can be drawn:

- brickwork panels, test results show that the increase in the shear load capacity, for double-sided reinforcement, is nearly three times higher than the shear capacity of unreinforced wall panels. For single-sided reinforcement, this increment reduced to about 70 %, ranging from 49.5 % to 80.5 %. The brickwork specimens showed the largest increase in shear capacity. The shear modulus variations were smaller in percentage and more scattered: for single-sided reinforcement, the stiffness of the wall panels increased in a range between -3.6 % and 150 %.

- Stone work panels, they indicate that the average shear capacity of both single- and double-sided reinforced panels was 84 % and 164 % stronger than the unreinforced wall panel.

- For both brickwork and stone unreinforced panels, the shear load – angular strain curves showed a quasi-elastic behaviour with a weak yield plateau: this was mainly caused by the development of a diagonal shear crack along the compressed diagonal. For the reinforced panels, shear load – angular strain curves underline two stages of the global behaviour: a first elastic and a second plastic.

- Although the number of tested panels was limited and not exhaustive, we can remark that the reinforcement caused a significant increase of the ultimate strength of the panels; the typical failure mode was due to masonry crushing.

- Furthermore, this initial attempt to model the GFRP-reinforced wall panels, while not complete, demonstrates that structural modeling is possible given accurate information on material property evolution and structural response of both unreinforced and reinforced panels. In addition, we require a better understanding of boundary conditions at interface coating-to-masonry. As we continue this part of the program we wish to develop further examples and isolate those details that are critical to making accurate predictions. The experimental data were implemented numerically using a non-linear constitutive law and adopting a 3D finite element model. The results of the numerical analysis are in agreement with the observations of the experimental tests: unit (stone or bricks) cracking was not noted, but failure mainly occurred at the bed and head joints. Moreover, the numerical ultimate shear capacity was then compared with laboratory results in order to evaluate the efficiency and accuracy of the proposed FEM. Considering that the maximum error of the numerical simulation was 14 %, it can be highlighted that FE model satisfactorily reproduced the observed experimental ultimate capacities.

Keywords: masonry structures, seismic motion, jerk, impulsive forces

Abstract. *Recent studies [1-9] highlighted aspects of the seismic motion and the structural response which are usually ignored or not properly considered: the chaotic and spatial nature of the seismic motion, the importance of the vertical seismic component and its effect on the vulnerability of the structures. Considering seismic acceleration as a vector in space, the path outlined by the vector at each instant is the 3D representation of the accelerograms. The study of spatial accelerograms reveals interesting new aspects related to the variation of acceleration and the impulsive nature of the seismic motion. The seismic jerk (first derivative of acceleration and third derivative of displacement) is the fundamental component of the impulsive actions associated to high frequency content of the seismic motion. During the seismic event, the continuous variation of acceleration, in terms of modulus and direction, causes impulses (hammering, shaking, disconnection, etc.). In masonry structures they lead to local failures of the connections, disaggregation and damage accumulation with loss of ductility. Monitoring the seismic jerk in three directions may provide more significant information on the damage rather than monitoring the interstory drift. A design process is finally outlined: the study of the seismic motion impulsive content leads to solutions for structural retrofit aimed at strengthening masonry elements and improvement of connections.*

1 SEISMIC MOTION: ACCELERATION

The classic representation of a seismic event is a set of acceleration time series (also known as accelerograms) where ground acceleration is sampled in three mutually orthogonal directions.

By combining the three components of ground acceleration, one may plot a 3D path where each point is defined by the three components of the acceleration vector applied in the origin of the system. In this chart acceleration is not plotted against time but time is involved in indirect manner since each point corresponds to a different instant.

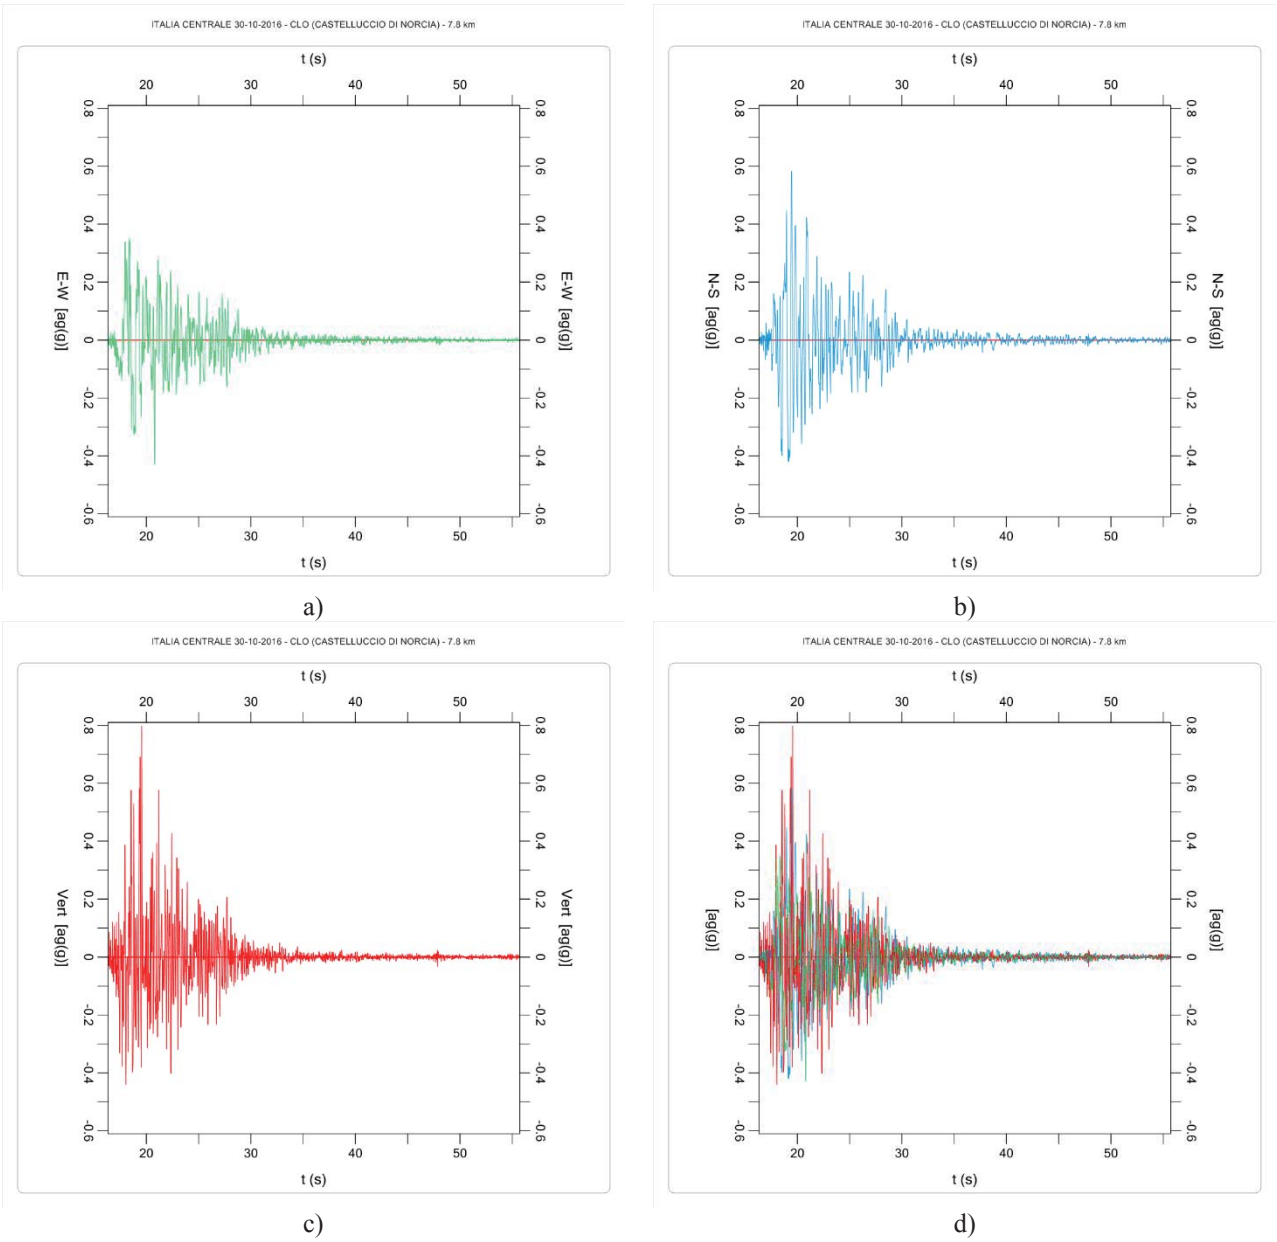

Figure 1. Traditional representation of accelerogram as time series: each component of ground acceleration is plotted against time. (a) EW component; (b) NS component; (c) Vertical component and (d) the three components overlaid in the same chart.

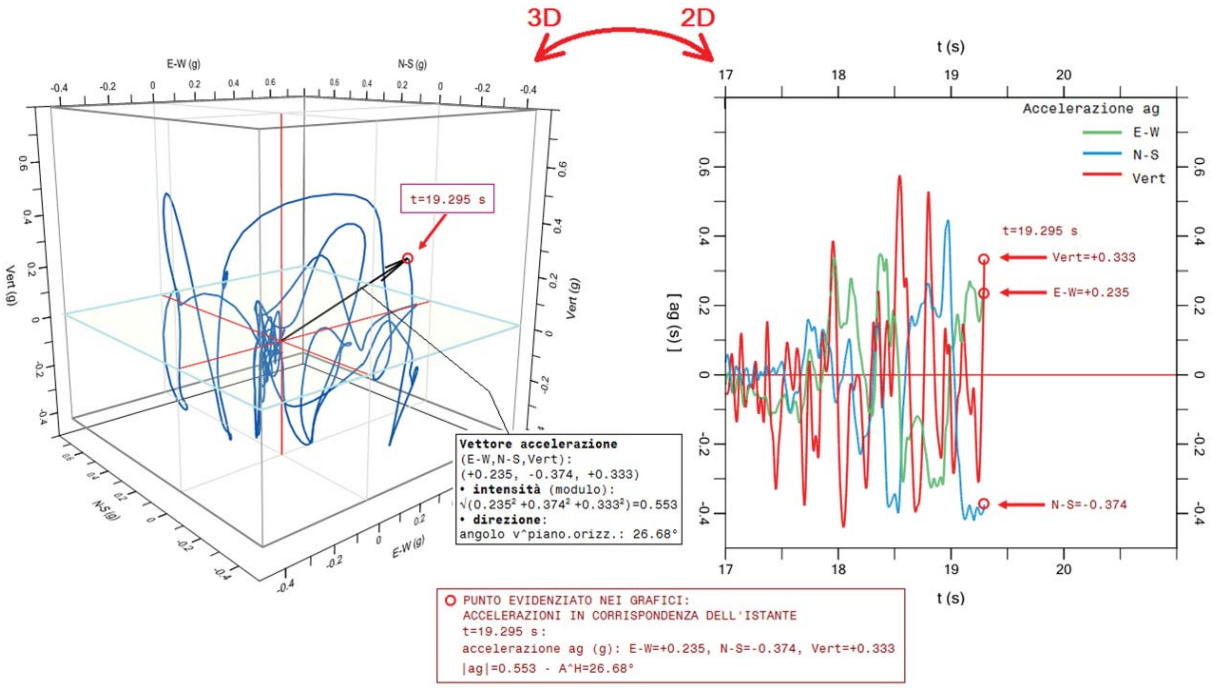
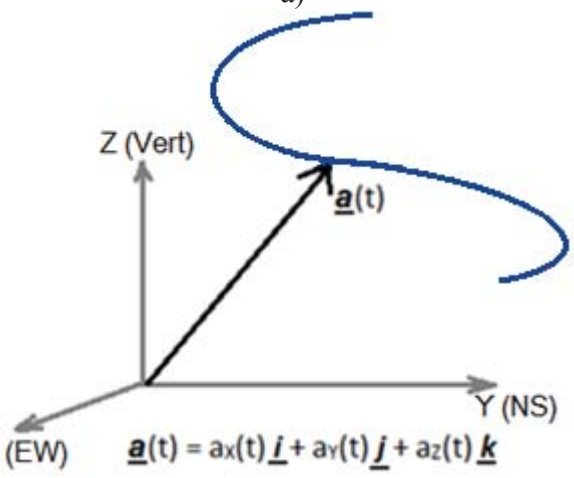
The 3D chart represents the seismic ground motion in a unified way: it highlights the simultaneity of the three components of ground acceleration and allows for direct comparison between them.

The graphic elaboration was carried out by means of the original software Seismic3D [10] specially developed for the purpose. Starting from the seismic event records, the software performs several elaborations aimed at studying the seismic ground motion.



a)



b)

Figure 2. (a) Evolution of the accelerogram from time series to 3D path (from plane to space) (b) Acceleration path outlined at any time by the acceleration vector

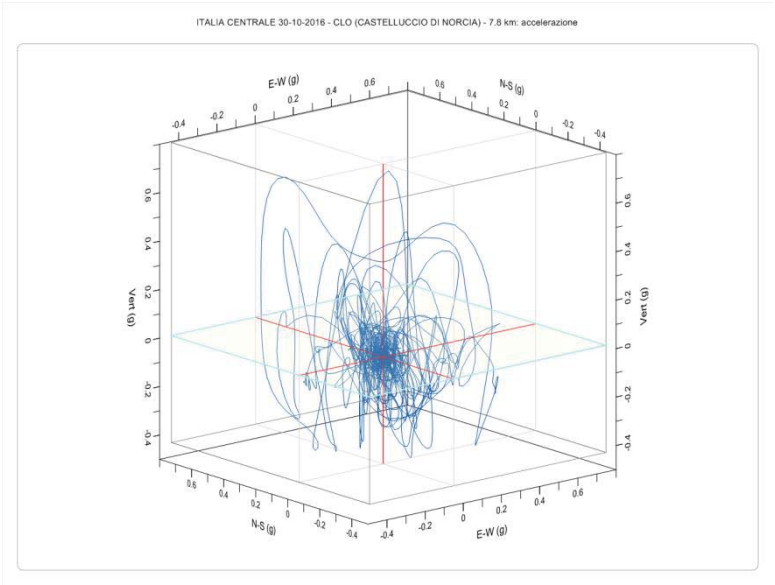
The 3D curve has the shape of a tangle: the more similar are the three components of acceleration the more compact and spherical is the tangle. In the following, the term “tangle” refers to the acceleration path when 2 or 3 components are considered.

Figures 1-2 show the evolution of the accelerogram from three separated time series in the plane (t, ag) to one 3D path in the space (a_gEW, a_gNS, a_gVert). The elaboration is based on

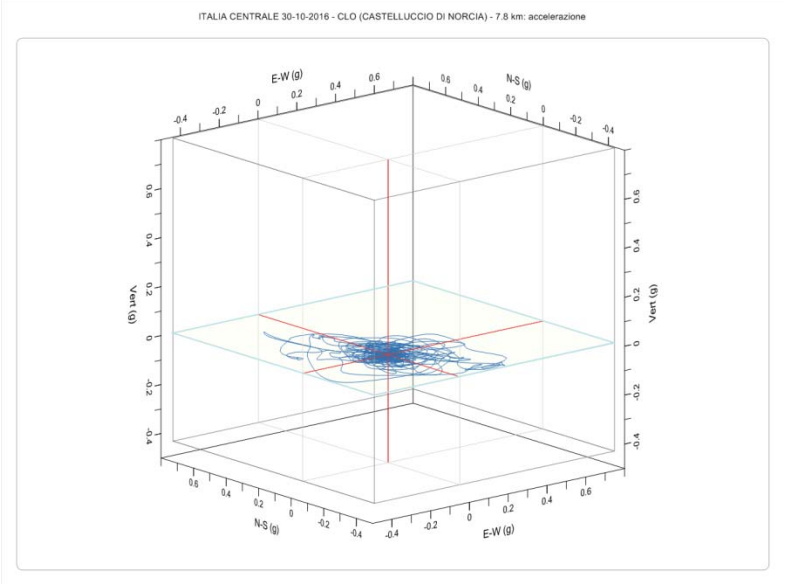
ground acceleration records at station CLO (Castelluccio di Norcia) from 30 October 2016 Norcia earthquake in Central Italy (mainshock).

The accelerograms in Figure 1 represent acceleration in a bracket duration: time span between the first and last peak exceeding 0.010 g.

At each instant, the acceleration vector is characterized by magnitude and direction. Magnitude (or modulus) is given by the square root of the sum of the squares of the three components. By ignoring one of the components, the 3D path is reduced to its projection on the plane of the other two components. For instance, by ignoring the vertical component we get a 2D path in the horizontal plane (a_gEW, a_gNS). Comparison between the 3D path and its projection on the horizontal plane highlights the contribution of the vertical component to total ground acceleration (Figure 3).



a)



b)

Figure 3. Acceleration paths (or tangles).
(a) 3D path considering the three components; (b) 2D path ignoring vertical component

Figure 4 shows the projection of the 3D acceleration path (tangle) on the horizontal plane (a_gEW, a_gNS) and on the vertical planes (a_gEW, a_gVert) and (a_gNS, a_gVert). By comparing the 2D tangles one may observe that in this particular record the maximum values of the three acceleration components are very similar to each other.

The charts show the chaotic nature of the acceleration paths and the sharp variation in magnitude and direction of the acceleration vector. The plane accelerogram as time series shows the variation of one acceleration component at a time. Even when the time series of the three components are overlaid in the same chart, they cannot explicitly represent the real nature of the seismic motion. The ground acceleration records conceal a more complex reality which is finally revealed by their combination into the plot of the acceleration paths.

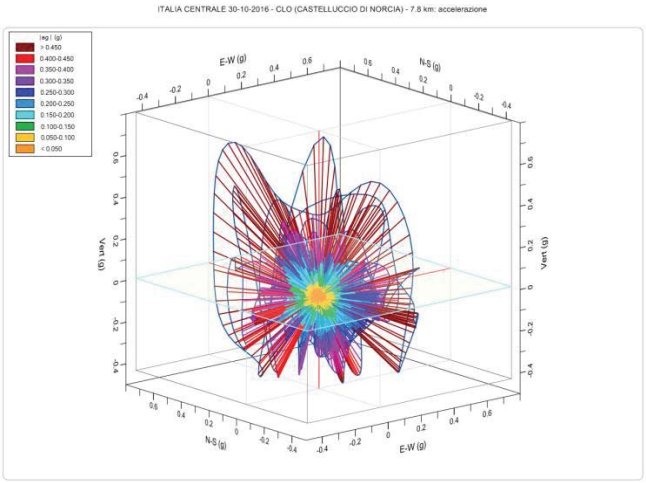

Figure 5. 3D Accelerogram: freezing motion of acceleration vector with color scale based on its magnitude

An interesting re-elaboration of the 3D chart can be obtained by "freezing" the motion of the acceleration vector at given time intervals, visualized with a color scale based on its magnitude (Figure 5).

As can be seen in Figure 5, the highest accelerations correspond to the "borders" of the path (characterized by dark red vectors) but the central core associated to lower accelerations (yellow or orange vectors) appears very dense showing countless variations in magnitude and directions which characterize a significant part of the seismic event.

To better understand the level of complexity one could zoom in the central core. Figure 6 shows the core in different levels of magnification. In order to reach this level of details, the acceleration record has been considered in a wide bracket duration, the time span between the first and last peak exceeding 0.005 g (15.385 s - 57.360 s, duration 41.985 s). In Figure 7 the same sequence is presented in the vertical plane (a_gNS, a_gVert).

These figures recall the fractals: whatever the scale, the curve always presents the same characteristics.

Figure 7. Different levels of magnification of the acceleration path: projection on vertical plane NS-Vert

The charts show what happened in Castelluccio di Norcia on 30 October 2016 in about 40 seconds. Considering the bracket time span between the first and last acceleration peak exceeding 0.250 g, we obtain the chart shown in Figure 8 for a time span of 6.48 s (17.435 s to 23.915 s). The red labels in the chart point out the acceleration reached at each second. In this way "time" re-appears in the chart highlighting the progression of the path.

In 6 seconds, the ground motion was characterized by violent accelerations especially in the vertical direction. The ground accelerations generated inertial and impulsive forces which caused collapses and severe damages to the buildings. A destruction happened in a very short time interval caused by a chaotic event, extremely different in its nature from the static actions that stress the buildings under operating conditions.

The 3D accelerograms, that are the paths outlined by the acceleration vector, indicate a new perspective: studying the shape of the curves and their evolution throughout the duration of the seismic event. The continuous changes of the acceleration vector in terms of magnitude and direction suggest to further investigate on the variation of acceleration. In fact, the safety verification applied in terms of resistance and deformation under inertial forces, may not be enough to fully describe the structural response. Assessment of the structural capacity cannot ignore verifications on the impulsive effects, that are the forces related to the short time intervals in which accelerations change, increase, decrease or change sign.

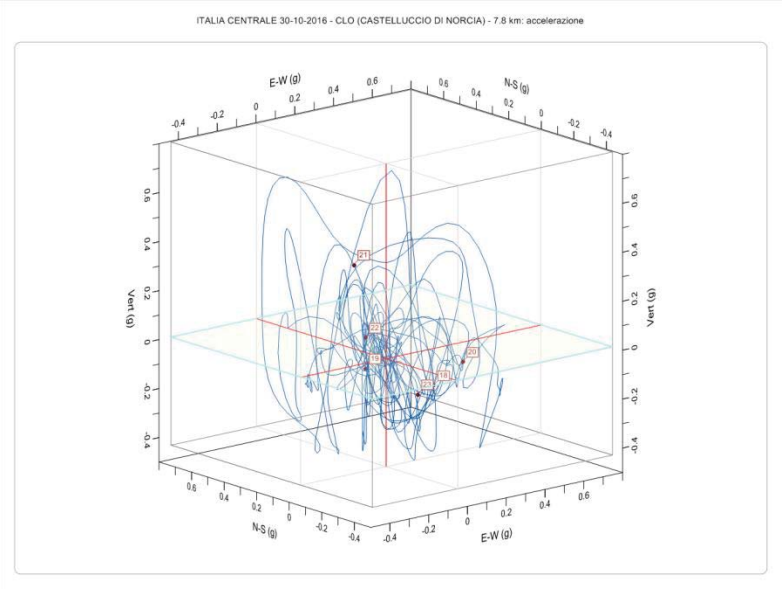

Figure 8. 3D Accelerogram at station CLO during 2016 Norcia mainshock: about 6 seconds while acceleration is above 0.25 g

2 JERK: FIRST DERIVATIVE OF ACCELERATION

The time derivative of acceleration (TDoA), that is the velocity of acceleration or the third derivative of displacement, is referred to as jerk and associated to the symbol j:

$$\boldsymbol{j} = \frac{d\boldsymbol{a}}{dt} \tag{1}$$

Since force acting on a body is equal to mass times acceleration, the jerk is related to the variation of the force acting on the body:

$$\boldsymbol{F} = m\boldsymbol{a} \Rightarrow \boldsymbol{j} = \frac{\left(\frac{d\boldsymbol{F}}{dt}\right)}{m} \tag{2}$$

In absence of jerk, a mass in constant acceleration is subject to static loading (constant force) and in this condition vibrations cannot occur. Therefore, when a body in motion undergoes vibration, jerk is always there.

Tong et al. (2005) [11] investigated on seismic jerk stating from the need of obtaining quantitative understanding about its amplitude, duration and frequency content. The study is based on records from the 1999 Chi-Chi Earthquake in Taiwan (M_W 7.6, 17:47, 20 September 1999) and one of its aftershocks (M_W 6.2, 00:14, 22 September 1999). At that time, jerk sensors were not widely available; therefore, jerk time series were obtained from ground acceleration records via numerical methods. This methodology, which can be applied to other seismic events where jerk records are not available, was implemented in the software Seismic 3D [10]

Seismic acceleration is a discrete signal, therefore seismic jerk can be calculated by the following mi-point differentiation formula:

$$j(t_i) = \frac{a(t_{i+1}) - a(t_{i-1})}{2\Delta t} \quad (i = 2, \dots, N-1) \tag{3}$$

where: $a(t_i)$ is the acceleration at instant t_i, N is the number of samples, Δt is the sampling period.

The formula is applied separately for each of the three components of the jerk vector **j.**

The accuracy of the jerk elaboration relies on the accuracy of the acceleration records and the sampling rate. Ground acceleration records of the main seismic events on the Italian territory are provided by ITACA [12] with a sampling period of 5 ms (200 Hz). The records are also corrected to reduce errors in high and low frequency; therefore, quality of the records is excellent for the purposes of this work.

At this point it comes naturally to represent the variation of jerk both as time series of its three components and as 3D path outlined by the jerk vector in space. In this way one can get graphs like the ones seen for acceleration.

In the 3D graph of the acceleration path it is worth noticing that the **j** vector is tangent to the path at each point.

Figure 9 shows the time series of the three jerk components at station CLO (Castelluccio di Norcia) from the 30 October 2016 Norcia earthquake. Table 1 summarize the maximum amplitude of acceleration (PGA) and jerk (PGJ) for each of the three components, and the instant in the record when they occur.

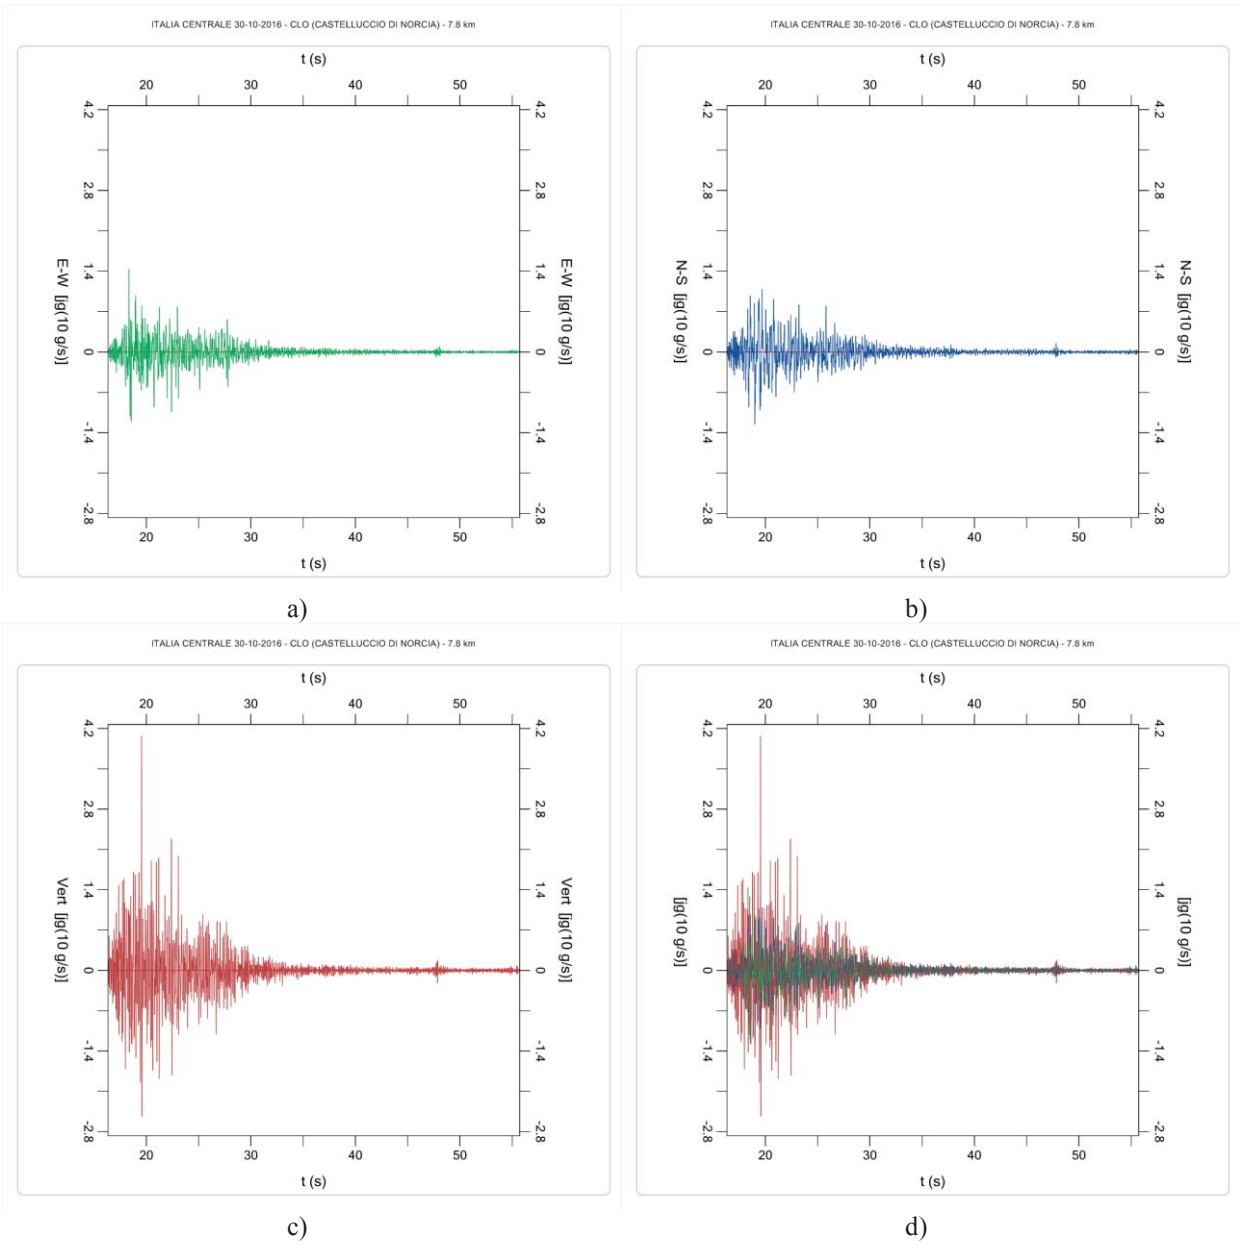

Figure 9. Jerk time series: each component of ground jerk plotted against time. (a) EW component; (b) NS component; (c) Vertical component and (d) the three components overlaid in the same chart.

	EW	t (s)	NS	t (s)	Vert.	t (s)
PGA (g)	0.427	20.775	0.583	19.445	0.797	19.560
PGJ (g/s)	14.36	18.335	12.50	18.995	40.70	19.540

Table 1. Station CLO (Castelluccio di Norcia), 30 October 2016 Norcia earthquake. Maximum acceleration (PGA) and maximum jerk (PGJ) for each of the three components and corresponding time instant

The maximum values of jerk (PGJ) occur at different instants of time than the ones of acceleration (PGA). They occur in a time interval between 18 s and 21 s and there is not a clear relationship with the occurrence of PGA values in the three directions.

In this event both vertical acceleration and jerk are rather strong with respect to the horizontal component. Vertical acceleration almost reached 0.8 g (Figure 1) and the vertical PGJ of about 40 g/s (Figure 9) is almost double than the horizontal ones.

In order to understand the relationship between acceleration and jerk, let us consider the time series of their vertical component focusing on a small time interval between 19.3 s and 19.8 s (0.5 s) in which both PGA and PGJ occur.

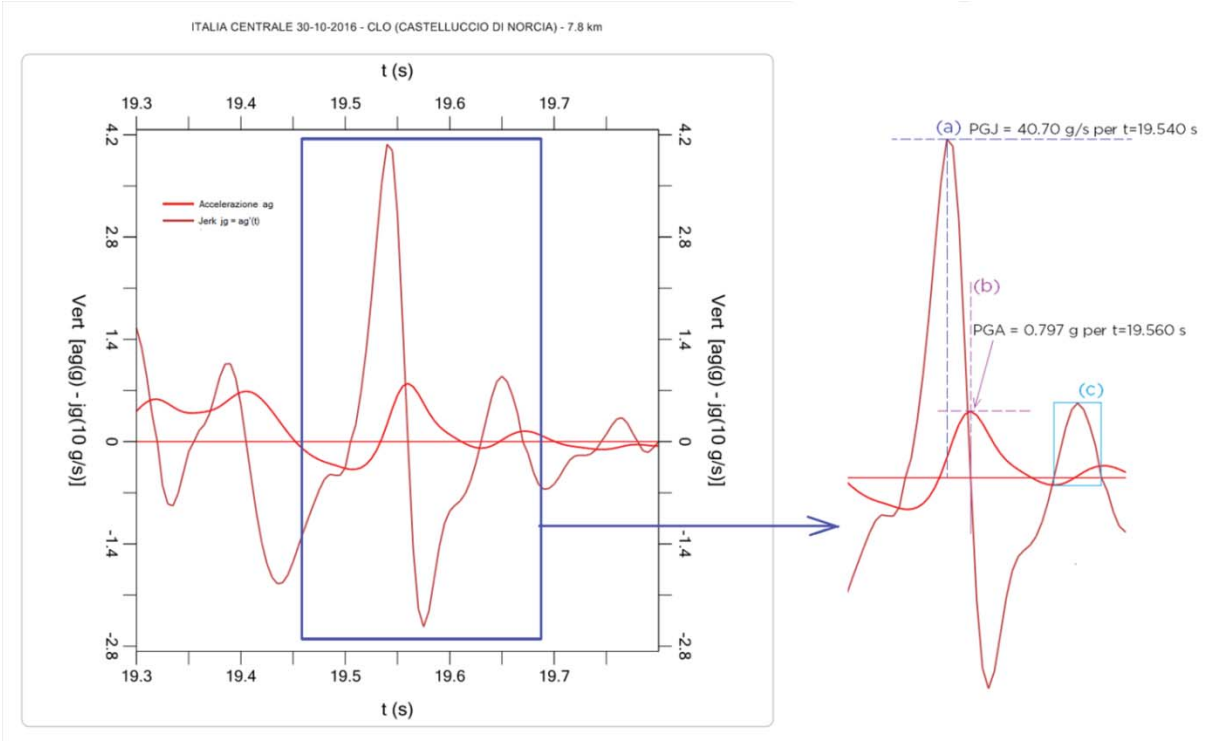

Figure 10. Comparison between acceleration and jerk time series. The detail on the right shows how the points where jerk is zero correspond to local maximum or minimum of acceleration.

Since jerk is the first derivative of acceleration it is equal to zero when acceleration shows a local maximum or minimum.

The detail in Figure 10 highlights (a) the absolute maximum of jerk (PGJ); (b) the absolute maximum of acceleration correspondent (like other local maximum) to zero in jerk; (c) the sector between two consecutive zeros of jerk correspondent to local minimum and maximum of acceleration.

Figure 11 shows the time series of acceleration and jerk for the three components in the time span between 18.0 s and 21.0 s. Jerk time series feature a higher number of fluctuations between positive and negative values: this is even more evident from the detail in Figure 12. Throughout the seismic event, the secondary fluctuation of acceleration corresponds to significant jerk peaks of alternate sign. The operation of derivation generates a “jerky” function characterized by denser peaks, that is in strict terms, by higher frequencies.

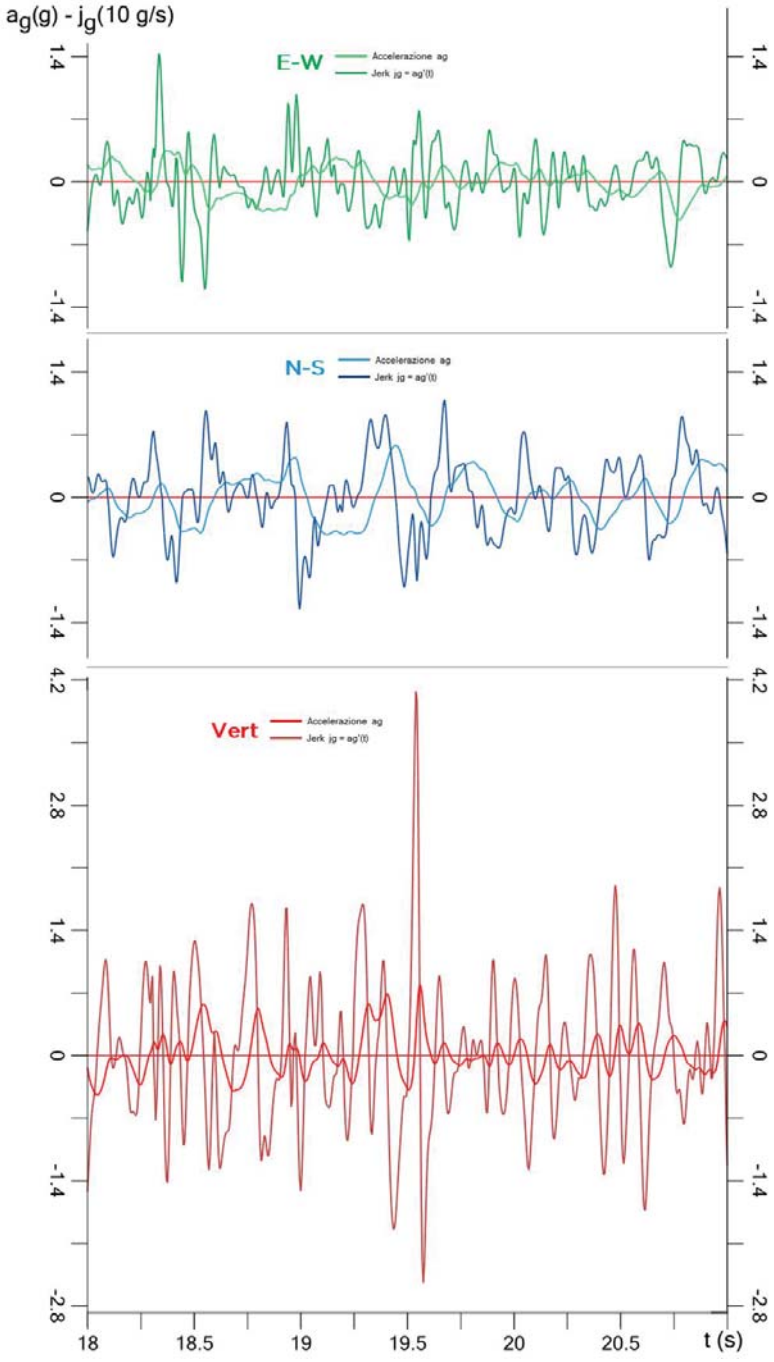

Figure 11. Acceleration and jerk time series for the three components (EW, NS, Vert)

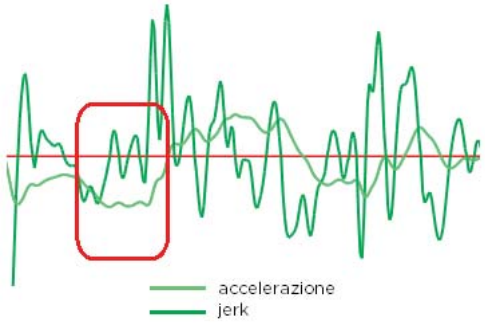

Figure 12. Secondary fluctuation of acceleration correspondent to jerk peaks

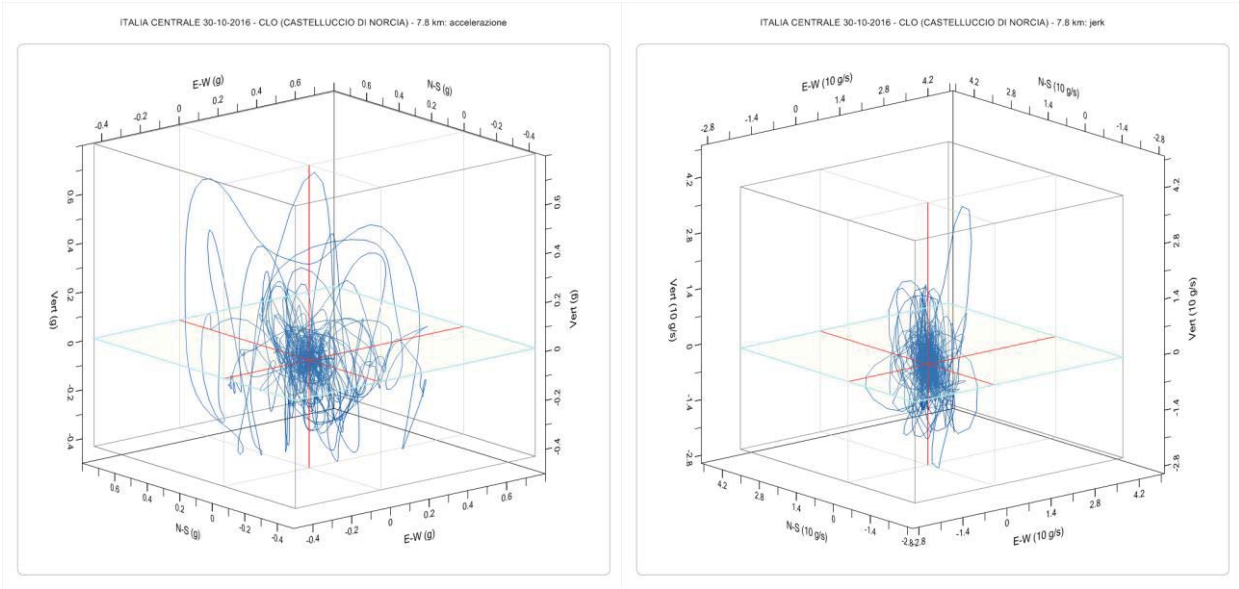
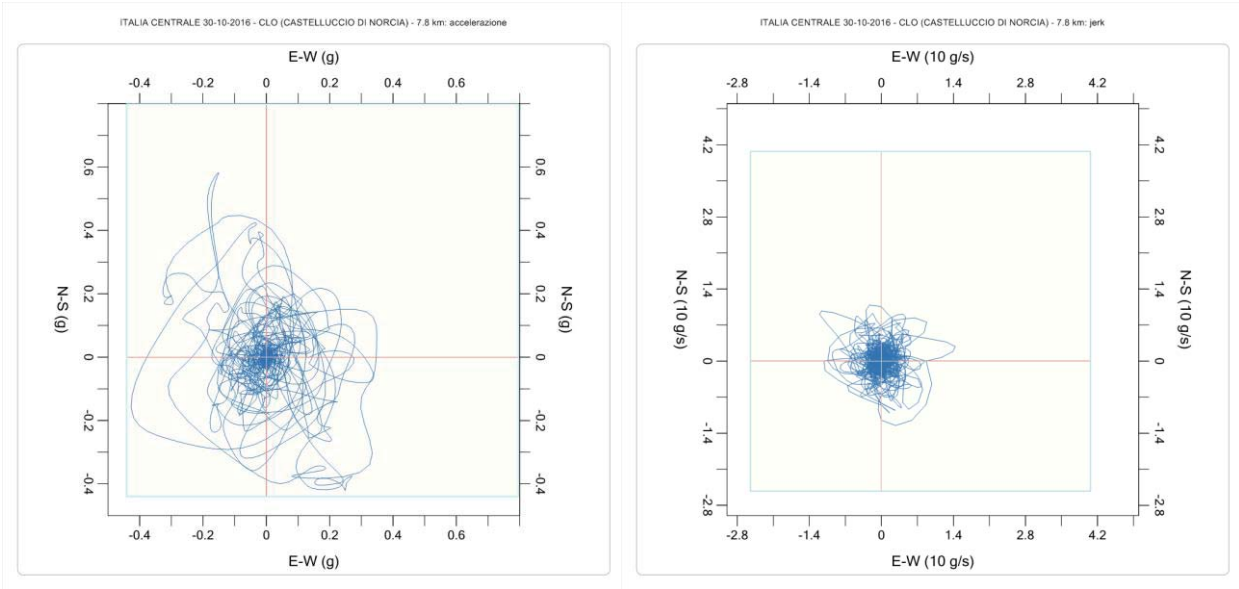
The graphs of jerk variation in space as the 3D path outlined by the **j** vector are similar to the ones already seen for acceleration. Comparison between acceleration and jerk paths is given in Figure 13 (3D view), Figure 14 (EW-NS plane), Figure 15 (EW-Vert plane) and Figure 16 (NS-Vert plane).



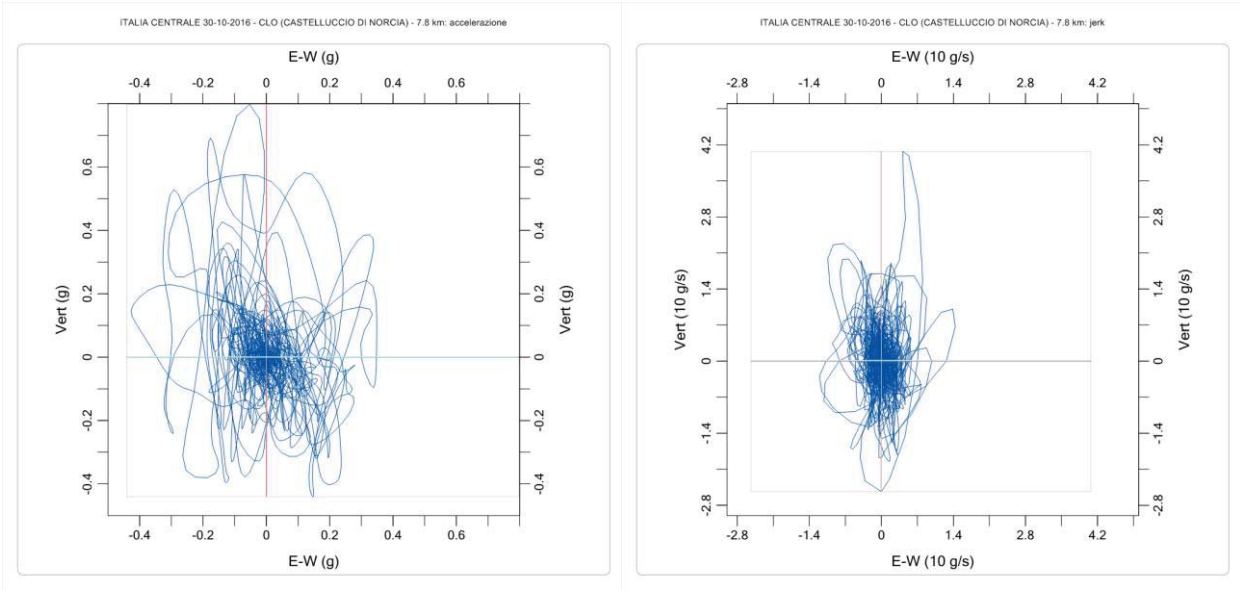
a) b)

Figure 13. Comparison between (a) acceleration and (b) jerk paths: 3D view



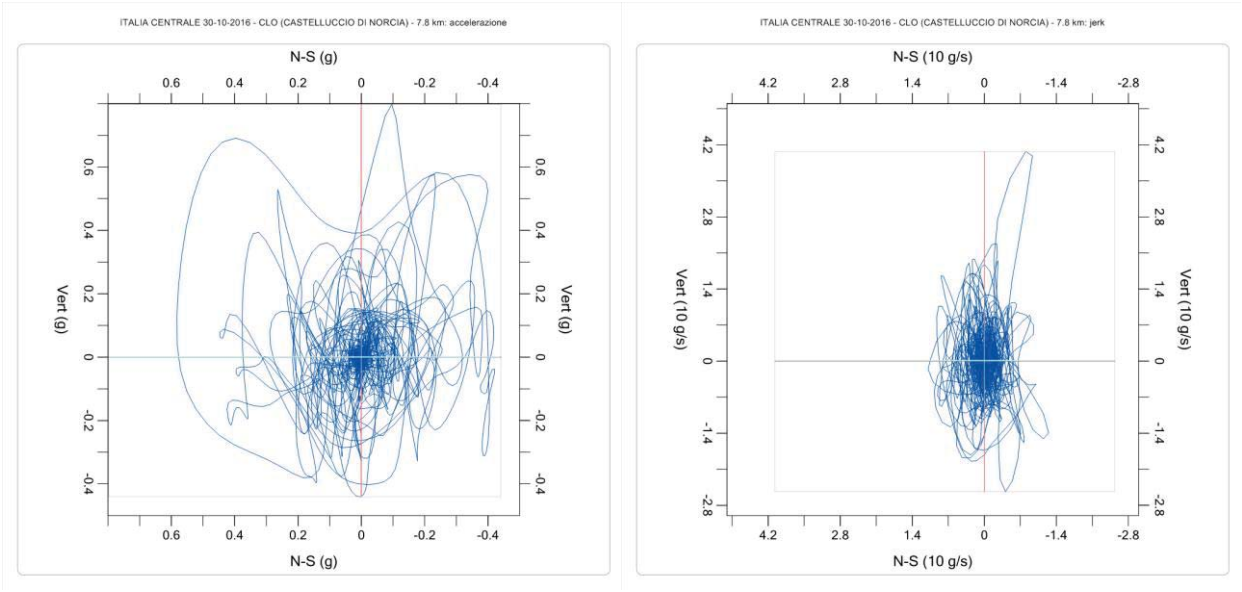
a) b)

Figure 14. Comparison between (a) acceleration and (b) jerk paths: projection on horizontal plane EW-NS



a) b)

Figure 15. Comparison between (a) acceleration and (b) jerk paths: projection on vertical plane EW-Vert



a) b)

Figure 16. Comparison between (a) acceleration and (b) jerk paths: projection on vertical plane NS-Vert

All the views highlight that the jerk tangle is denser than the acceleration one: this is in agreement with what previously noted in the comparison between acceleration and jerk time series. The projection of the jerk tangle on the vertical planes appears stretched in the vertical direction and this points out the importance of the vertical seismic component.

It is worth noticing that even the jerk paths feature a fractal type shape. Figure 17 shows different levels of magnification of the jerk path, from the box which envelopes the curve to the 0.5 g/s box.

This proves the chaotic nature of the represented phenomenon: the zoom in the core of the paths clearly highlights that, although the amplitude is lower, the number of fluctuations is

very high: this leads to the hypothesis that the phenomenon may disrupt the intimate constitutive bonds of the materials.

Since jerk is the first derivative of acceleration, a good way to understand its evolution is to represent the $\boldsymbol{j}$ vector on the acceleration path. Applying differential geometry of curves in $\mathbb{R}^3$, it can be proved that at the i-th instant t_i the vector $\boldsymbol{j}(t_i)$ is tangent to the curve in the point $\boldsymbol{a}(t_i)$. The modulus of vector $\boldsymbol{j}$ is given by the square root of the sum of the squares of its three components, each one being the time derivative of the correspondent acceleration component evaluated at instant t_i:

$$|\boldsymbol{j}(t_i)| = j_{3D}(t_i) = \sqrt{j_{EW}^2(t_i) + j_{NS}^2(t_i) + j_{Vert}^2(t_i)} \quad (i = 2, \dots, N-1)$$
$$where: \qquad (4)$$
$$j_{EW}(t_i) = \left.\frac{da_{EW}(t)}{dt}\right|_{t=t_i}, \quad j_{NS}(t_i) = \left.\frac{da_{NS}(t)}{dt}\right|_{t=t_i}, \quad j_{Vert}(t_i) = \left.\frac{da_{Vert}(t)}{dt}\right|_{t=t_i}$$

Jerk $\boldsymbol{j}$ is the rate of change of acceleration, that is, velocity of acceleration: there is complete analogy with velocity $\boldsymbol{v}$ as rate of change of displacement. Figure 18 shows the jerk vector on the 3D accelerogram (acceleration path). The bracket duration is defined as the time span between the first and last acceleration peak exceeding 0.250 g (17.435 – 23.915 s). The j vector is represented at instant t = 19.375 s by a red arrow, which of course is tangent to the curve from any point of view.

Figure 17. Different levels of magnification of the 3D jerk path

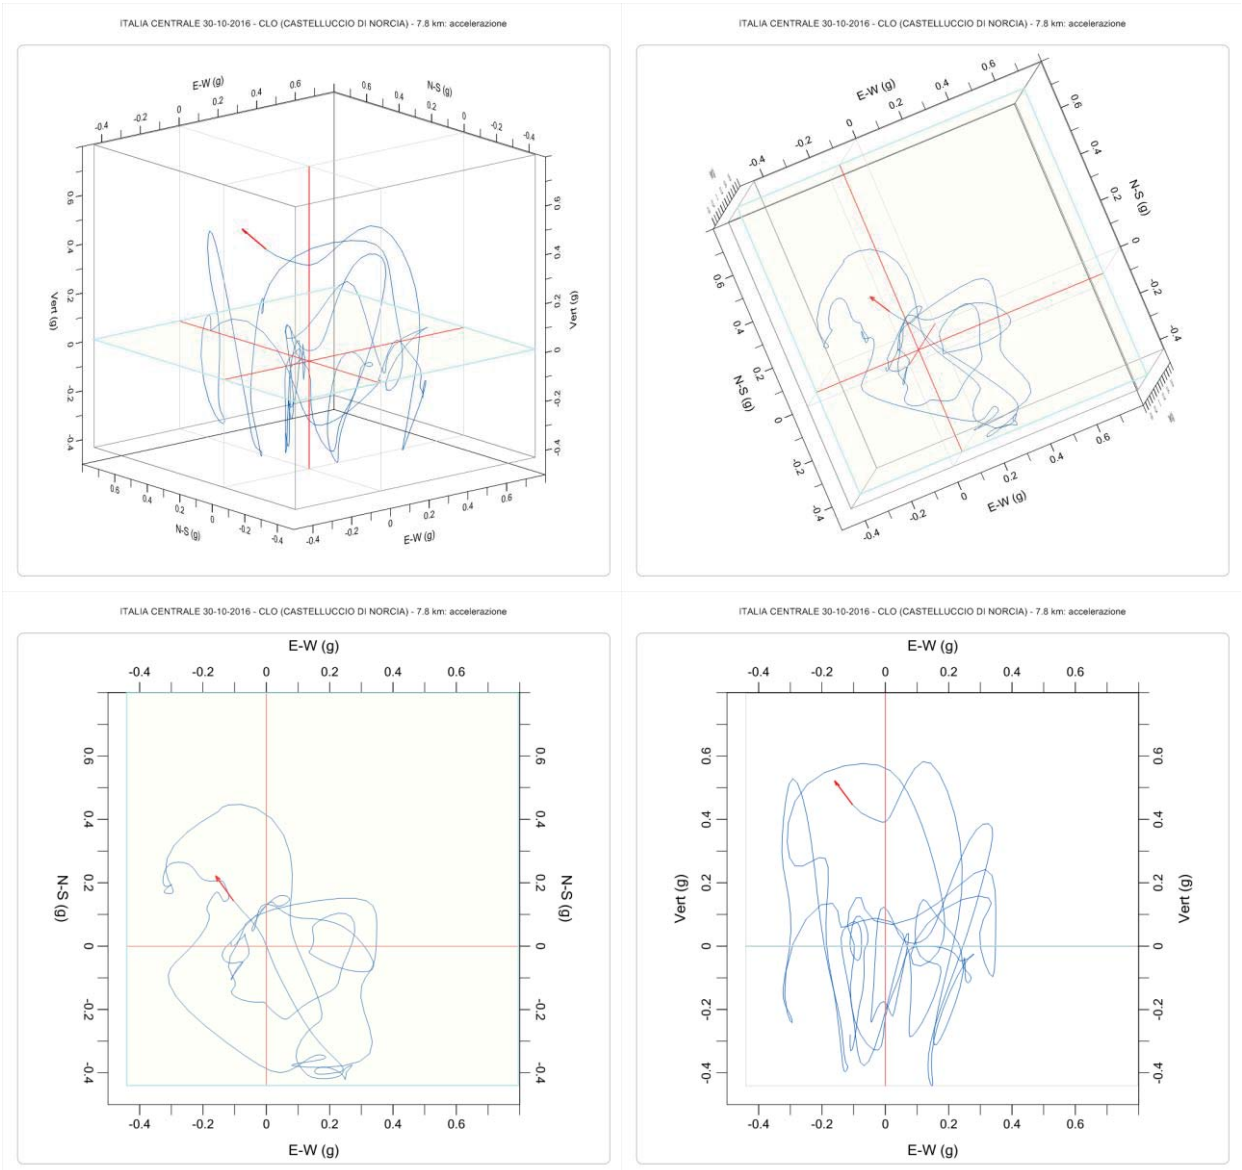

Figure 18. The jerk vector on the 3D accelerogram (acceleration path) from different points of view

Considering acceleration and jerk as vectors in space, PGA and PGJ may not only be expressed for the three separated components but also with respect to the magnitude (modulus) of the vectors. Therefore, Table 2 updates Table 1 with the inclusion of global PGA and PGJ and the instant when they occurred.

	EW	t (s)	NS	t (s)	Vert.	t (s)	3D	t (s)
PGA (g)	0.427	20.775	0.583	19.445	0.797	19.560	0.829	19.410
PGJ (g/s)	14.36	18.335	12.50	18.995	40.70	19.540	41.69	19.540

Table 2. Station CLO, 30 October 2016 Norcia mainshock. Peak ground acceleration (PGA) and peak ground jerk (PGJ). Three separated components and magnitude of the 3D vectors

Peaks of vectors magnitude are of course higher than the peaks of the singular components and they generally occur at different time instants. The maximum effects of seismic ground motion, both in terms of acceleration and jerk, did not occur along one of the three axes of the reference system (X,Y, Z) but along a random direction in space.

Figure 19 shows the time series of acceleration and jerk magnitude (3D) for two different bracket duration. The maximum values of these time series are given in Table 2 as 3D values.

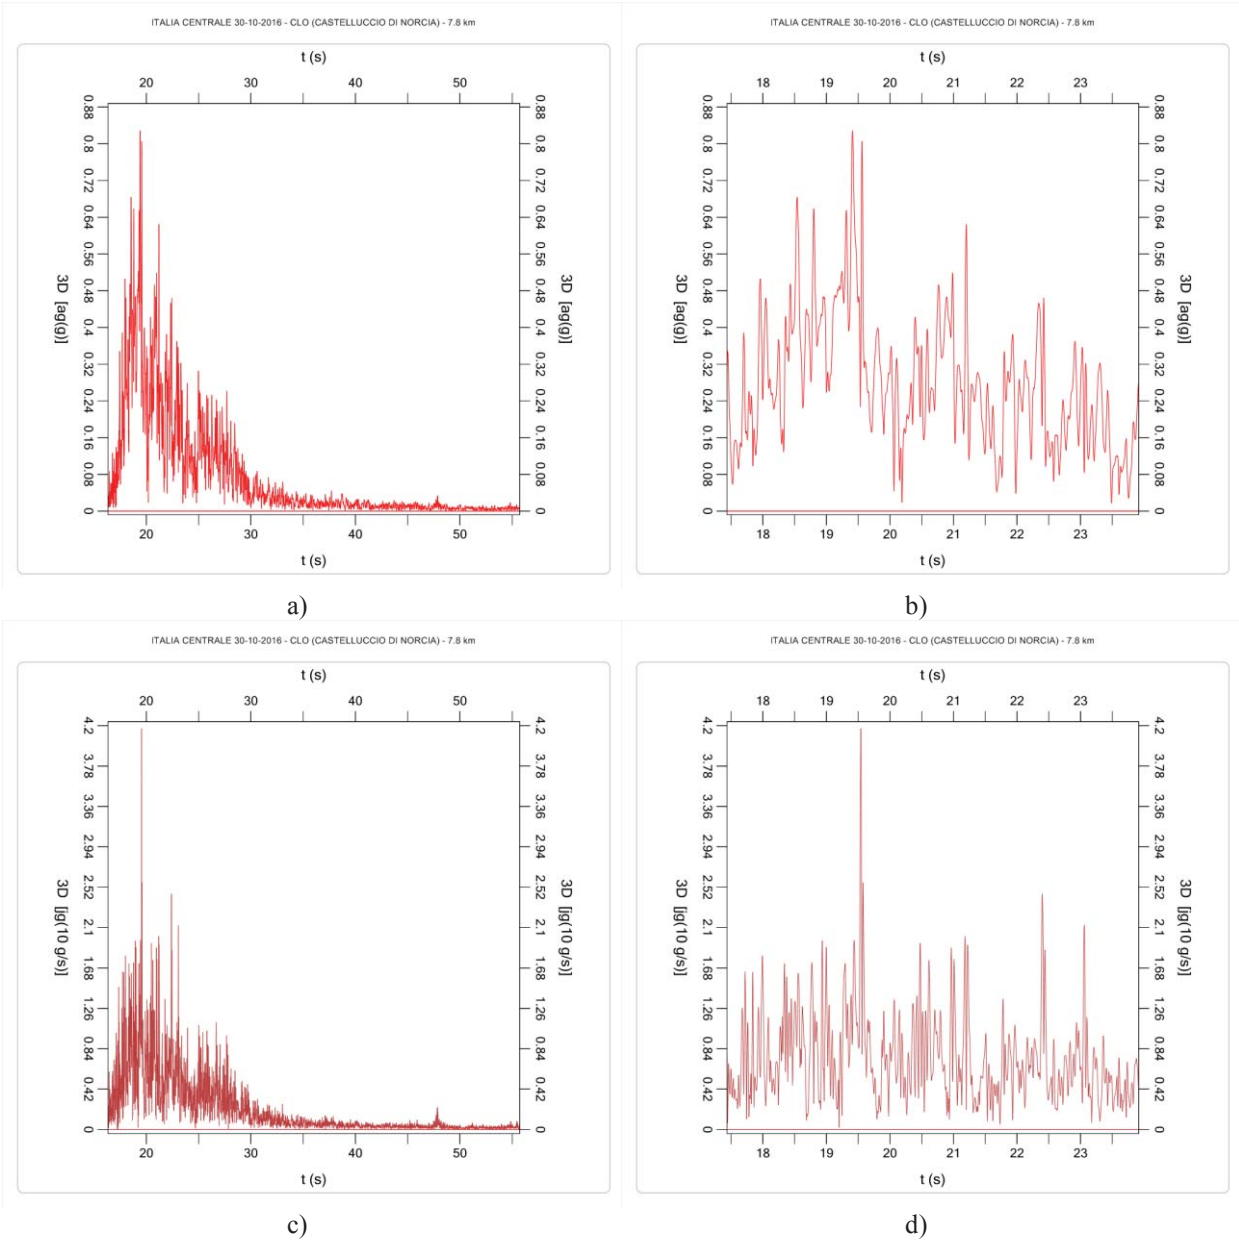

Figure 19. Station CLO, 2016 Norcia mainshock: acceleration and jerk 3D magnitude time series.

(a, c) time series cut-of at the acceleration threshold of 0.010 g (16.330 - 55.715 s);
(b, d) time series cut-of at the acceleration threshold of 0.025 g (17.435 - 23.915 s).

3 IMPULSIVE FORCES DUE TO JERK

During a seismic event, ground acceleration varies quickly, and the correspondent inertial forces also fluctuate in short time intervals of the order of few milliseconds. This sharp variation causes "jolts", that is, impulsive forces that act very briefly. Therefore, jerk could become a useful parameter for structural analysis and design if it is considered with the corresponding impulsive forces. A new approach is introduced below.

The study is based on ground acceleration records at station CLO (Castelluccio di Norcia) from 30 October 2016 Norcia mainshock: the same records considered in previous paragraphs.

Impulsive forces due to seismic jerk are distinct from inertial forces due to acceleration. The former are generated by the variation of acceleration and may be much higher than the latter. Their influence on a structure depends on the frequency content of the jerk and the dynamic properties of the structure itself.

The integral of jerk is, by its own definition, an acceleration. Since acceleration, according to Newton's Second Law, is force per unit mass, the definite integral of jerk in the interval between two consecutive zeros may be referred to as "impulsive force per unit mass" (F_{imp}/m). Two consecutive zeros of jerk correspond to a maximum and a minimum of acceleration, or vice-versa. The signed area bounded by the jerk function in that interval corresponds to the impulse of acceleration or deceleration. Therefore, considering the interval between instants t_1 and t_2, the impulsive force per unit mass is given by:

$$\frac{F_{imp}}{m} = \int_{t_1}^{t_2} j(t)\, dt \tag{5}$$

This expression can be applied to any of the three jerk components, each one characterized by its own sequence of zeros.

Figure 20 illustrates the definition of impulsive force per unit mass as the area bounded by the jerk function $j(t)$ between two consecutive zeros. Yellow color indicates the positive impulsive force corresponding to an interval where acceleration increases: $a(t)$ goes from a minimum to a maximum. Instead, green color indicates the previous negative impulsive force corresponding to the interval where acceleration decreases going from a maximum to a minimum.

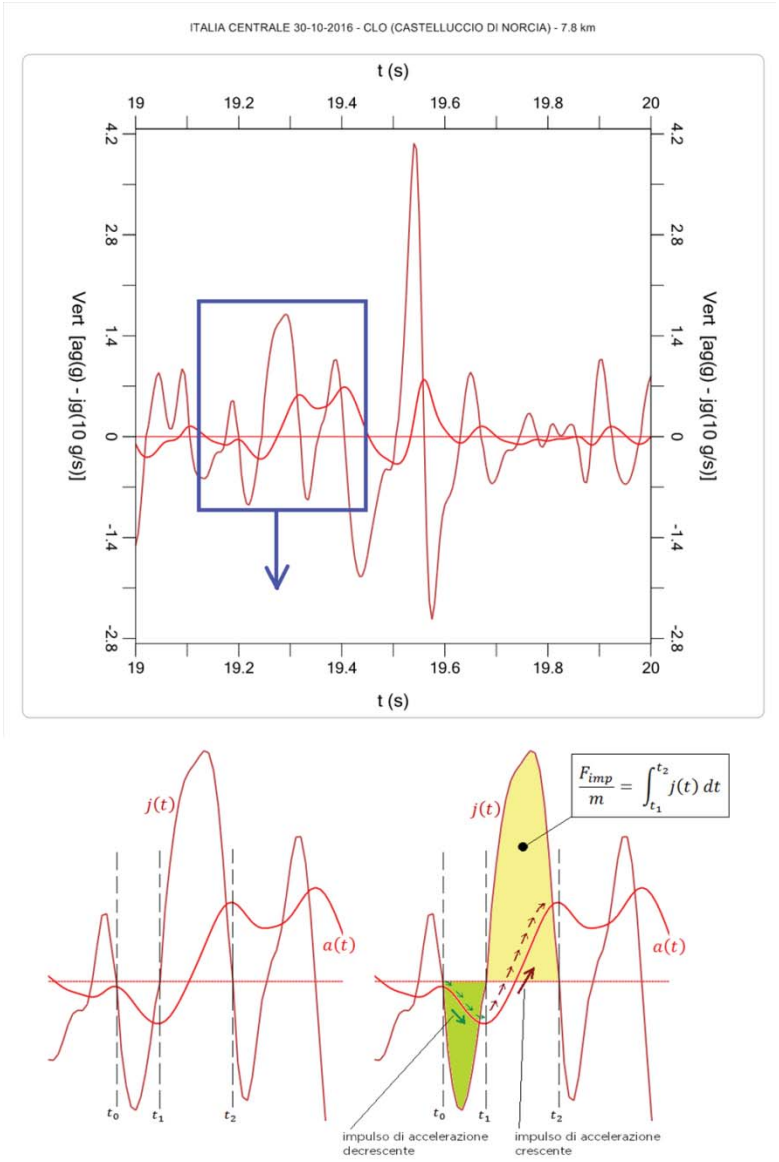

Figure 20. Impulsive force per unit mass, defined as the integral of jerk between two consecutive zeros

Figure 20 refers to the vertical component of the ground motion recorded at station CLO (Castelluccio di Norcia) from 30 October 2016 Norcia mainshock in the time interval (19.000 – 20.000 s).

It is worth noticing the very short duration of the impulsive forces. The considered jerk zeros correspond to the following instants in the record: t_0 = 19.200 s, t_1 = 19.245 s, t_2 = 19.320 s. The negative impulsive force corresponding to decreasing acceleration lasts 45 ms while the following positive impulsive force lasts 75 ms.

Thus, impulsive force may be calculated throughout the record for each time interval between two consecutive jerk zeros. The result is a step function that represents the time series of impulsive force per unit mass.

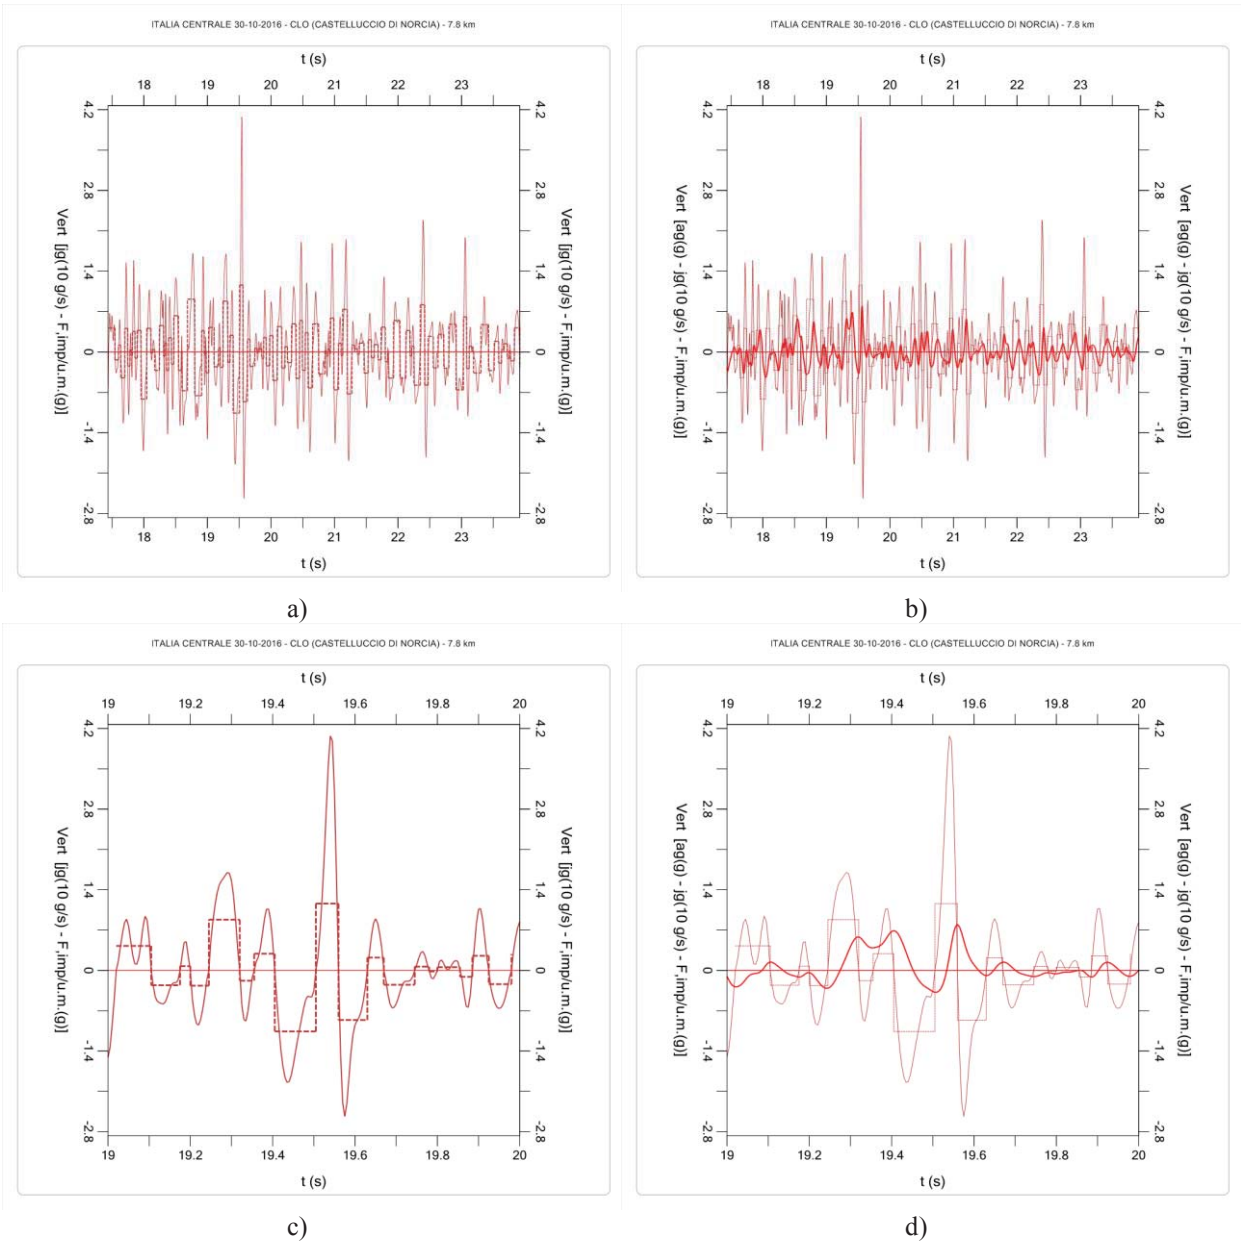

Figure 21. Jerk and impulsive forces per unit mass for the vertical seismic component. CLO - 30 October 2016 Norcia mainshock

Figure 21 shows jerk time series and step function of impulsive forces per unit mass (dashed line) for the vertical component of the reference seismic motion. The graphs on the right (b, d) also display the correspondent acceleration time series. The graphs at the top (a, b) refer to the time span between first and last acceleration peak exceeding 0.250 g, while the graphs at the bottom (c, d) refer to a shorter time interval (19.000 – 20.000 s).

The detail shown in Figure 22 highlights an important aspect: the value of the impulsive force cannot be directly correlated to the jerk level because it depends also on the time interval between two zeros. Therefore, lower jerk peaks with longer duration may yield higher impulsive forces than higher jerk peaks with shorter duration (cfr. Impulsive forces A and B in Figure 22).

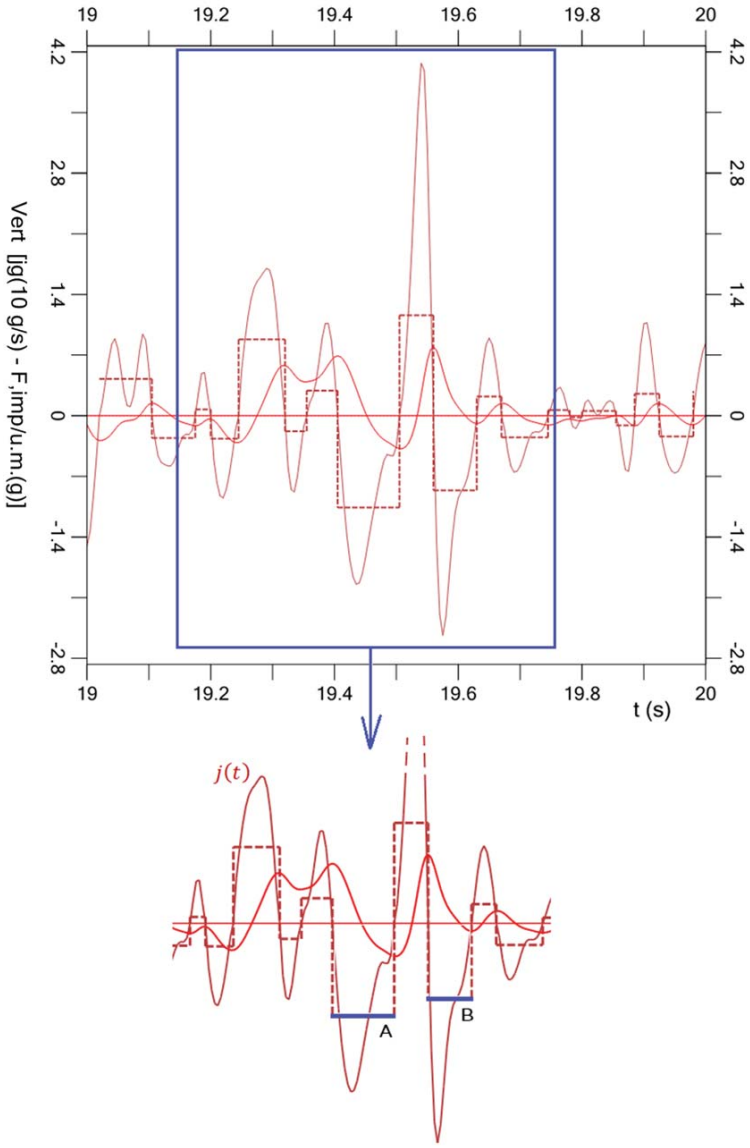

Figure 22. Peaks of jerk and correspondent impulsive forces

This behavior has general validity, it applies to all the components of seismic motion and different seismic events: the maximum values of jerk and impulsive force do not occur at the same time. The same happens between peaks of acceleration and peaks of jerk. Therefore, we get to the following property: PGA, PGJ and $F_{imp,max}$ are not simultaneous and there is not a direct relationship between them. This applies for any seismic event, any station, any of the three components of seismic motion.

Figures 23-25 show, for the reference seismic motion, the time series of impulsive force for each of the three components cut-off at the acceleration threshold of 0.250 g. The graphs on the left also include overlaid jerk time series (scale is uniform among the graphs on the left and among the graphs on the right).

Figure 26 shows the time series of the three components of impulsive forces overlaid in the same graph.

Thus, the dynamic nature of the seismic action is expressed, through jerk, by a series of consecutive impulses which determine vibrations; these are concept well known in Mechani-

cal Engineering, where forces induced by jerk are kept under control e.g. in order to optimize production processes [13].

Table 3 extends the information given in Table 2 with the maximum impulsive forces so to compare them with PGA and PGJ. Given their instantaneous nature and the independence between the three components, the impulsive forces are not combined in a unified 3D value. However, given the chaotic nature of the seismic motion, high values of impulsive force may occur simultaneously in different directions.

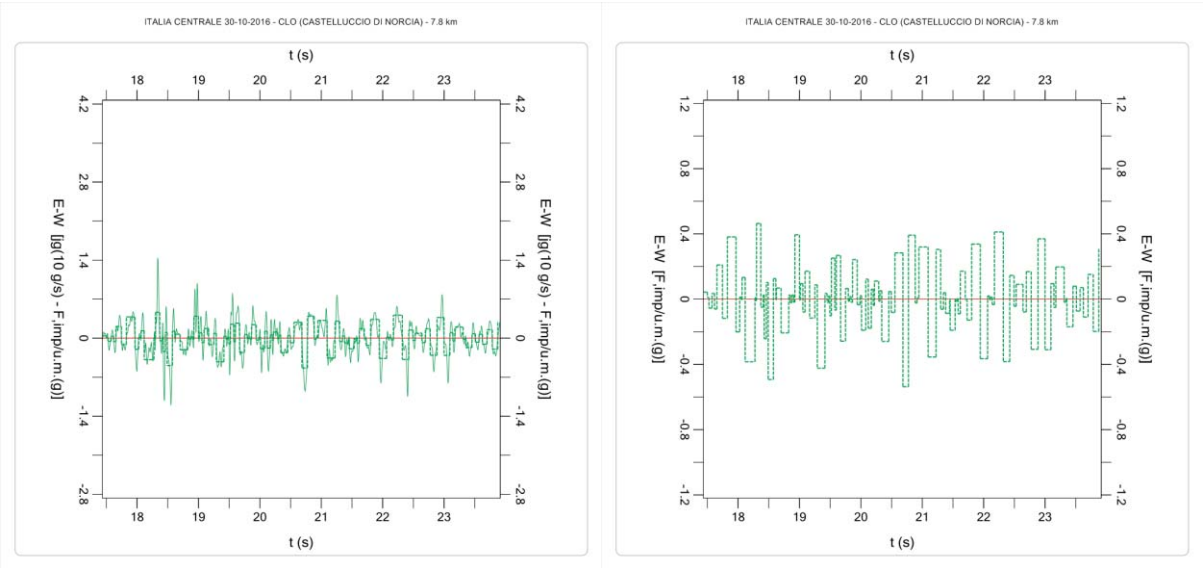

Figure 23. Jerk and impulsive force per unit mass: EW component

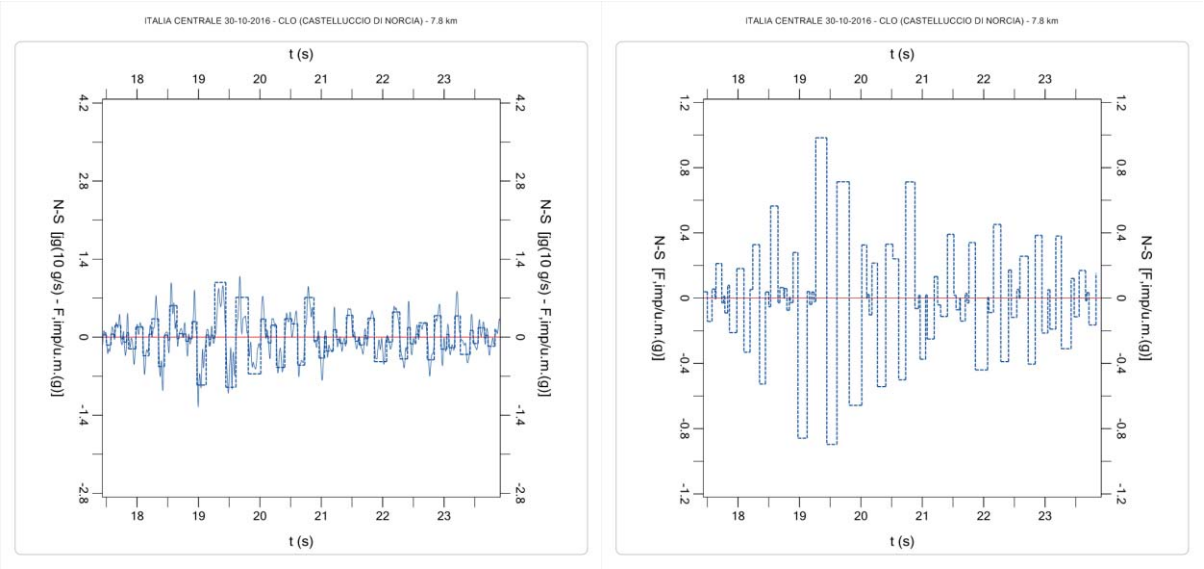

Figure 24. Jerk and impulsive force per unit mass: NS component

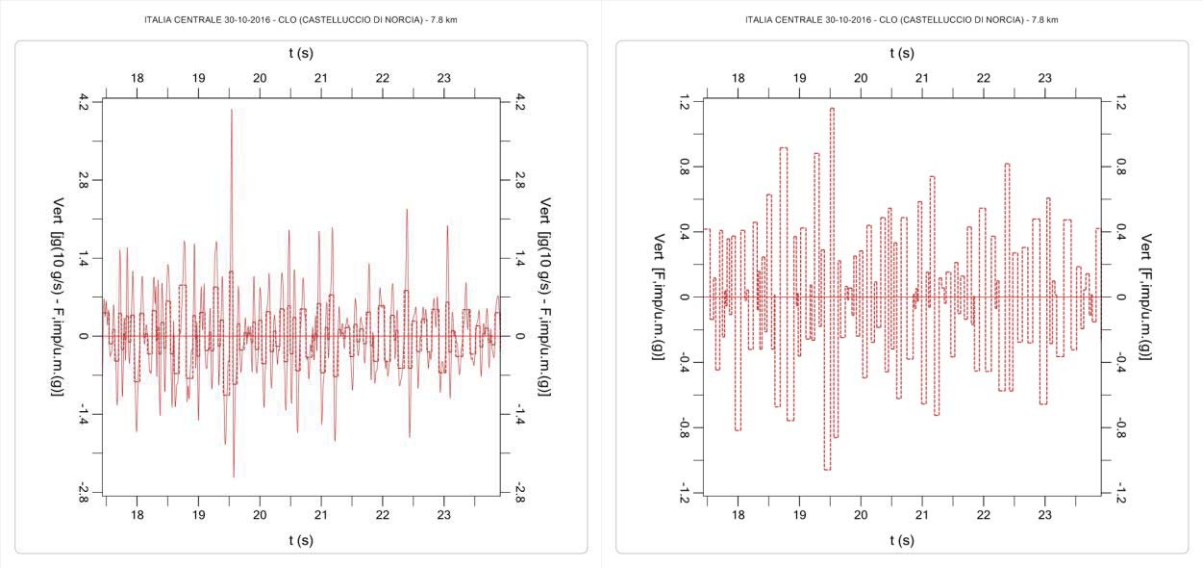

Figure 25. Jerk and impulsive force per unit mass: vertical component

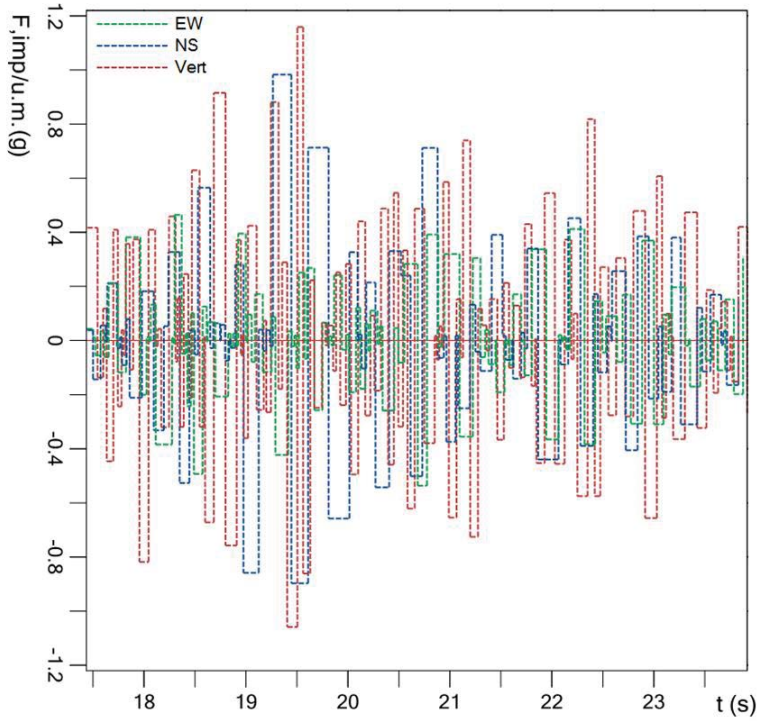

Figure 26. Time series of impulsive force per unit mass. All three components overlaid

Table 3 made clear how high the values of impulsive forces may be: for the reference seismic event (CLO, 30 October 2016 Norcia mainshock) the vertical impulsive force per unit mass exceeds gravity and reaches 1.159 g.

This means that during the seismic event there was a short time interval (55 ms, 19.505 s – 19.560 s) where the vertical "jolt" induced a force which exceeded weight (force of gravity) by more than 15%. Structures were subject to very demanding dynamic stress causing damages and collapses which cannot be fully understood if the analysis considers only the inertial forces due to ground acceleration.

Jerk thresholds significant for building damages need to be identified. Tong et Al. (2005) [11] highlighted that jerk larger than 2 g/s causes discomfort in people inside buildings. It is a threshold much higher (about 10 times higher) than criteria used by the transportation industry to ensure passenger comfort (about 0.2 g/s). The threshold of 10 g/s is the one within which structural damages may become severe.

Furthermore, the effects of jerk must be related to its frequency content: these aspects may be addressed through Fourier analysis.

	EW	t (s)	NS	t (s)	Vert.	t (s)	3D	t (s)
PGA (g)	0.427	20.775	0.583	19.445	0.797	19.560	0.829	19.410
PGJ (g/s)	14.36	18.335	12.50	18.995	40.70	19.540	41.69	19.540
$\frac{F_{imp,max}}{m}$ (g)	0.537	20.685 20.775 (**90** ms)	0.984	19.265 19.445 (**180** ms)	1.159	19.505 19.560 (**55** ms)		

Table 3. Peaks of acceleration, jerk and impulsive force per unit mass. Station CLO, 2016 Norcia mainshock

4 FREQUENCY ANALYSIS

The frequency content of a time series is expressed by the Fourier amplitude spectrum. Identification of the dominant frequency of the seismic motion is crucial for the comparison with the fundamental frequency of the structures.

Tong et al. (2005) [11], in their study on the 1999 Chi-Chi earthquake in Taiwan, provided Fourier amplitude spectra both for acceleration and jerk. The dominant frequency contents of the acceleration and jerk time series are between 1 and 10 Hz; however, jerk distributes in a much wider frequency band and its higher frequency contents are prominent.

This characteristic, observed for the first time in this seismic event in Taiwan, is confirmed for all seismic events in the Italian territory elaborated in this work. The jerk Fourier spectrum features a window of dominant frequency wider than the acceleration one. The jerk higher frequency content appears more important.

A parameter that characterized the frequency content is the mean period T_m, defined as the average of periods in the Fourier spectrum, each weighted by the square of its Fourier amplitude (Rathje et al. [14])

While the mean period of acceleration is generally quite large with values even higher than 1 s, the mean period of jerk is much lower with values comparable to typical fundamental periods of buildings.

Fourier analysis has been performed on the seismic records from station CLO (Castelluccio di Norcia) for 30 October 2016 Norcia earthquake. Figures 27-29 show the Fourier amplitude spectra of acceleration and jerk with the indication of the mean period for the three components of the seismic motion (EW, NS, Vert.).

acceleration and jerk Fourier amplitude spectra for EW component

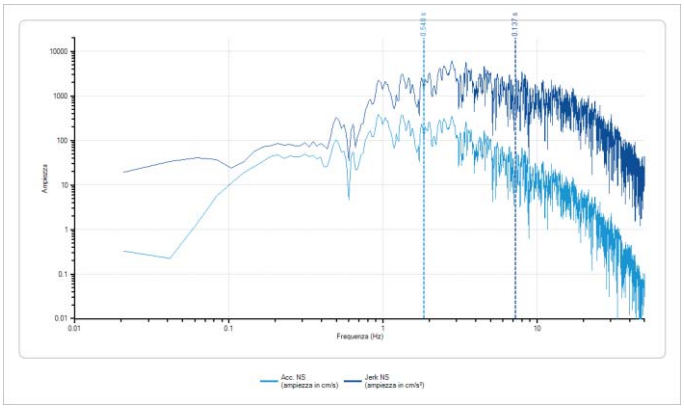

Figure 28. CLO, 2016 Norcia earthquake:
acceleration and jerk Fourier amplitude spectra for NS component

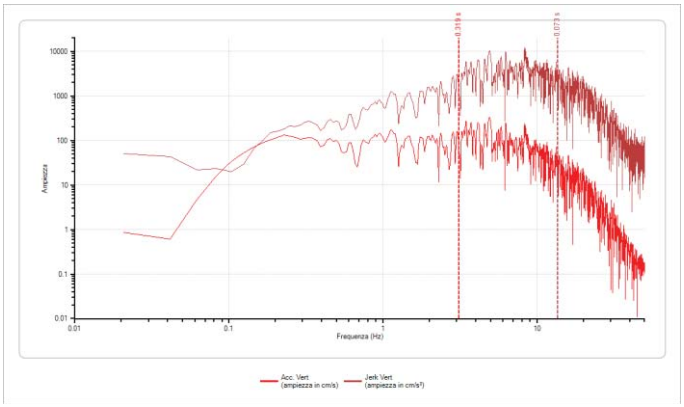

Figure 29. CLO, 2016 Norcia earthquake:
acceleration and jerk Fourier amplitude spectra for vertical component

T_m(s)	EW	NS	Vert.
Acceleration	0.657	0.540	0.319
Jerk	0.107	0.137	0.073

Table 4. Mean period of acceleration and jerk. CLO, 2016 Norcia earthquake

Table 4 highlights an important aspect: the main frequencies of the vertical component are significantly higher than the horizontal ones. This is also evident by the overlaid three-components Fourier spectra shown in Figures 30-31 for acceleration and jerk respectively. The jerk mean periods appear very close to fundamental periods of rigid structures like masonry buildings. This points out the prospect of critical issues caused by impulsive action on structural elements.

Records from CLO station for 30 October 2016 Norcia earthquake have been taken as reference for the elaborations presented so far, but the highlighted observation can be generalized and deepened through the analysis of a larger number of records.

5 SEISMIC EVENTS ON ITALIAN TERRITORY: ELABORATIONS AND ANALYSES

The following study is based on ground motion records provided by ITACA project [12] for 8 reference seismic events: 30 October 2016 Norcia; 24 August 2016 Accumuli; 29 May 2012 Emilia; 6 April 2009 L'Aquila; 26 September 1997 Umbria-Marche; 23 November 1980 Irpinia; 19 September 1979 Valnerina; 6 May 1976 Friuli.

ITACA database provides records of these events taken from numerous stations. The signals are already corrected, thus, can be directly elaborated for the purposes of this work.

The performed elaborations highlighted some common aspects:

- the farer is the station from the epicenter, the shorter is jerk duration and the lower is its peak value.
- the farer is the epicenter the lower are the impulsive forces per unit mass; however, they remain higher than peak ground acceleration.
- the mean period of the vertical jerk component is always significantly lower than the horizontal components. Jerk represents the impulsive content of the seismic motion which is enhanced in the vertical component.
- stations farer form epicenter show attenuation of impulsive content through jerk drop. Vertical jerk component attenuates with respect to other horizontal components.

As an example, Table 5 reports the results for three stations recording 30 October 2016 Norcia mainshock.

Through statistical elaboration of the records, trend lines correlating PGA, PGJ and Impulsive Forces may be outlined.

This constitutes the first step for considering impulsive forces in structural design. If ground jerk and correspondent impulsive forces are not known, an estimation is required in order to evaluate their effects on structures.

Seismic parameters and unit of measure:

$\Delta t(j_g \geq 2.0$ g/s)	(s)	Time span between first and last jerk peak exceeding 2.0 g/s
PGA	(g)	Peak ground acceleration
PGJ	(g/s)	Peak ground jerk
F_{imp} max	(g)	Maximum impulsive force per unit mass (based on jerk)
T_m	(s)	Mean period from Fourier amplitude spectra

Table 5. Acceleration and jerk and impulsive forces for 30 October 2016 Norcia earthquake

Among all the ground station records available for the 8 events considered, the ones taken into account in the statistical analysis were those with bracket duration of ground acceleration record longer than 100 ms when the threshold of 0.005 g is applied. In total 447 station records were considered. For each of them and for each of the three components (EW, NS, Vert.) the following parameters were elaborated by means of the software Seismic 3D:

1. peak ground acceleration (PGA)
2. peak ground jerk (PGJ)
3. maximum value of impulsive force per unit mass (F_{imp})
4. mean period (T_m) of acceleration and jerk from Fourier spectra

The statistical elaboration was performed separately for horizontal and vertical components. In the pursuit of useful correlation between the considered parameters, distinction between the two horizontal components (coming from different stations) appears inappropriate.

The correlations obtained between PGA, PGJ and F_{imp} are illustrated in Figures 33, 34, 35.

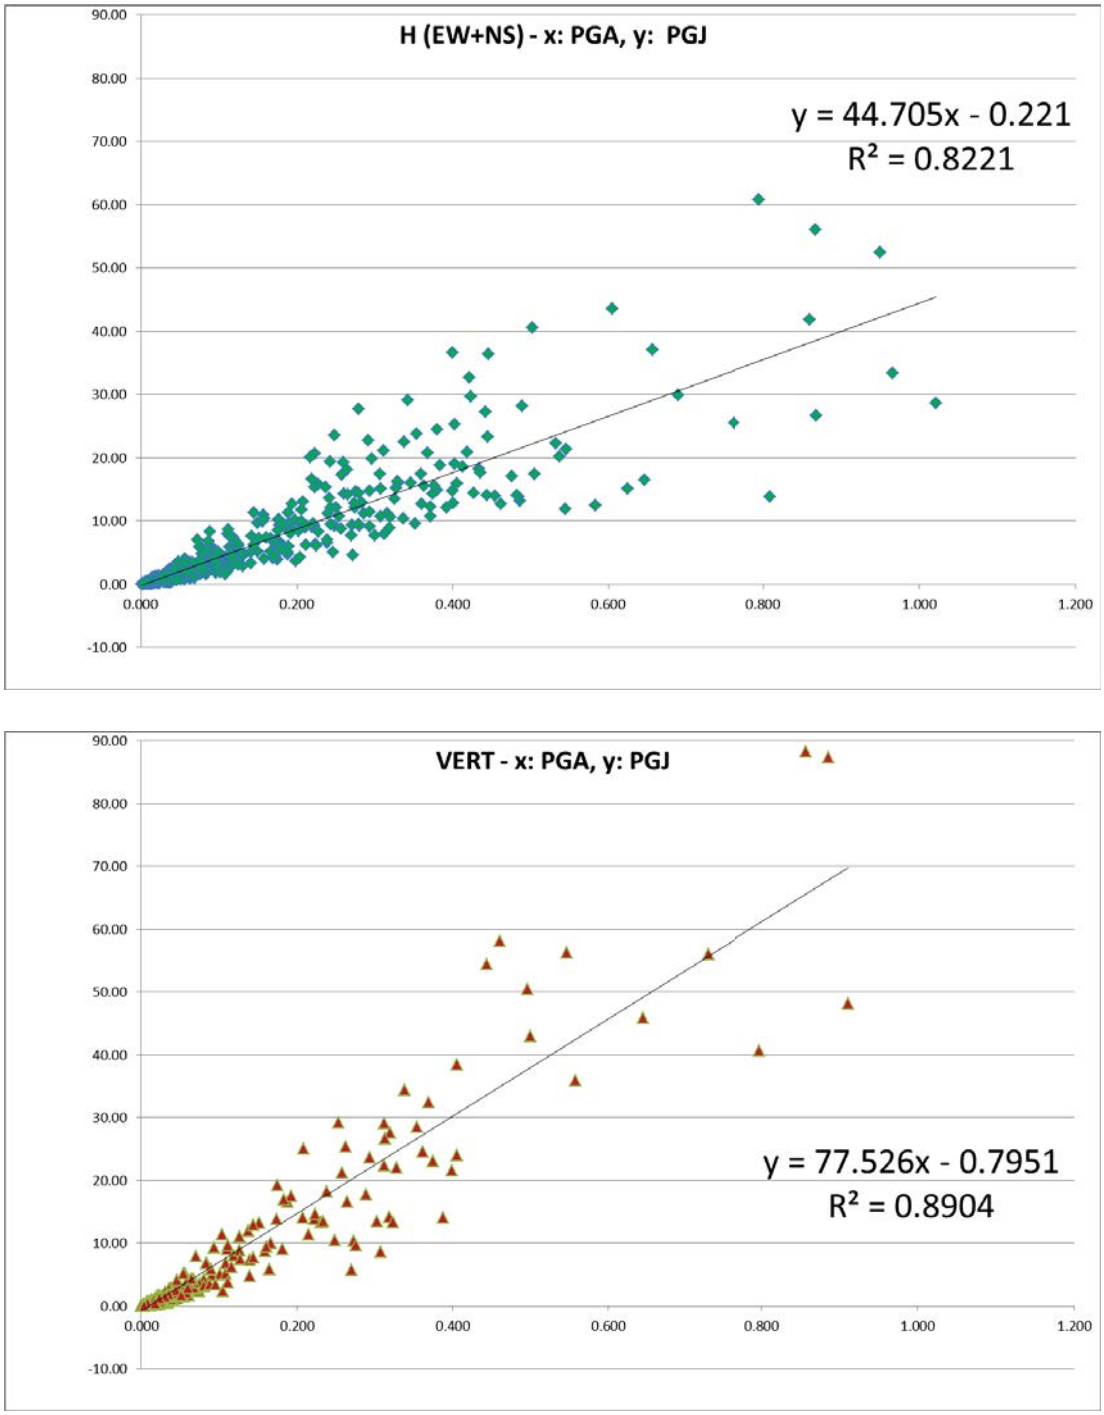

Figure 33. Correlation PGA-PGJ for horizontal and vertical components

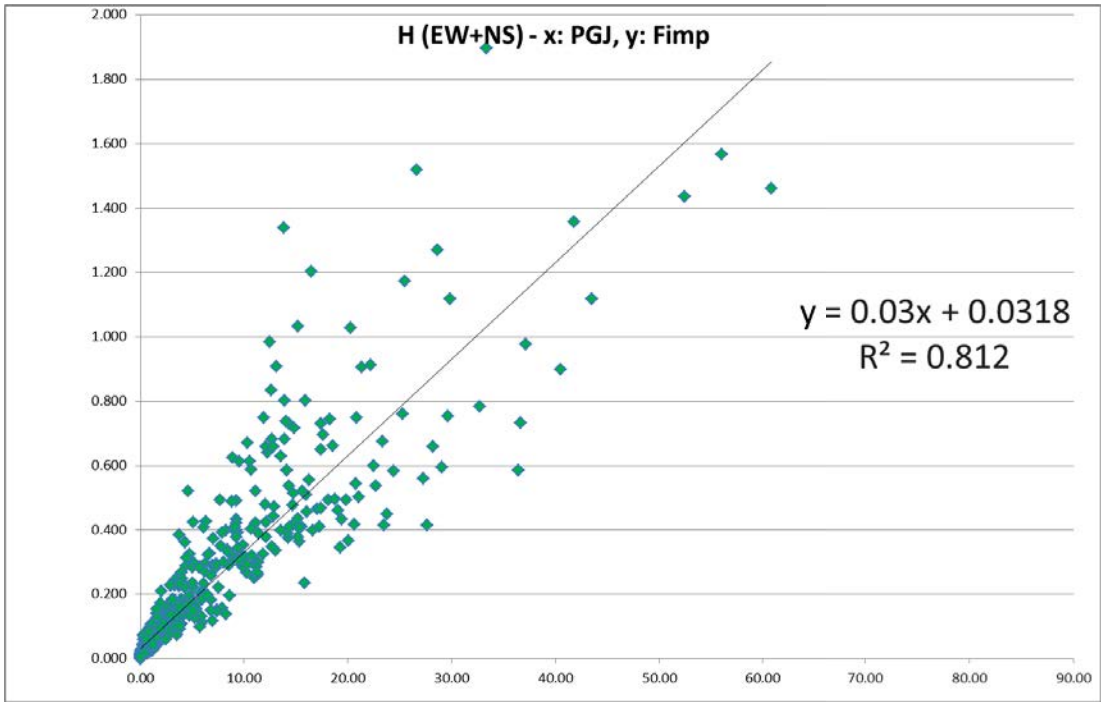

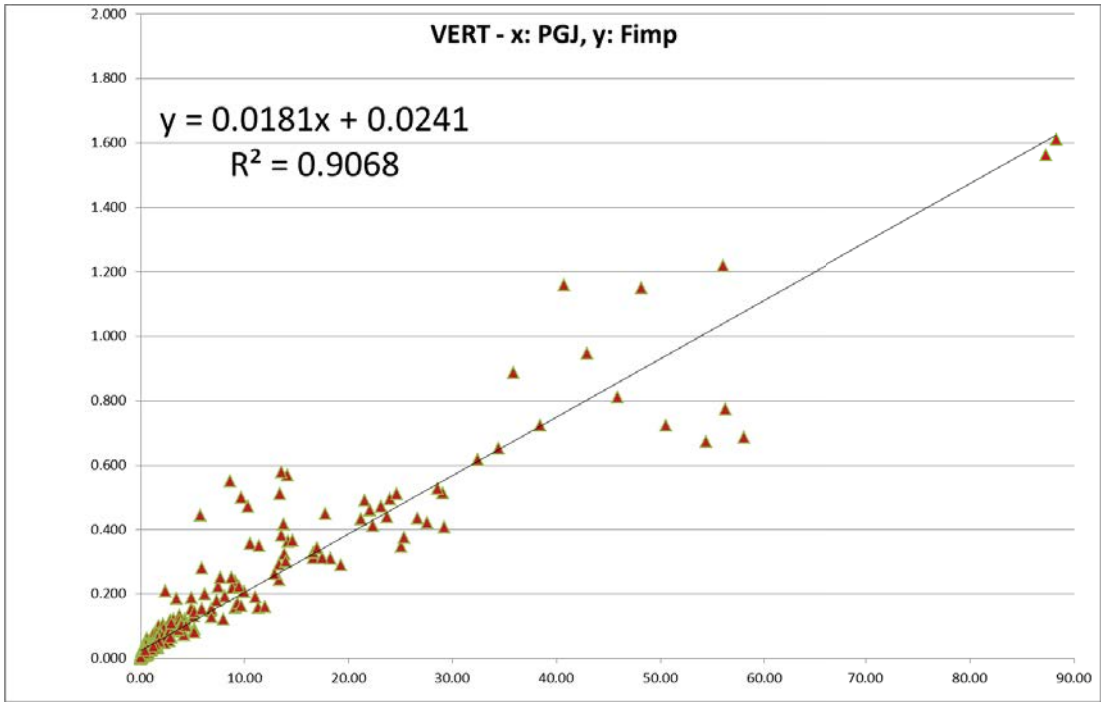

Figure 34. Correlation PGJ-Fimp determined through (5), for horizontal and vertical components

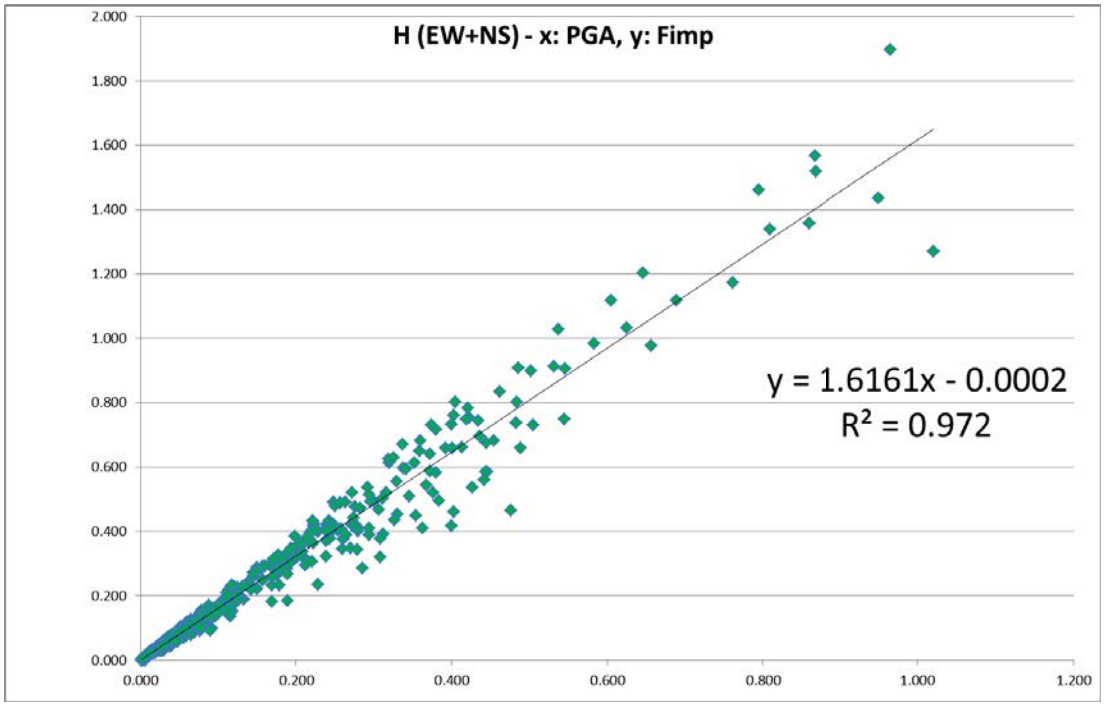

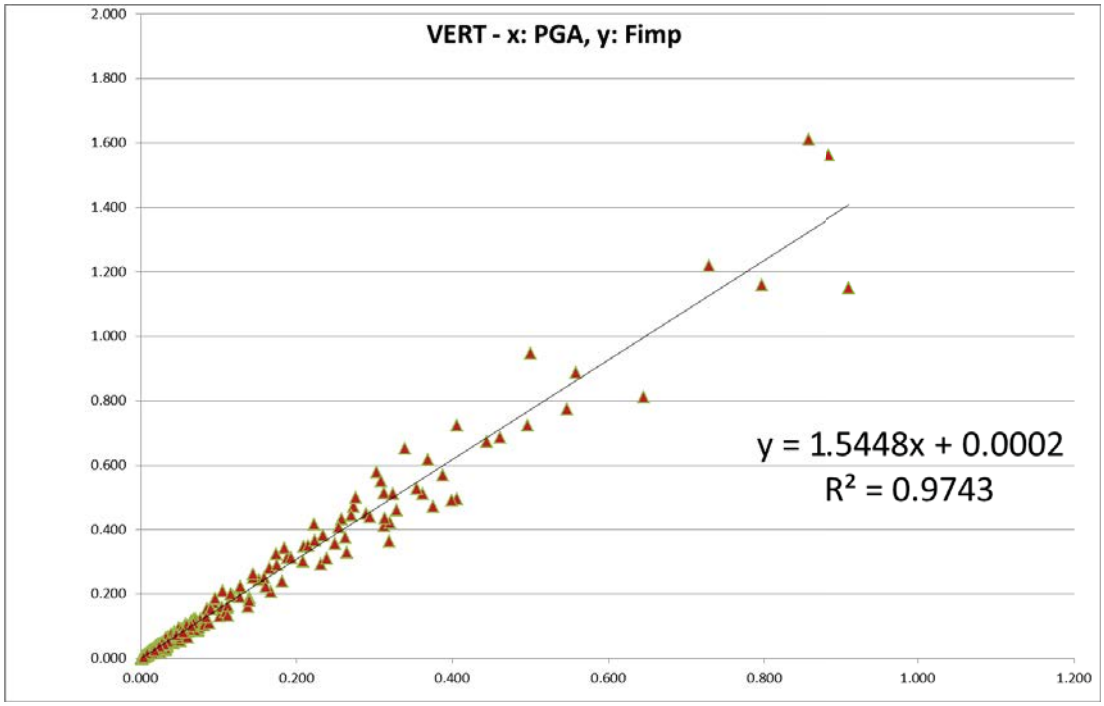

Figure 35. Correlation PGA-F_{imp} for horizontal and vertical components

The PGA-F_{imp} graphs show an excellent correlation: the relationship between peak ground acceleration and peak impulsive force is well described by the trend line.

Acceleration, jerk and impulsive force are generated by a chaotic phenomenon: the analytical operations carried out for determining jerk (through derivation of acceleration) or for calculating the impulsive forces are processes which do not correspond to a predefined analytical function.

The correlation between PGA and impulsive forces, obtained through elaboration of the main seismic events in Italy, is an intrinsic property of the events themselves. The fact that the cor-

relation has a coefficient of determination very close to 1 represents an excellent support for estimating the impulsive actions based on ground acceleration data.

The correlation obtained through statistical analysis between PGA (s) and PGJ (g/s) and between PGA (g) and maximum impulsive force per unit mass (g) are summed up in the following expressions (H stand for horizontal component, V stands for vertical component):

$$PGJ_H = 44.705\, PGA_H - 0.221 \quad (6)$$

$$PGJ_V = 77.526\, PGA_V - 0.795 \quad (7)$$

$$F_{imp,max,H} = 1.616\, PGA_H \quad (8)$$

$$F_{imp,max,V} = 1.545\, PGA_V \quad (9)$$

In order to validate the relationships determined through statistical analysis on Italian seismic events, we operate a comparison between the jerk values elaborated by Tong et al. [11] for the 1999 Chi-Chi earthquake in Taiwan and those calculated from PGA with expressions (6-7).

Station	Component	PGA (g)	PGJ (g/s) (Tong et Al.)	PGJ (g/s) (Mariani, Pugi)	PGJ delta vs Tong et Al.	F_{imp} (g)
CHY028	EW	0.630	21.50	27.94	30%	1.018
	NS	0.764	26.30	33.93	29%	1.235
	VERT	0.342	23.20	25.72	11%	0.529
TCU095	EW	0.378	13.80	16.68	21%	0.611
	NS	0.712	31.80	31.61	-1%	1.150
	VERT	0.255	19.80	18.97	-4%	0.394

Table 6. Comparison between the elaborations of Tong et Al. (2005) [11] and Mariani and Pugi (2020)

CHY028 station yields a difference of about 30% for the horizontal component. The difference is rather high, but it drops to 11% for the vertical component. Given the fact that the seismic event in Taiwan has no relation whatsoever with the Italian events and that the analytical procedure for calculating jerk (based on numerical differentiation) has been carried out independently, the result is satisfactory. Considering that the impulsive phenomenon is particularly associated to the vertical component, the value of 25.72 g/s estimated through (7) is in good agreement with the 23.20 g/s in Tong et Al. Moreover, these jerk values are rather high, definitely higher than the 10 g/s threshold considered the cause of important damages on buildings: the values of 25.72 and 23.20 g/s would result in similar effects induced on the structures.

A surprisingly high agreement is obtained for TCU095 station where the peak ground jerk for the NS component is practically coincident with the value calculated through (7): 31.61 vs. 31.80 (g/s). Also, the vertical jerk component is very close: 18.97 vs 19.80 g/s.

The statistical investigation carried out on jerk should be completed with the analysis of the frequency content. In fact, the effects of seismic motion depend on the way they are filtered by the structures: a reliable model for the evaluation of jerk impulsive action effects on structures requires a frequency analysis which could be carried out through the study of the mean period from Fourier amplitude spectra.

The definition of a statistical value of the mean period T_m would provide a realistic estimation of the main frequencies of acceleration and jerk.

The mean period T_m calculated from Fourier spectra has no relations with peak ground acceleration, peak ground jerk or maximum impulsive forces. Therefore, the investigation on the mean periods is carried out comparing directly the T_m values of the 447 station records considered. Some stations yielded T_m values significantly far from average due to local site effects. Since the scope of the analysis is the pursuit of a T_m value which could be representative of acceleration and jerk for generic events, it is preferable to associate it to the median value rather than the mean. The median value is less influenced by extremely large or small values and gives a better idea of which is the "typical" value.

Figures 36-41 report for the three components of acceleration and jerk the following information:

- the mean period T_m for each station considered. The graphs also show the mean value (black line) and the median value (red line) which in all the cases is lower than the mean.
- the frequency distribution with discretization of the periods in intervals of 0.1 s for acceleration and 0.025 s for jerk

Vert.	0.506 (15% for 0.300)	0.078 (28% for 0.075)

Table 7. Representative T_m for acceleration and jerk

From the analysis of the Fourier spectra it is evident that the main jerk frequencies are much higher than the acceleration ones. This aspect was already clear by the comparison of the Fourier spectra elaborated for Castelluccio di Norcia records of 2016 Norcia earthquake (Figures 27-29). This highlights the very nature of jerk which can be associated to the impulsive content of acceleration.

Moreover, while for acceleration there are not significant differences among the horizontal and vertical components, all characterized by $T_m \cong 0.500$ s, for jerk the difference is substantial ($T_m \cong 0.100$ s for horizontal components and $T_m \cong 0.075$ s for the vertical).

Therefore, jerk consists of higher frequency than acceleration and the vertical component accentuate this characteristic with respect to the horizontal components.

Jerk vertical component is particularly important since it represents the most impulsive content of seismic motion.

The conception that buildings, being designed to resist vertical loading, can undergo impulsive seismic action without damages while they suffer only the horizontal seismic action effects, is definitely overcome.

Moreover, in lights of the study on jerk, the negative effects of the vertical seismic component involve failures triggered by the rapid alternation of compression and decompression induced by vertical vibrations.

The seismic motion is a dynamic phenomenon; thus, the structural response is totally different from that under static loading.

Where the main frequencies of the seismic motion are close to the fundamental frequencies of buildings, seismic effects undergo maximum amplification and structural elements are subject to the most demanding actions.

Studying the different building typologies one can identify the cases where jerk effects may be critical and potentially cause damages: e.g., the fact that jerk mean periods are close to fundamental periods of masonry buildings suggests to investigate the link between impulsive forces and local damages such as masonry disaggregation and connection failures.

6 EFFECTS OF IMPULSIVE ACTIONS ON BUILDINGS

During this research, the few available studies on the variation of seismic acceleration were collected. Based on the various considerations of the authors and the results of this work, the following 7 aspects may be highlighted:

1) Inertial force induced by acceleration and impulsive action due to variation of acceleration are two complementary aspects: both should be considered when assessing the structural behavior (Tong et Al. [11]);
2) During 1999 Chi-Chi earthquake acceleration records obtained from sensor placed at different levels of seven-story RC building showed that jerk amplification is substantially similar to that of acceleration (Tong et Al. [11]);
3) The attenuation of the Jerk design response spectrum with respect to the elastic spectrum is lower than what occur for acceleration. For low periods (rigid structures) the impact reduction factor R_J is practically equal to 1, so the jerk design response spectrum is almost coincident with the elastic one (Haoxiang He et Al. [15]).
4) In general, improving ductility jerk effect will reduce, that is, the impact reduction factor R_J increases, in a manner similar to the behavior factor q for acceleration spectra (Haoxiang He et Al. [15]). For the horizontal components of the seismic motion, useful information for design purposes are given by the jerk response spectra illustrated in Figures 42-43 (Haoxiang He et Al. [15]).
5) The propagation of jerk vibrational waves is directly related to stress concentration and local damages, which in homogeneous material are initiated by molecular bond separation (Y. Xueshan et Al. [16]). In the case of masonry, it comes naturally to extend this concept to the macroscopic level of stones separation for mortar disaggregation.
6) In existing masonry buildings, strengthening interventions aimed at confining the structural elements prevent local concentration of stresses and improve the response with respect to jerk (Sofronie [17-18]). Considering the short duration of the impulsive action and the rigid-brittle behavior of masonry, such interventions may be verified in terms of resistance. In general, in existing masonry buildings, it is crucial to ensure resistance with respect to local damages such as masonry disaggregation and failure of connections between different structural elements.

7) The effects of jerk are particularly important in vertical direction. In fact, the vertical components are more impulsive than the horizontal ones, as described by the lower mean period in Fourier spectra (Table 7).

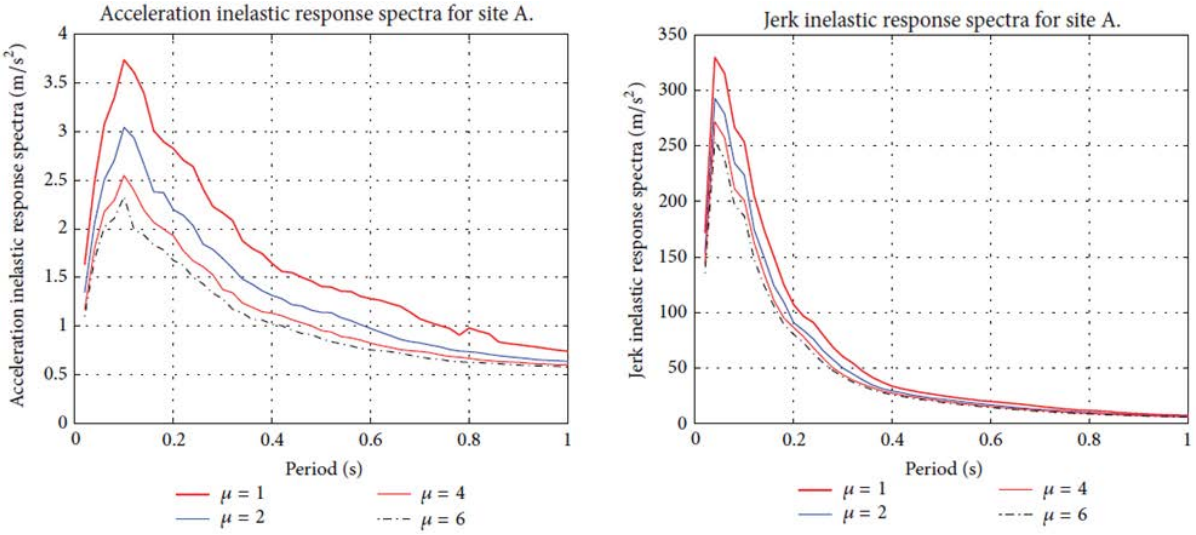

Figure 42. Acceleration and jerk inelastic response spectra for site A.
Statistical elaboration by Haoxiang He et Al. [15]

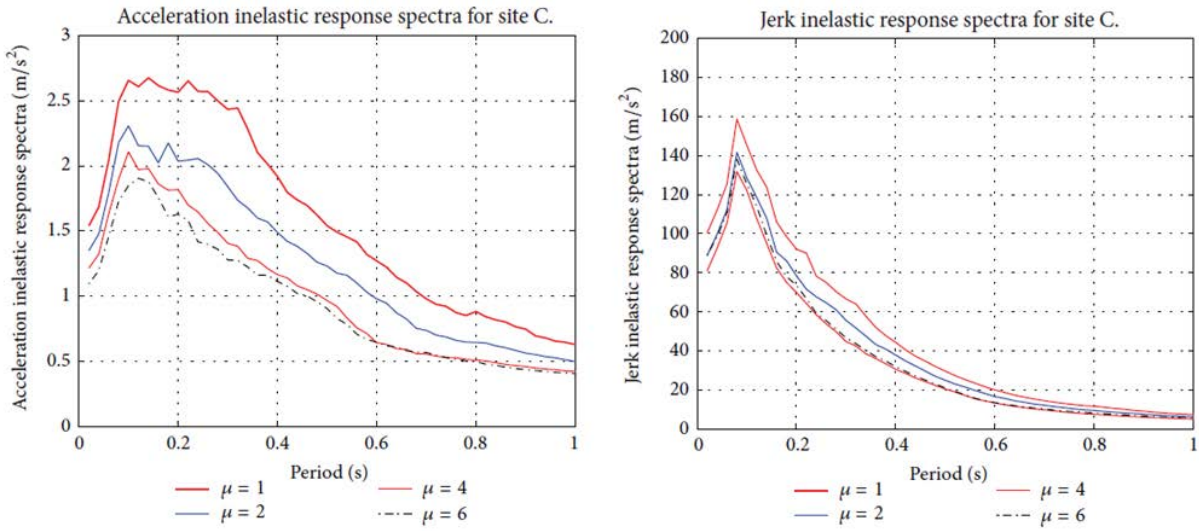

Figure 43. Acceleration and jerk inelastic response spectra for site C.
Statistical elaboration by Haoxiang He et Al. *[15]*

In light of the correlation between seismic jerk and physical damage of materials and structural elements during a seismic event, some considerations on seismic monitoring activity should be made.

At the moment, drift ratio, that is the relative displacement between two floors divided by the vertical distance between them, is the main parametric indicator of damage condition in a monitored building [19].

This parameter is monitored through software processing real-time measurements of displacements acquired through double integration of accelerometer time-series data. Other mon-

itored parameter are the periods of vibration, the peak ground acceleration (PGA) and peak structure acceleration (PSA), but only in the two horizontal direction X and Y.

Drift ratio is truly representative of damage condition in framed steel or RC structures; but in masonry structures, very rigid and strongly characterized by brittle types of failures, this parameter appears less consistent with respect to jerk monitoring.

The difference between the two parameters is also the possibility to represent through jerk the spatial effects of seismic motion, including the vertical component: drift ratio completely disregards this aspect.

Furthermore, jerk monitoring may provide important information on the assessment of local failures in other structural typologies: e.g. joint failures in steel frames [20, 21].

Given the relation between high values of impulsive forces and damage in areas with high stress concentration, the maximum values of jerk (PGJ and PSJ) play a significant role in the assessment of the negative effects induced by the seismic motion.

Placement of triaxial jerk sensor, available for some years now [16], or the real-time analytical calculation of jerk time series, may further enhance the quality of the monitored information with clear benefits on the quick definition of the damage scenarios, one of the main objectives of seismic monitoring.

The negative effects of the vertical jerk component are highlighted by the impulsive nature of the phenomenon and the high vertical stiffness of the structure. Therefore, amplification effects due to high similarity between fundamental period of the structures and jerk mean period should be investigated.

Jerk is characterized by high frequencies. The statistical analysis on the main recent seismic events in Italy found that the representative mean period of the vertical jerk component is about 0.075 s, which is very close to the fundamental period of vertical vibration of many rigid structures, such as masonry buildings.

To be more specific about the amplification of the structural response in terms of displacements and internal actions, considering that seismic input is a combination of many harmonic excitations, we can refer to the theory of driven harmonic oscillators with viscous damping.

Study of the simple oscillator leads to an amplification factor C_{ampl} given in expression (10):

$$C_{ampl} = \frac{1}{\sqrt{\left(1 - \frac{T_1^2}{T^2}\right) + 4\,\xi_{eq}^2\,\frac{T_1^2}{T^2}}} \tag{10}$$

where: T_1 is the fundamental period of the structure; T is the period of the applied force (in this case coincident with the mean period of vertical jerk component); ξ_{eq} is the equivalent viscous damping coefficient.

By applying (10) we get that with a period of the applied force T = 0.075 s, the vertical impulsive effect is amplified for fundamental periods T_1 in the range [0 - 0.105 s] with maximum amplifications for T_1 in the range [0.050 s – 0.090 s].

With T = 0.050 s, the amplification is obtained for T_1 in the range [0 - 0.070 s] with maximum amplifications for T_1 in the range [0.040 s – 0.060 s].

With T = 0.050 s, the amplification is obtained for T_1 in the range [0 - 0.140 s] with maximum amplifications for T_1 in the range [0.075 s – 0.120 s].

In all the examined cases, amplification occurs for ranges of vertical fundamental periods T_1 which include those of a wide class of masonry buildings. This aspect is crucial for determining the vertical impulsive actions along the building elevation and their effects on the structural elements.

Moreover, the structural effects of the impulsive actions are also affected by jerk variation, that is, the time derivative of jerk referred to as snap [21-22]. We can imagine that the variation of acceleration generates a "jolt" which in turn contains a series of smaller "jolts" related to higher-order derivatives. Snap can be represented in space as a vector with one component tangent to the acceleration path (thus parallel to jerk) and one orthogonal component associated to the change of direction. When the changes of direction are particularly important, strengthening elements able to resist "jolts" along different and suddenly variable directions should be designed. Therefore, the strengthening intervention should provide resistance distributed as much as possible.

7 CONSTRUCTION DETAILS FOR MASONRY ELEMENTS STRENGTHENING

In light of the findings of this research about the effects of impulsive actions on existing masonry buildings, two construction details of particular strengthening interventions are presented.

The interventions aim at enhancing the resistance of structural discontinuity regions, load application points, stress concentration areas, joints, etc., in agreement with current Technical Standards (Italian guidelines: CNR DT 214/2018 - Istruzioni per la valutazione della robustezza delle costruzioni, §6.1.1).

This work highlighted the importance of masonry confinement and improvement of connections between distinct structural elements, both in vertical and horizontal planes. The interventions aim at enhancing structure robustness through three-dimensional ties.

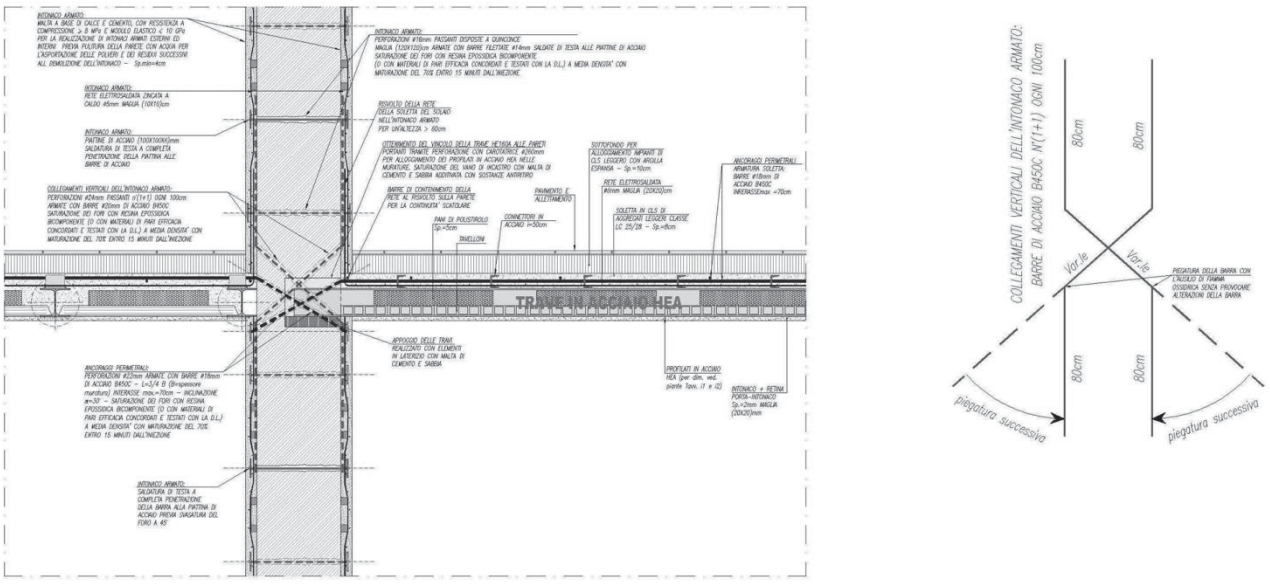

Figure 44. Vertical connection between reinforced mortar and internal masonry pier in correspondence of a steel slab (original drawings by Massimo Mariani)

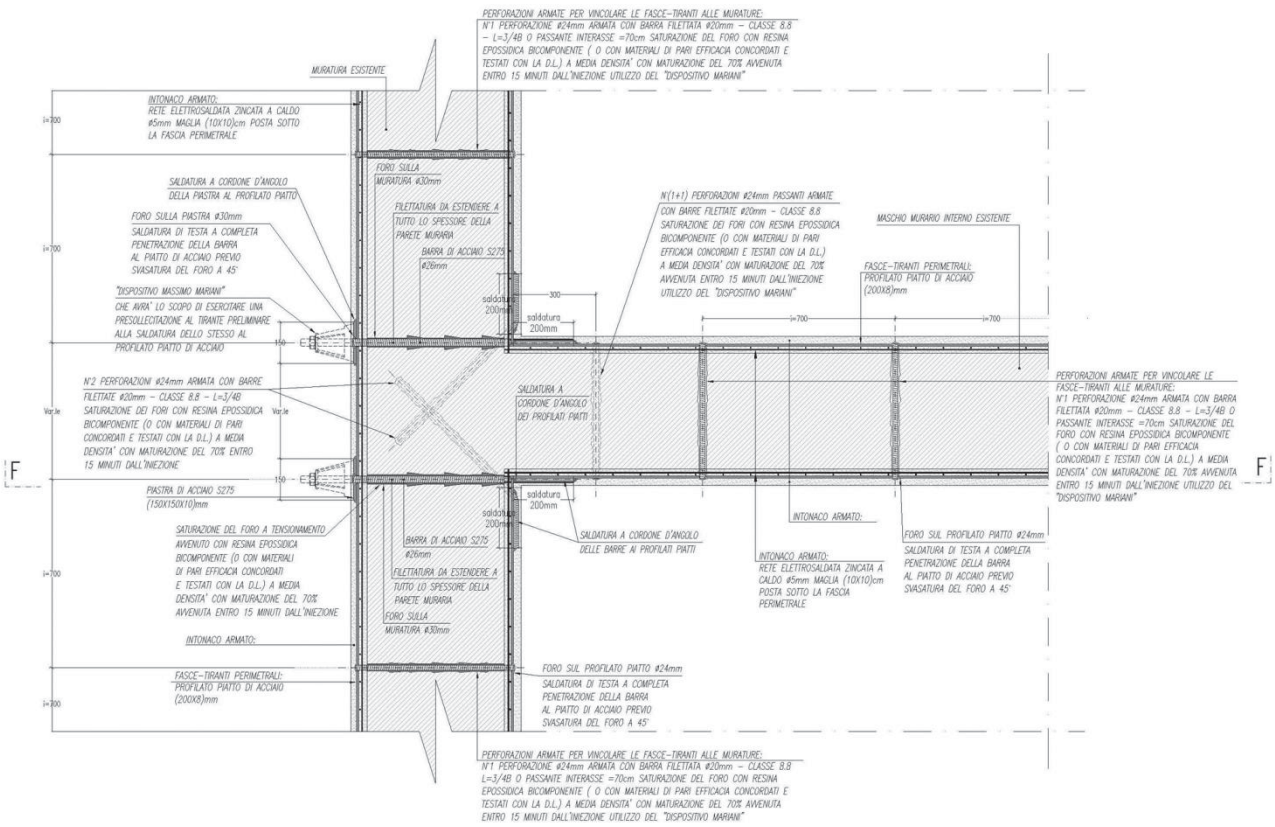

Figure 45. Horizontal connection between orthogonal masonry piers in presence of reinforced mortar on both faces and internal wrapping with steel plates connected to masonry through the "Dispositivo Massimo Mariani", a device allowing to manually prestress the connection jacks in order to enhance the collaboration between steel plate and masonry structure. Prestress is exerted through torque wrench; ties and steel plate are fully covered by the mortar (original drawings by Massimo Mariani)

8 CONCLUSIONS

This work outlined that the variation of acceleration covers an important role in the design of strengthening interventions on existing structures, in particular for masonry buildings. The variation of acceleration is responsible of local failures such as masonry disaggregation and loss of connection between structural elements.

In this context, particularly important is the vertical component of the seismic motion. In that direction the structures feature a non-dissipative behavior and the seismic input may undergo amplification related to resonance phenomena.

As indicated by current technical standards, the seismic evaluation of a structure cannot prescind form an accurate assessment of the local capacities. The latter should always precede analyses that count on the structural dignity of the elements and assess the behavior of the structure as a whole.

This research will be continued by the Authors with the objective of dimensioning the strengthening elements applied in the proposed construction details and providing design solution and analysis methods that take into account the effects of the three-dimensional impulsive actions.

ACKNOWLEDGEMENTS

The authors appreciate the support of colleagues and collaborators that contributed to this research. They would like to thank Luca Ranocchia, Alessia Travanti and Nicola Pero Nullo for the composition and drawing of the construction details; Fulvio Massimo Mariani for the selection of records on ITACA database; Alessio Francioso for the elaborations of Fourier spectra. They also wish to thank Aedes Software for the software Seismic3D developed by Francesco Pugi as part of applied research activities.

Keywords: Stability, Riera, RC Containment, Impact, Aeroplanes.

Abstract. *Nuclear power plants are considered vital structures for generating electricity worldwide. In general, a nuclear power plant structure includes two containments, external and internal ones. The internal containment surrounds the main reactor as a primary shield. The external containment is considered as a final shield between the internal of the reactor and the environment. This paper studies the integrity of external containment after being hit by different aeroplanes. Analytical model is constructed using ANSYS® software in order to simulate the RC containment including the circular shell and dome subjected to impact of different aeroplanes. An existing design of the typical external containment is used in modeling. According to ASCE 58, the circular wall and the dome are considered lined with inner steel liner plates in order to reduce the radiation emission to the environment in case of accidents. The studied external RC containment is subjected to the impact of different aeroplanes, Boeing 747-200c and Boeing 707-320. Riera Method is used to simulate the impact load with respect to time at the outer surface of the external shell, at a vertical level of 30m above the upper foundation level. The impact load is concentrated at 16 nodes at the outer surface of containment. Heavy weight concrete is used for the RC containment with a compressive strength of 60MPa. The analysis of RC containment after the impact of the different aeroplanes showed the displacement, velocity, acceleration and the shape of the cracks. It was found that the containment is stable after the impact of an aeroplane, but clear damage affected the elements within the impact region. From the impact of different aeroplanes on RC containment, Boeing 747-220c is the most damaging according to results concerning the displacement, velocity and acceleration on the RC containment.*

1 INTRODUCTION

Nuclear Power Plants include several structures such as the internal, external containment structures and others. The external RC containment structure is the physical building that separates the reactor from the outer atmosphere, and houses the internal containment structure that surrounds the nuclear reactors and the associated chain reactions [1]. Most typical current external containment structures ranges from 150 to 200 feet tall with a diameter of approximately 150 feet. The RC containment structure should be airtight to prevent the release of radioactive particles into the atmosphere. The secondary containment is necessary when radiation levels at the site boundary exceed the allowable limits [1], [2].

Concrete containments for Boiling Water Reactor Mark II and parts of Mark III are mainly reinforced deformed bar concrete, whereas for the Pressurized Water Reactors both deformed bar and pre-stressed concrete containments are common. The design loads consist mainly of internal pressure, temperature, tornado, and earthquake, all of which result in different states of stresses in the concrete elements such as tension, compression, radial and tangential shears. These loads are categorized as axisymmetric loads, such as the internal pressure and temperature, and non-axisymmetric loads, such as tornadoes and earthquakes [1]. In addition, most current external containment structures have been designed as RC structures. Concrete containment structures lined with steel are even more economical than steel containment structures for dry containment design [1]. This is attributed to the fact that a steel containment structure would require a concrete shield structure, thus concrete is required in either case, and the more economical choice is typically used.

The response of the containment structure due to impact of an aeroplane can be determined by equating the work done by the impact load to the strain energy produced in the structure through applying the three basic principles of mechanics: conservation of energy, conservation of linear momentum, and virtual work principle. In addition, in the evaluation of the aeroplane crash on the outer containment structure, the following steps are considered [3]:

- Global structural response including excessive structural deformations or displacements.
- Localized structural damage due to the effects of missile impact, including penetration, perforation, scabbing, that may lead to the failure of structural elements as a result of the effects of an aeroplane impact.

In the carried out analysis, the normal impact was chosen, according to Riera formulation, since it corresponds to the worst condition for the containment structure accident scenario. It was also assumed that the concrete may undergo gradual failure modes representing the progressive cracking and crushing of concrete itself caused by the abrupt stiffness changes [3]. Moreover in the impact analysis, the damping effect was considered to be negligible as it does not affect the maximum response to impulse loading. Moreover, concrete as a construction material is commonly used for biological shielding in nuclear power plants and atomic research and testing facilities [4].

1.1 Problem Definition

The damage caused by missile impact might lead to the leakage of nuclear radiation. Earlier research showed that RC containments with thicknesses greater than 1.4 m, permanent damage is negligible, whereas for thicknesses lower than 1.0 m considerable plastic strains occurred on opposite surfaces of the containment shell [5]. This is the case where the impact load of an aeroplane on the outer RC containment results from the effects of a finite amount of kinetic energy that depends upon the inertial and stiffness properties of the missile and

target structure [3]. This paper studies and evaluates the effects of impact caused by impact of an aeroplane Boeing 747-200c upon typical external RC containment of the nuclear power plants. Nonlinear response of such impact is studied then analyzed to identify the propagating damage in the containment structure. Two different aeroplanes were hitting the external RC containment, were made as parametric study to show the most damage aeroplane on the RC containment and its effect on displacement, velocity and acceleration of the RC containment.

1.2 Case Study

The studied RC outer containment consists of 3 major components, the cylindrical wall, the hemispherical dome, and the cylindrical base mat foundation as shown in Figure(1) at which the external RC containment wall is fixed to the foundation. In addition, based on an existing design, the cylindrical wall is assumed to be 1.2m thickness whereas the thickness of the RC hemispherical dome is assumed to be 1.05m [1]. The effective concrete cover is 150mm at both faces till the reinforcement. The height of the cylindrical wall from the top of foundation till the spring line is 36.45 m. The total height of containment from the top of foundation till the apex of the dome is 60m. The cylindrical wall and dome of the RC containment is axisymmetric, inner diameter of the containment is 45 m as shown in Figure (1).

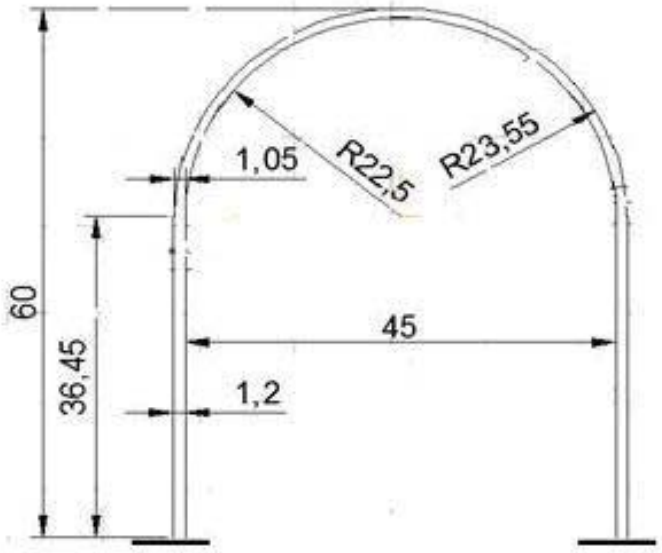

Figure 1: Section elevation of the RC containment wall and dome

The massive concrete containment structure was described as follows as per [2]. The RC dome is typically three and a half feet thick with two layers of reinforcement for the typical containment structure; #18 bars at 12 inches [6]. The cylindrical walls are even larger in order to carry the entire dead load including the shell to the base slab. The walls are at least four feet thick with #18 vertical bars at 12 inches for each face and #18 horizontal bars on both sides of the vertical reinforcing as shown in Figure (2).

Moreover, since the containment structure must be airtight to prevent any fission emissions from bypassing, and knowing that concrete as a material is porous, then the studied containment is assumed to have a steel liner on the entire internal surface. This lining thus acts as a part of the system for the concrete wall. Based on [2], [1] the required minimum thickness for the steel liner plates is a quarter of an inch; however, the studied existing design considered the steel liner plate of thickness three-eighths of an inch as shown in Figure (2).

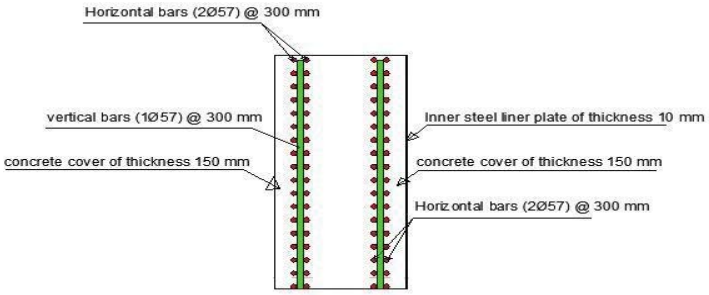

Figure 2: Cross section elevation details of shell wall reinforcement

2. MODELING

In the finite element model applied in ANSYS® software, the connection between the foundation and the cylindrical wall is assumed to be fixed. In addition, the local details in the RC containment structure, including penetrations, temporary openings, and embedded parts, were not considered in modeling. The meshing of the containment volume is as shown in Figure (3).

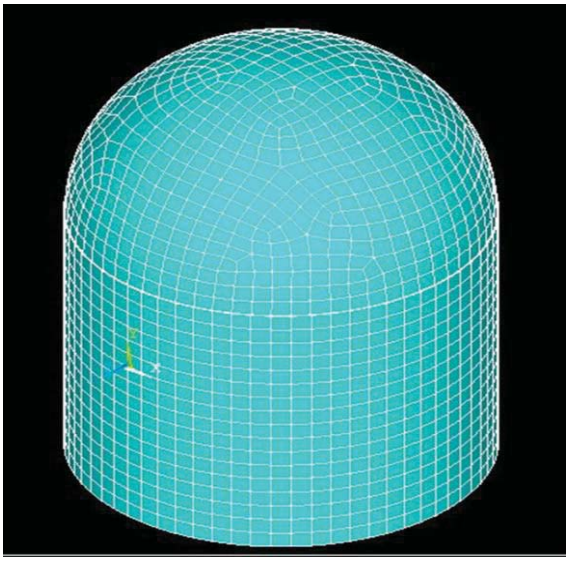

Figure 3: Meshing of the external RC containment building

2.1. Jet Impact Modeling on RC Containment

Impact loads due to the effects of a finite amount of kinetic energy that depends on the inertial and stiffness properties of missile and target structure, differs from the “impulse” load that is generally a force independent of the inertial and stiffness properties of missile and target. As a result of a jet impact, kinetic energy is transferred from the aeroplane to the building walls and thereby absorbed by the building components in the form of strain energy.

From literature review, it was observed that the Riera method is an efficient in evaluating damage of RC structures from severe impact loads. The riera method is an approximate method for constructing a force-time history for an aeroplane striking a rigid wall based on a known distribution of mass and crushing characteristics of the aeroplane along the length [7], [8]. This is the case where the riera approach assumes that the aeroplane can be represented like a soft missile. Moreover, it is assumed that as the aeroplane strikes the target, a part of it close to the target gets crushed and the remaining portion of projectile undergoes elastic deformation.

The basic assumptions of the Riera method [7] can be summarized in:

- The target is rigid
- The aeroplane axis is perpendicular to the target; angle of incidence is 90 degree.
- The aeroplane is separated into two parts, one being uncrushed and moving with velocity (v) and the other crushed with zero velocity.
- All crushing takes place within a local region adjacent to the rigid target.
- The crushing or material behavior of the missile is rigid-perfectly plastic.
- The crushed mass of the aeroplane moves with the target structure.

Consequently, some parameters clearly affect the impact scenario. Such parameters include the velocity and impact angles of the aeroplane, the mass and stiffness of the aeroplane as a function of the aeroplane length as shown in Table (1) [3].

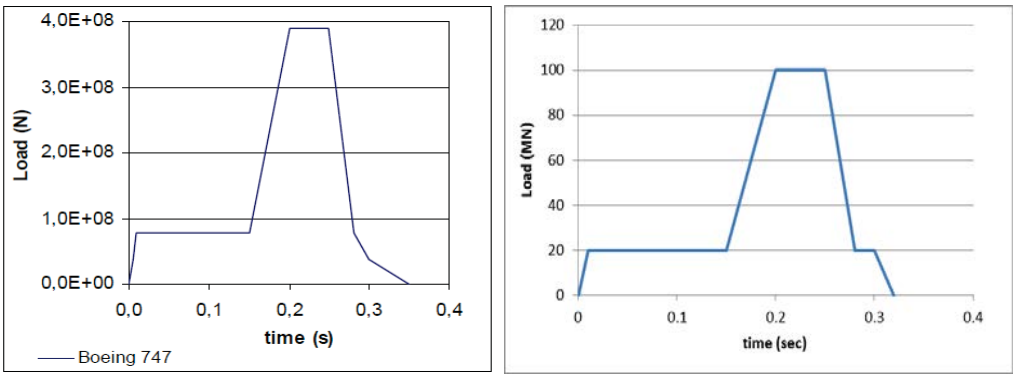
Air plane type	**Boeing 747-200c**	**Boeing 707-320**
Mass at take-off (Kg)	350000	150000
Engine mass (Kg)	4 x 21300	4 x8100
Impact speed (m/s)	269	272

Table 1: Parameters of different aeroplanes

Furthermore, it is assumed that the load versus time curve affect a constant equivalent area to the average of total cross-sectional area of fuselage and wings. Thus, the impact contact area of the Boeing 747-200c in the analysis model is assumed to be 37 m^2 [3]. Moreover, in this analysis, the load is assumed to act on 16 nodes as concentrated point loads on the outer external RC wall of the containment. Figure (4) shows a schematic of the distribution of the loads on the loaded nodes.

Figure 4: Impact load distribution on nodes in the impact region

The impact force, F(t), acting on the rigid fixed containment is calculated with the riera method as shown in Figure (5) [3].



(a)- Boeing 747-200c (b)-Boeing 707-320

Figure 5: Load-time history curve of different aeroplanes

The key formula in the computation of the force applied to the rigid target, F(t), or the impact force time history is given by equation (1) [8].

$$F(t)=Pc(x)+\mu(x)(dx/dt)^2 \quad (1)$$

where x (t) is the crushed length of the missile, the distance from the nose of the missile when uncrushed to the point at which crushing has progressed at time t, Pc(x) is the static force required to axially crush a cross-section of the missile at location x, and μ(x) is the mass per unit length at location x.

2.2. Containment Materials Modelling

2.2.1. Concrete modelling

The concrete material is assumed to be homogenous and isotropic. The compressive multi-linear stress-strain relationship for concrete [9], as defined by ANSYS®, is shown in Figure (6), and calculated by the following equations:

$$f_c = E_c \varepsilon \quad \text{for } 0 < \varepsilon < \varepsilon_1 \quad (2)$$

$$f_c = f_c' \quad \text{for } \varepsilon_o < \varepsilon < \varepsilon_{cu} \quad (3)$$

$$f_c = E_c \varepsilon / (1 + (\varepsilon/\varepsilon_o)^2) \quad \text{for } \varepsilon 1 < \varepsilon < \varepsilon o \quad (4)$$

$$\varepsilon_1 = (0.3 \times f_c)/ E_c \quad (5)$$

$$\varepsilon_o = (2 f_c)/ E_c \quad (6)$$

Where ε_1 is the strain corresponding to 0.3 f_c, ε_o is the strain at peak point, and ε_{cu} is the ultimate compressive strain [9].

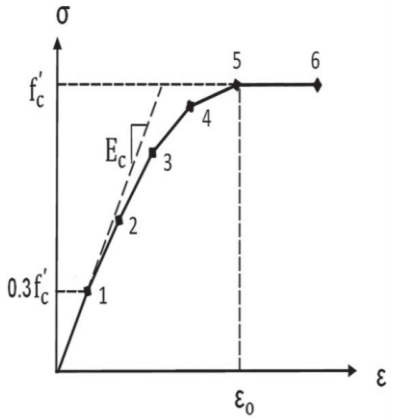


Figure 6: Uniaxial compressive stress-strain curve for concrete

Furthermore, the Poisson ratio for concrete is taken 0.2, and the modulus of elasticity, E_c, is calculated from Equation (7), whereas the modulus of rupture for concrete, f_r, is calculated from Equation (8) according to [10] specifications [9].

$$E_c = 4700\sqrt{f'c} \quad (7)$$

$$f_r = 0.62\sqrt{f'c} \quad (8)$$

In the analysis, the uniaxial compressive strength of concrete is assumed to be 60 MPa, whereas the uniaxial rupture stress f_r is assumed to be 4.8 MPa. Moreover, the shear transfer coefficients ranges from 0.0 to 1.0, with 0.0 representing a smooth crack (complete loss of shear transfer) and 1.0 representing a rough crack (no loss of shear transfer). This specification may be made for both the closed and open crack as shown in Table (2) [11], [12].

Input strength parameter	Values
Open shear transfer coefficient	0.3
Closed shear transfer coefficient	0.9
E (Modulus of Elasticity of concrete)(MPA)	36406.043

Table 2: Concrete strength input data

2.2.2. Reinforcing Rebar Modeling

The reinforcement rebar used in the containment structure is according to ASTM A-615 Grade 60 steel [13]. The stress-strain curve of the reinforcing bar is assumed to be elastic perfectly plastic as shown in Figure (7). Figure (7) also shows the bilinear material model defining the linear isotropic hardening of the reinforcement in which the yield stress is assumed to be 400 MPA, the elastic modulus, E_s is assumed 2×10^5 N/mm^2, and the Poisson ratio assumed 0.3 [13].

In addition, within ANSYS® software, rebar reinforcement is treated as an equivalent uniaxial material, the reinforcement layers were thus defined using the smeared reinforcement option of the SOLID65 element. The reinforcement is assumed to be uniformly spread throughout the defined layer and has uniaxial stiffness only in each direction. The amount of reinforcement was defined by material number and the orientation angles of the reinforcing bars. The shell wall reinforcements for horizontal and vertical are modeled as continuous layers inside the wall section, and the same applies for the dome reinforcements. The thicknesses of the reinforcement layers were calculated from Equation (9) [12].

$$h=A/s \tag{9}$$

Where h is the equivalent reinforcement layer in each direction, A is the cross section area of the reinforcement rebar, and S is the spacing between the reinforcement rebar in each direction.

2.2.3. Steel Liner Modeling

The (0.9375 cm) thick steel liner plate has a bilinear isotropic hardening plasticity model in which its yield stress is 165 Mpa as shown in Figure (8), and the elastic modulus, E_S, and the Poisson's ratio are assumed to be 2×10^5 N/mm^2 and 0.3 respectively [13].

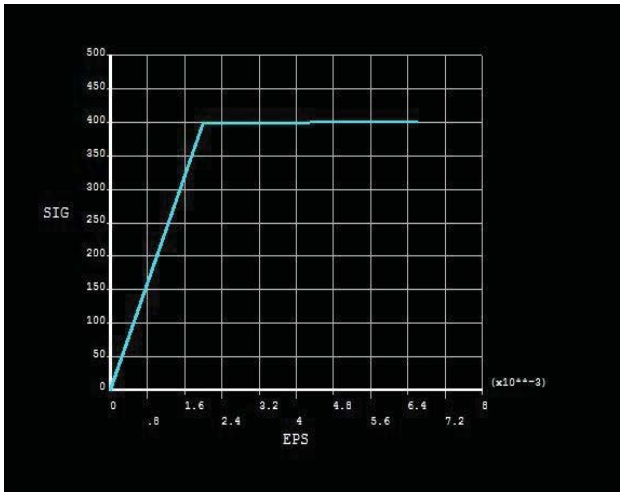

Figure 7: Stress strain curve for steel reinforcing rebar

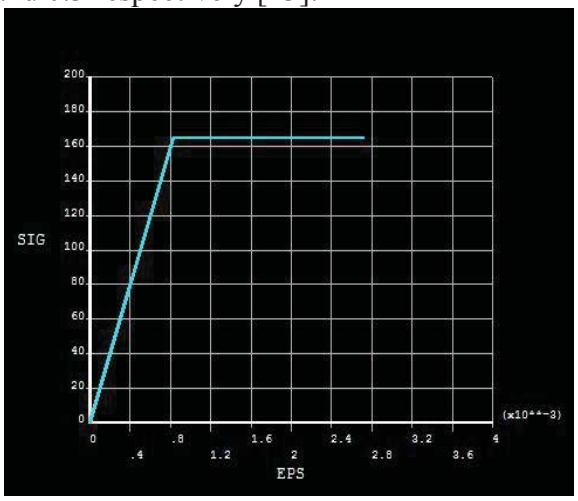

Figure 8: Stress strain curve for the inner steel liner plate

2.3. Used Model Elements from ANSYS® Library

2.3.1SOLID65 element

The SOLID65 element is used for the 3D modelling of the RC wall and dome. The solid element is capable of cracking in tension and crushing in compression. The element is defined by eight nodes having three degrees of freedom at each node: translations in the nodal X, Y, and Z directions and the isotropic material properties. The element has one solid material and up to three rebar materials. The orientation of any rebar layer is defined by two angles in degrees from the element coordinate system [12]. The assumptions for the SOLID65 element include that the concrete material is homogenous and isotropic where cracking is permitted in three orthogonal directions at each integration point.

2.3.2. SOLID45 element

The SOLID45 element is used for the 3D modeling for the inner steel liner plate. The

element is defined by eight nodes having three degrees of freedom at each node: translations in the nodal x, y, and z directions [12].

2.4. Failure criteria of concrete

The concrete material model predicts the failure of brittle materials. Both cracking and crushing failure modes are accounted for. The criterion for failure of concrete due to a multi axial stress state can be expressed in the form [14], [12]:

$$\frac{F}{fc} - S \geq 0 \tag{10}$$

Where:

F = a function of the principal stress state (σ_{xp}, σ_{yp}, σ_{zp}).

S = failure surface expressed in terms of principal stresses and five input parameters f_t, f_c, f_{cb}, f_1 and f_2 .

f_c = uniaxial crushing strength .

σ_{xp}, σ_{yp}, σ_{zp} = principal stresses in principal directions.

If Equation (10) is satisfied, the material will crack or crush.

However, the failure surface can be specified with a minimum of two constants, f_t and f_c. The other three constants default to [14]:

$$f_{cb} = 1.2\ fc \tag{11}$$

$$f_1 = 1.45\ fc \tag{12}$$

$$f_2 = 1.725\ fc \tag{13}$$

These default values are valid only for stress states where the condition is satisfied.

$$|\sigma h| \leq \sqrt{3}\ f_c \tag{14}$$

$$\sigma_h = \text{hydrostatic stress state} = \frac{1}{3}(\sigma_{xp} + \sigma_{yp} + \sigma_{zp}) \tag{15}$$

Both the function F and the failure surface S are expressed in terms of principal stresses denoted as σ_1, σ_2, and σ_3 where:

σ_1 =max (σ_{xp}, σ_{yp}, σ_{zp})

σ_3 =min (σ_{xp}, σ_{yp}, σ_{zp})

and $\sigma 1 \geq \sigma_2 \geq \sigma_3$. The failure of concrete is categorized into four domains:

1. $0 \geq \sigma_1 \geq \sigma_2 \geq \sigma_3$ (compression - compression - compression)
2. $\sigma_1 \geq 0 \geq \sigma_2 \geq \sigma_3$ (tensile - compression - compression)
3. $\sigma_1 \geq \sigma_2 \geq 0 \geq \sigma_3$ (tensile - tensile - compression)
4. $\sigma_1 \geq \sigma_2 \geq \sigma_3 \geq 0$ (tensile - tensile - tensile)

3. ANALYSIS OF RESULTS

A full transient dynamic analysis was applied with considering a small displacement transient response. The impact analysis is considered seven load steps in impact load-time curve as shown in Figure (5-a). The transient dynamic analysis requires two sets of initial conditions since the dynamic equations are of second order. The initial displacement, u_o, and

initial velocity ($\mathring{u}_o$) are assumed to be zero. In addition, the initial accelerations ($\ddot{u}_o$) are also assumed to be zero [5]. Furthermore, Damping was also included in the analysis through identifying the mass damping and stiffness damping. Thus, Rayleigh damping with coefficient β=0 was applied to the model. The coefficient α was reflected with a magnitude of 3.0 for the RC and 0.1 for the structural steel such that the damping matrix, C, was identified from equation (16) [5].

$$C=\alpha m+\beta K \tag{16}$$

The outer RC containment response under the impact load of an aeroplane Boeing 747-200c was studied at different time instances. Figure (9) shows the deformation shape of the impact region at time 0.2sec. It was observed that the elements within the impact region deformed in the direction of loading, which generated significant large tensile stresses at the inner surface of steel liner plates, and compressive stresses at the outer surface of concrete. The maximum displacement was found to be 46.658mm in the region of impact at time 0.2 sec. Meanwhile, other regions near the impact showed maximum displacements of 1.958 mm outside the containment as shown in Figure (10).

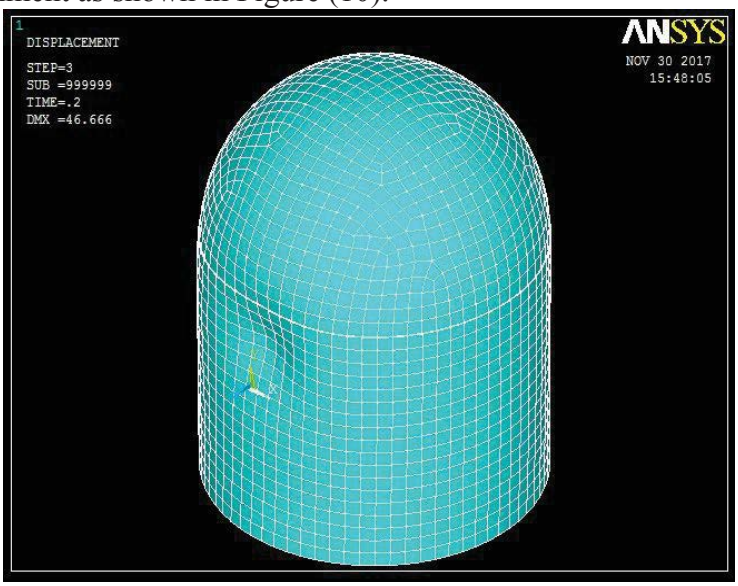

Figure 9: Deformation shape of the containment at time 0.2 sec

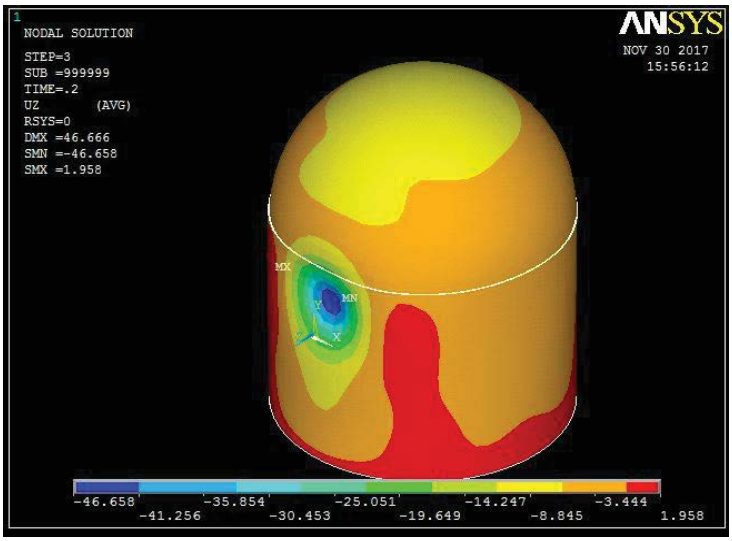

Figure 10: Displacement distribution of the containment at time 0.2 sec

The impact effect on the displacement of the RC containment

The maximum displacement of the RC containment is at the impact region which reached a value of 46.658 mm. The displacement vanished at a distance of 16 m from the impact region along the circumference direction from right and left hand sides as shown in Figure (11).

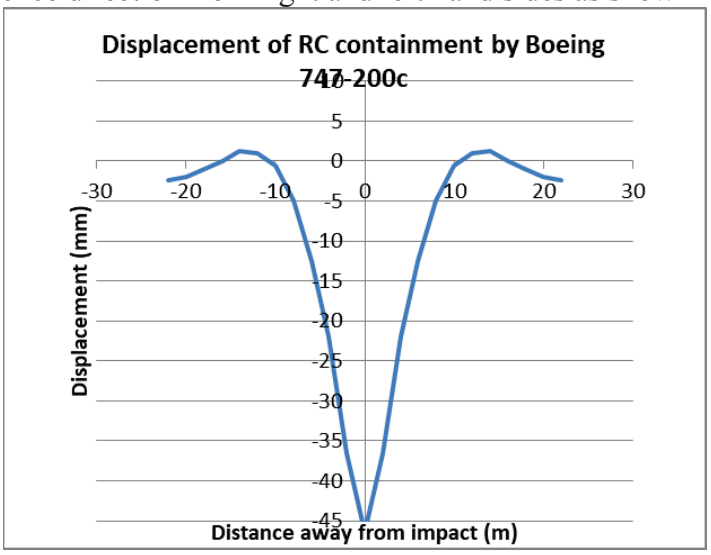

Figure 11: Containment displacement with respect to distance from the impact region at time 0.2 second

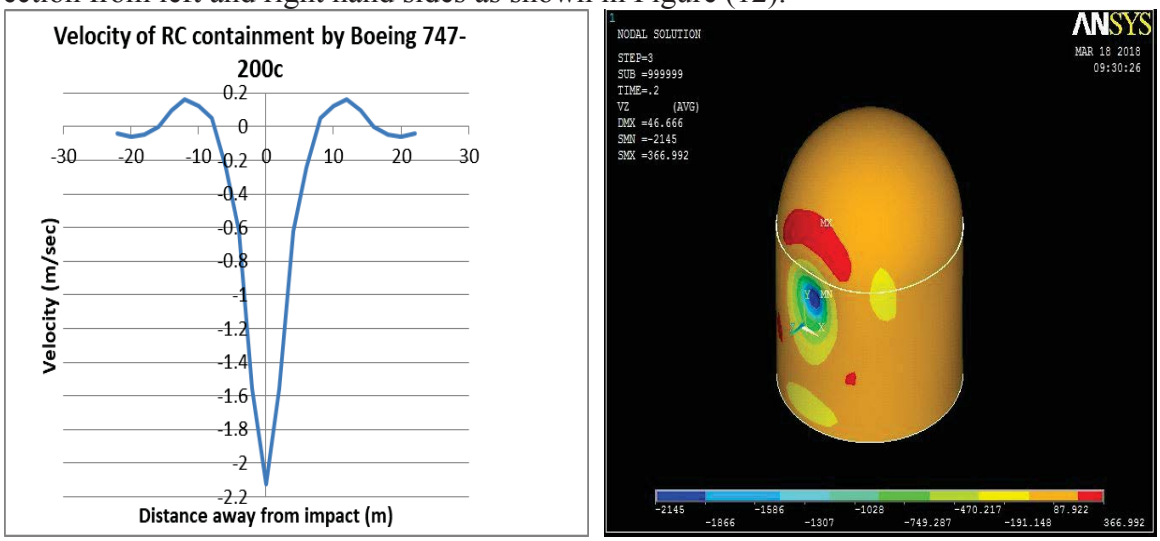
The impact effect on the velocity of the RC containment

The velocity of the RC containment reached a value of 2.145 m/sec at the impact region. The velocity vanished at a distance of 16m from the impact region along the circumference direction from left and right hand sides as shown in Figure (12).

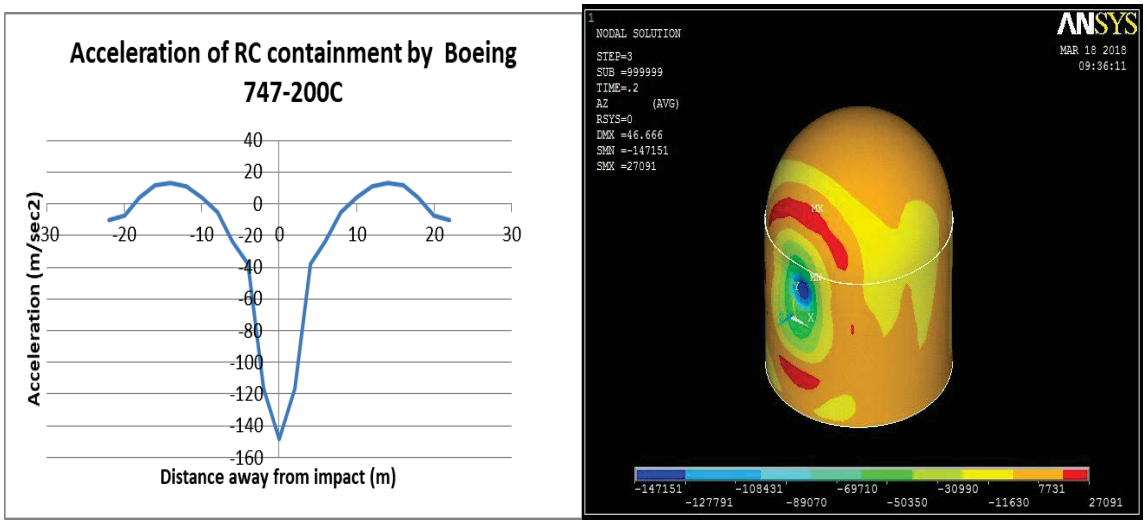


(a)- Velocity of the RC containment along the circumference (b) - Velocity distribution of the RC containment

Figure 12: Velocity of the RC containment due to impact of an aeroplane Boeing 747-200c at time 0.2 second

The impact effect on the acceleration of the RC containment

The acceleration of the RC containment reached a value of 147.151 m/sec^2 at the impact region in direction of loading. The acceleration vanished at a distance of 18m from the impact region along the circumference direction as shown in Figure (13).



(a)- Acceleration of the RC containment along the circumference (b)- Acceleration distribution of the RC containment

Figure 13: Acceleration of containment with respect to distance away from impact region at time 0.2 second

The impact effect on the cracks of the RC containment

From the previous mentioned results, thus, the elements within the impact region were clearly crushed. In addition some tension cracks (flexure cracks) appeared at the bottom of the fixation of containment. In addition, shear cracks appeared far from the impact region as shown in Figure (14). The failure criterion for the concrete built in Ansys12 due to a multi-axial stress state was used to identify cracks. This is the case where in a concrete element, cracking occurs when the principal tensile stress in any direction lies outside the failure surface. After cracking, the elastic modulus of the concrete element is set to zero in the direction parallel to the principal tensile stress direction. In addition, crushing would occur when all principal stresses are compressive and lies outside the failure surface. Consequently, the elastic modulus is set to zero in all directions, and the element effectively disappears [15], [12]. It was observed that the RC containment remained fully intact after the impact of an aeroplane, and the damage region extended 34m from the impact region of aeroplane at both sides of the impact. The severe damage was clear in the impact region of the studied aeroplane.

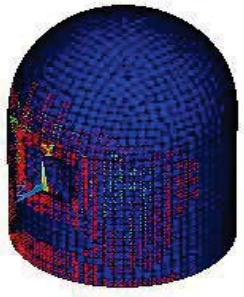


Figure 14: Crack propagation within the RC containment

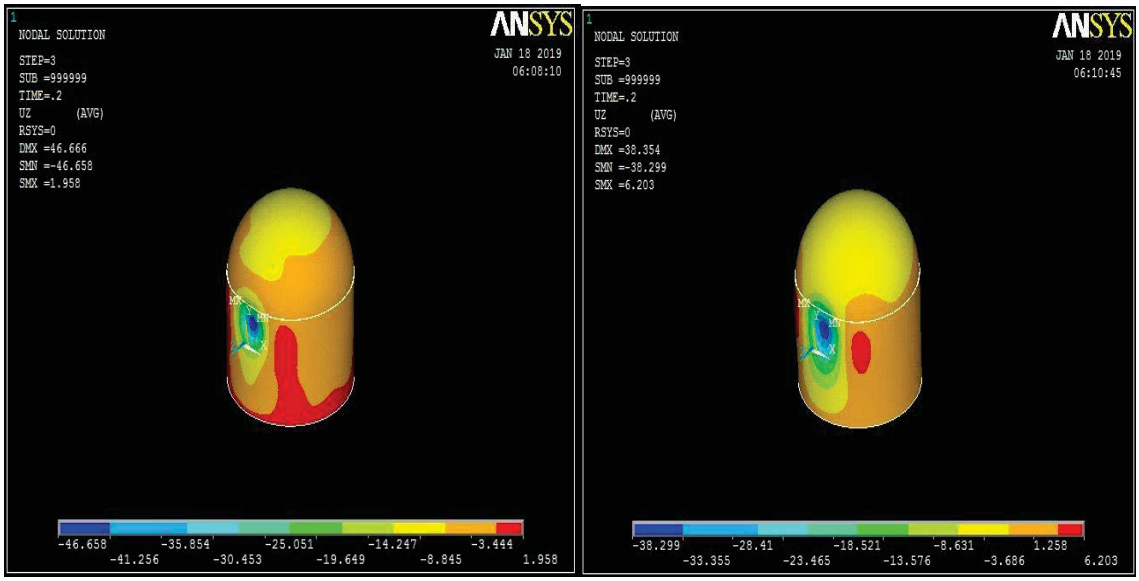
The effect of different aeroplanes impact on RC containment

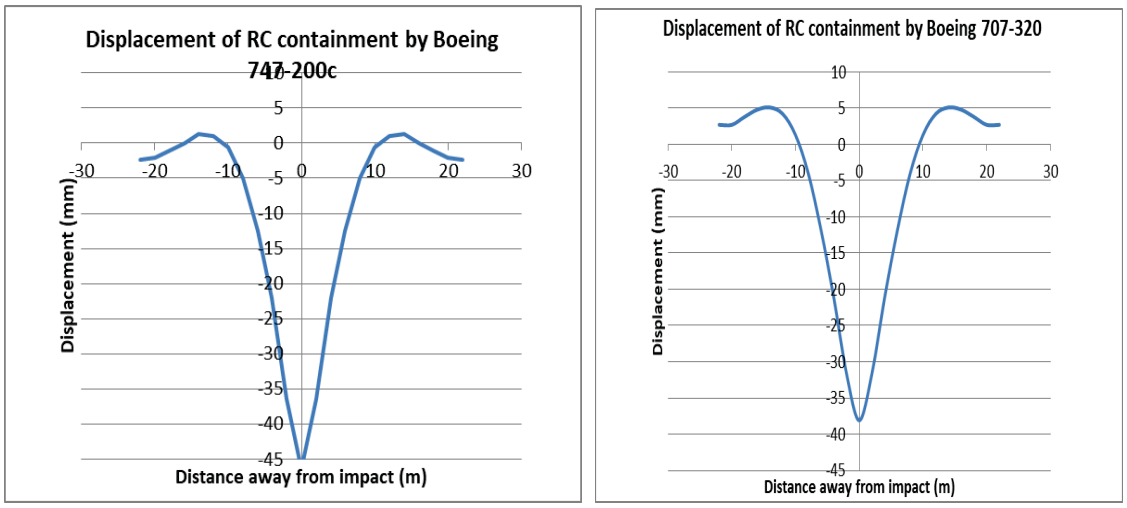
The parameter used in this model is modeling the studied RC containment to be hit with

different aeroplanes such as Boeing (747-200c) at speed of 269 m/sec, Boeing (707-320) at speed 103 m/sec. This is in order to see the effects on the displacement of RC containment as shown in Figure (15 (a),(b),(c),(d)). The two aeroplanes impact varies according to velocity, mass and the size of the effective impact area. This effective impact area is calculated as the area of a circular with a diameter equal to the maximum fuselage diameter (maximum body diameter) of each aeroplane.

The maximum displacement of RC containment reached a maximum value of 46.658mm on being hit with Boeing 747-200c in contrast to Boeing 707-320 where the displacement reached 38.299 mm as shown in Figure (15). It was observed that the displacement of the RC containment due to the impact of Boeing 747-200c was greater than the impact of Boeing 707-320 by 17.91%.



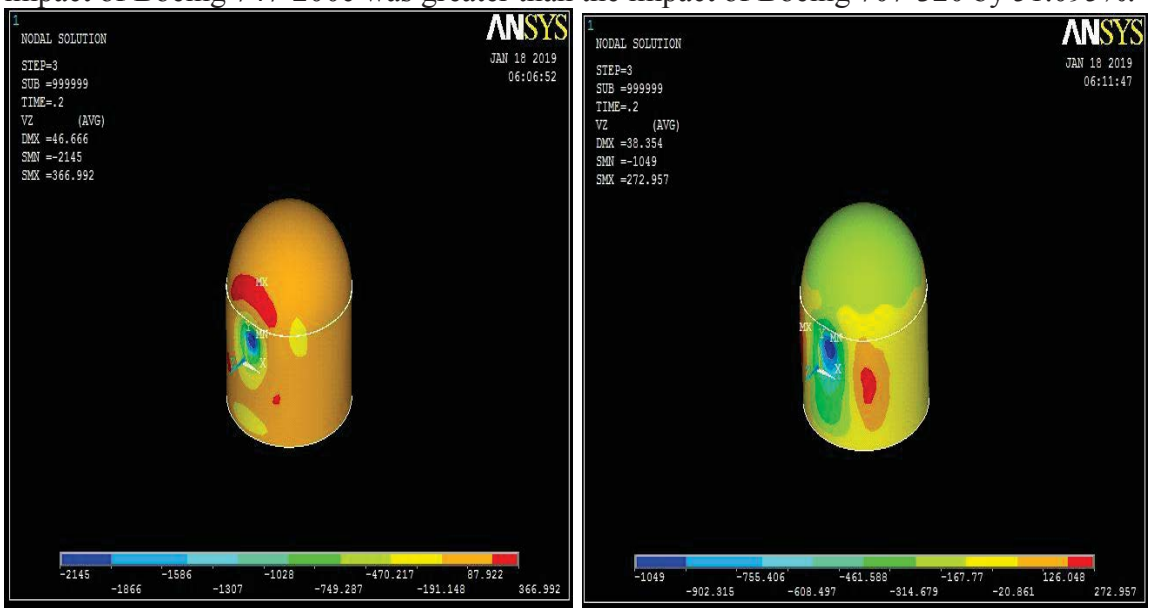
(a) Impact of Boeing 747-200c (b) Impact of Boeing 707-320



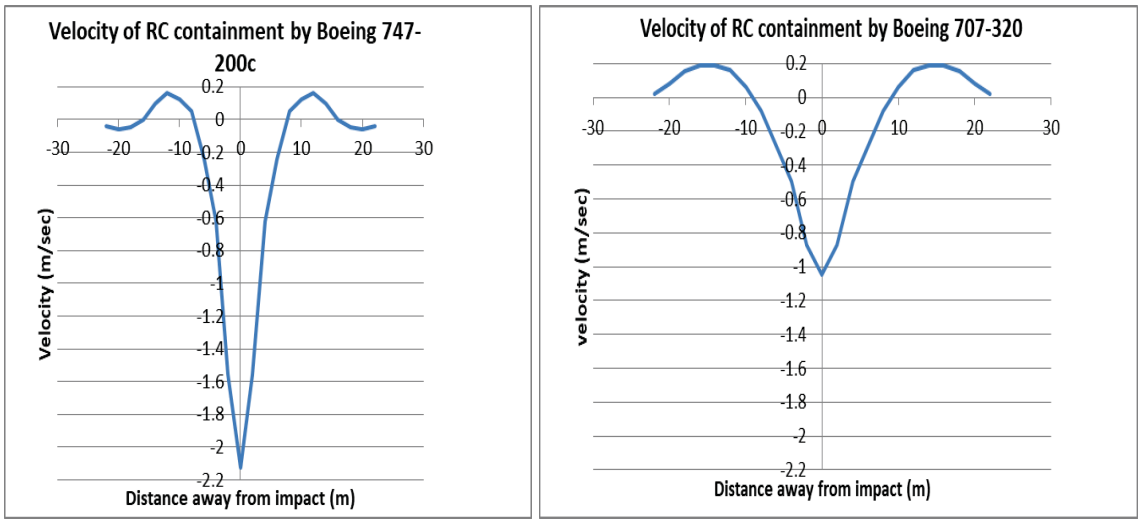
(c) Impact of Boeing 747-200c (d) Impact of Boeing 707-320

Figure 15: Displacement of RC containment due to impact of different aeroplanes at time of 0.2 second

The velocity of the RC containment reached a value of 2.145 m/sec due to impact of Boeing 747-200c at 0.2 second as shown in Figure (16 (a)). The velocity of the RC containment reached a value of 1.049 m/sec due to impact of Boeing 707-320 at 0.2 second as shown in Figure (16 (b)). It was observed that the velocity of the RC containment due to the impact of Boeing 747-200c was greater than the impact of Boeing 707-320 by 51.095%.



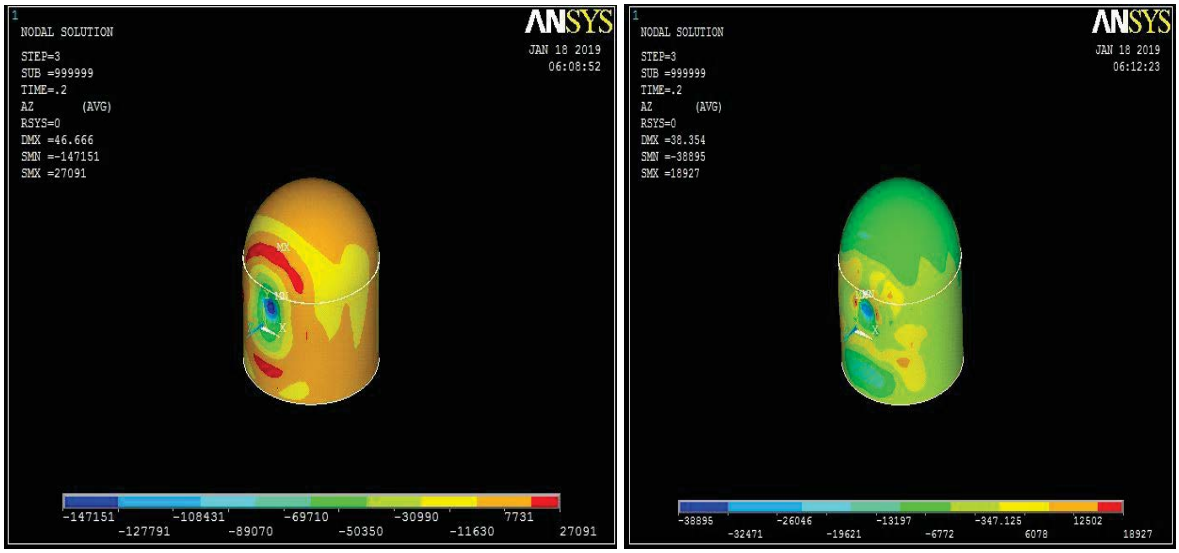
(a) Impact of Boeing 747-200c (b) Impact of Boeing 707-320



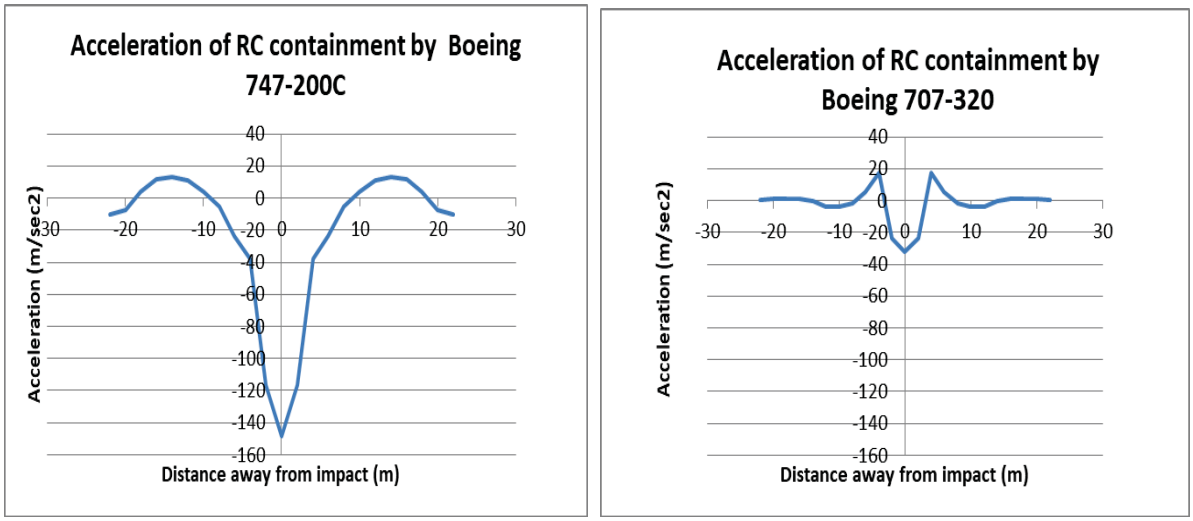
(c) Impact of Boeing 747-200c (d) Impact of Boeing 707-320

Figure 16: Velocity of RC containment due to impact of different aeroplanes at time of 0.2 second

Furthermore, the acceleration of the RC containment reached a value of 147.151 m/s^2 due to the impact of Boeing 747-200c at 0.2 second as shown in Figure (17 (a)). In contrast, the acceleration of the RC containment reached a value of 32.471 m/s^2 due to impact of Boeing 707-320 at 0.2 second as shown in Figure (17 (b)). It was observed that the acceleration of the RC containment due to the impact of Boeing 747-200c was greater than the impact of Boeing 707-320 by 77.93%.



(a) Impact of Boeing 747-200c (b) Impact of Boeing 707-320



(c) Impact of Boeing 747-200c (d) Impact of Boeing 707-320

4. CONCLUSIONS AND RECOMMENDATIONS

The external RC containment is used as the case study designed according to ASCE 58. The external RC containment structure is subjected to normal impact load of a Boeing 747-200c aeroplane using the Riera method load time curve in order to see the response of the containment and to analyze the resulting deformations, displacements and shapes of cracks that would occur due to the impact of an aeroplane. The elements within the impact region showed locally damage indicated from displacement, velocity and acceleration. The maximum displacement, velocity and acceleration in direction of loading were 46.658 mm, 2.145 m/sec and147.151 m/sec^2 respectively reached a maximum value within impact region due to the impact load of an aeroplane Boeing 747-200c. From all the above results it was observed that locally damage has been occurred to the elements within the impact region only due to impact of an aeroplane Boeing 747-200C. It was observed that the displacement, velocity and acceleration of the RC containment due to the impact of Boeing 747-200c were greater than the impact of Boeing 707-320 by 17.91%, 51.095%, and 77.93% respectively. It

was observed that Boeing 747-200c aeroplane is more damaging than Boeing 707-320 aeroplane.

Abstract. *Increasing demands for high performance of vibration control drives the development of nonlinear vibration control devices to overcome the limitations of traditional linear vibration control methods. A novel and compact X-structured mount (X-mount) with an oblique spring is designed and investigated in this paper which demonstrates beneficial nonlinear stiffness and damping, tunable payload and resonant frequency property, and a special enlarged quasi-zero-stiffness region, which thus lead to excellent vibration isolation performance without instability or other strong nonlinear response such as jump phenomenon. The X-mount is designed, based on a bio-inspired X-shaped structure, and a special oblique spring is introduced which can effectively widen the working quasi-zero-stiffness range by employing negative stiffness due to a special contact stiffness. The oblique spring can also help to reduce the dynamic stiffness achieving an ultra-low natural frequency and broadband effective vibration isolation range. The mathematical modeling, theoretical analysis and experiment results show the high performance of this X-mount, potentially providing a promising solution for vibration control in many engineering practices.*

INTRODUCTION

Vibration generated by machines or other environmental sources are often troublesome and unavoidable. However, their influences on dynamical systems or structures can be suppressed through properly designed vibration isolators. To achieve an effective vibration suppression effect, the natural frequency of an isolation platform must be smaller compared with the excitation frequency. For the low-frequency vibration environment, this requirement can be achieved by using a soft spring/stiffness component, but this might sacrifice the static loading capacity of the isolation platform. To conquer this intractable problem, some quasi-zero-stiffness (QZS) vibration isolators are developed to achieve a low dynamic frequency and maintain the static loading capacity simultaneously [1-11]. A traditional QZS isolator consists of three springs, where the negative stiffness provided by the horizontal springs is designed to offset the positive stiffness from the vertical spring, thus quasi-zero-stiffness is achieved. While, QZS isolators could lead to unstable problems, e.g., jump phenomenon, multi-stable [8, 11, 12]. Moreover, QZS isolators are limited in large vibration motion and very sensitive to the loading. Therefore, proper nonlinearity should be considered to avoid the strong nonlinear problems and the disadvantages mentioned above. For instance, the benefits of the applications of the geometric nonlinearity was summarized in Gatti et al [13] which may provide solutions for the problems above. The applications of the QZS in shock isolation can be found in [9, 14, 15]. The methods of realizing negative stiffness and QZS inlcude horizontal spring [7, 10, 11, 16], buckled beams [14] or magnetic components [1, 17] and structures [2]. Another important component for an isolation system is its damping. The limitation of the linear damping is that increasing the linear damping can suppress the resonant peak but will deteriorate the performance in higher frequencies. Therefore, nonlinear damping attracts attentions recently for the advantages. Among the nonlinear damping, the displacement-dependent damping shows advantages in both of the resonance and the high frequencies [18, 19].

Recently, a bio-inspired structure called X-shaped or limb-like structure (LLS) attracted many attentions due to the beneficially nonlinear stiffness and damping properties, and could be conveniently designed for many engineering applications [6, 12, 20-26], which presents an alternative and totally new approach for creating QZS or negative stiffness with only simple bio-inspired structure design. Based on this X-shaped structure, an innovative X-mount is thus proposed in this paper. This X-mount is optimally designed with a special oblique spring which can reduce the equivalent stiffness before contact and achieve a wider QZS range when the contact happens. This contact stiffness can contribute to remove/offset the negative stiffness after the zero-stiffness point, and the combination effect enhances the system isolation performance with an obviously enlarged QZS range. In addition, the obliqueness of this spring can be used for reducing the system stiffness further to achieve an ultra-low natural frequency and broadband effective isolation range. Experimental validation is conducted, together with theoretical analysis to verify the effectiveness of the proposed method.

1 MATHEMATICAL MODELLING

1.1 Static force

The X-mount is presented in Fig. 1 with specification of the structural parameters. The structural parameters are defined as: L is the length of the rod, θ is the initial assembly angle, n is the number of the layer, M is the isolated mass and K is the stiffness of the spring. z-axis is the vertical direction and x-axis is the horizontal direction, φ is the rotational angle of the rod, Δx is the relative displacement in the horizontal direction, z_1 is the total relative displacement in vertical direction. By changing H, the initial angle θ_1 between the oblique spring

and the horizontal plane can be adjusted correspondingly. Introducing β to describe the oblique level of the spring. l_0 is the original length of the spring and l_1 is the tension length of the spring. $\Delta l = l_1 - l_0$ is the deformation length.

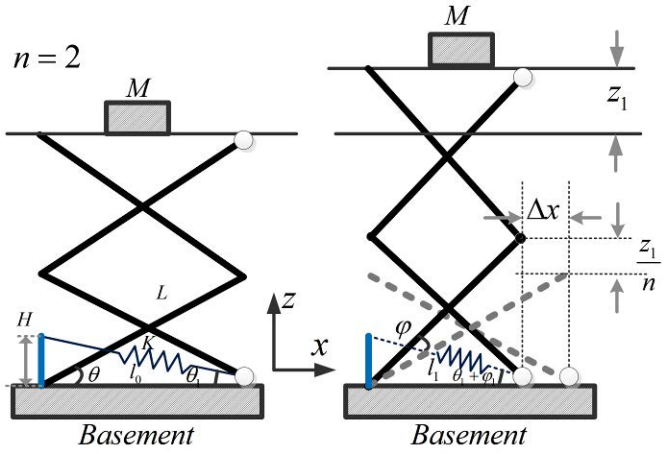

Figure 1: X-mount with an oblique spring

The variable φ, Δx and Δl can be obtained as

$$\Delta x = L(cos(\theta) - cos(\theta + \varphi)) = L\,cos(\theta) - \sqrt{L^2 - (L\,sin(\theta) + \frac{z_1}{n})^2} \tag{1}$$

$$\varphi = arctan\left(\frac{L\,sin(\theta) + \frac{z_1}{n}}{L\,cos(\theta) - \Delta x}\right) - \theta \tag{2}$$

$$\Delta l = \sqrt{H^2 + (Lcos(\theta) - \Delta x)^2} - \sqrt{H^2 + (Lcos(\theta))^2} \tag{3}$$

And other parameters are defined as

$$\varphi_1 = arctan(\frac{H}{Lcos(\theta) - \Delta x}) - arctan(\frac{H}{Lcos(\theta)}) \tag{4}$$

$$\alpha = (\theta + \varphi) - (\theta_1 + \varphi_1) \tag{5}$$

As shown in Fig. 2(a), the static force before the contact can be obtained as

$$F_1 = \frac{1}{2}(K\Delta l_1 \sin(\theta_1 + \varphi_1) + \cos(\theta_1 + \varphi_1)\tan(\theta + \varphi) + \frac{\sin(\alpha)}{\cos(\theta + \varphi)}) \tag{6}$$

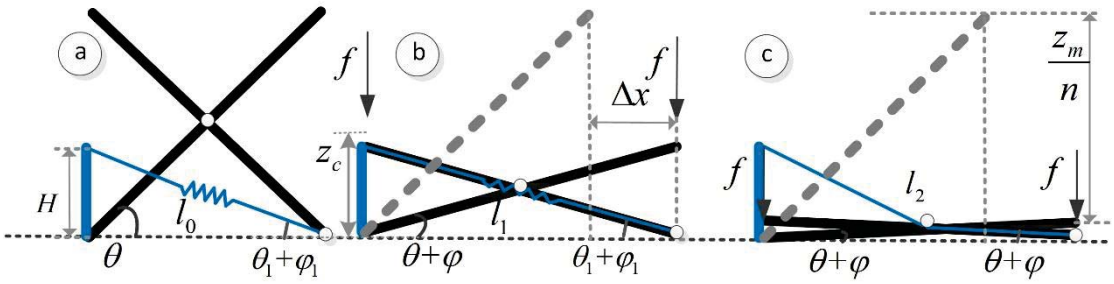

Figure 2: The loading process

And the parameters after contact are defined as follows:

$$l_2 = \frac{1}{2}L + \sqrt{(\frac{1}{2}Lcos(\theta+\varphi))^2 + (H - \frac{1}{2}Lsin(\theta+\varphi))^2} \tag{7}$$

$$\Delta l_2 = l_2 - l_0 \tag{8}$$

Where the relative spring forces and geometric angles are defined as

$$f_{s2} = K\Delta l_2,\ f_o = 2f_{s2}cos\ (\theta'),\ f_{ov} = f_o cos\ (\theta'') \tag{9}$$

$$\theta' = \frac{\theta_2 + \pi/2 + \theta + \varphi}{2},\ \theta'' = \theta' - \theta_2 \tag{10}$$

The static force after the contact can be obtained as

$$F_2 = f_{s2}(sin(\theta+\varphi) - f_{s2}tan(\theta+\varphi)cos\ (\theta')sin(\theta'') + \frac{1}{2}f_{ov} \tag{11}$$

The whole loading process can be combined and written as a piecewise function:

$$F = \begin{cases} F_1, if\ z_1 < z_c \\ F_2, if\ z_1 \geq z_c \end{cases} \tag{12}$$

1.2 Dynamic model

By utilizing the Lagrange equation, the dimensionless dynamic equation of the X-mount can be written as follows

$$z_1'' + Kf_{eq}(z_1) + 2\xi_x z_1' = \Omega^2 A_0\ cos\ \Omega\tau \tag{13}$$

Where ξ_x in the nonlinear damping ratio which can be found in [20] and the piecewise stiffness can be written as

$$f_{eq}(z_1) = \begin{cases} f_b(z_1), if\ z_1 \geq -z_c \\ f_a(z_1), if\ z_1 < z_c \end{cases} \tag{14}$$

And the stiffness before contact and after contact can be obtained as

$$f_b(z_1) = \Delta l \frac{\partial(\Delta l)}{\partial z_1},\ f_a(z_1) = \Delta l_2 \frac{\partial(\Delta l_2)}{\partial z_1}\frac{\partial z_1}{\partial z} \tag{15}$$

2 ANALYSIS RESULTS

2.1 Optimal working position

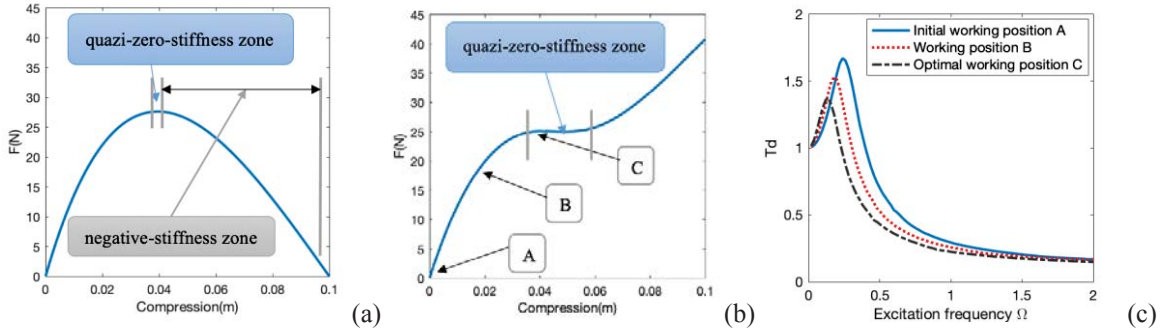

Figure 4: Optimal working position analysis: (a) static force curve with horizontal spring, (b) static force

curve with oblique spring and the contact stiffness, (c) the relative isolation performance

In Fig 4, the parameters are set as K=10000, M=10, A=0.005, L=0.1, $\theta = \pi/6$, n=2, $\beta = 0.6$, $c_r = 0.15$, $c_h = 1$. Fig. 4(a) shows the static force of the X-mount with a horizontal spring which has a very limited QZS zone. While, with the oblique spring and the contact stiffness in Fig. 4(b), the negative stiffness can be offset effectively by the vertical positive stiffness due to the contact, and the X-mount can maintain the QZS in a considerable wide range. In the Fig. 4(c), the displacement transmissibility curves are obtained with three working positions: A, B and C. The result shows the X-mount in the optimal working position C (working angle is 0.314) has the best vibration isolation performance: wider isolation frequency range and smaller transmissibility value in the resonance. Both are desirable properties for vibration isolation.

2.1 Comparison with benchmark QZS isolator

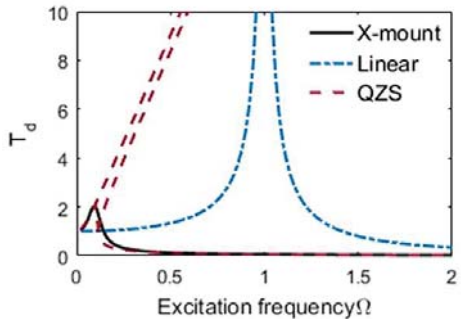

Figure 5: Comparison result of the X-mount, linear isolator and benchmark QZS isolator

The comparison results are shown in Fig. 5. Three models are evaluated and compared: the linear isolator with the linear stiffness and damping, the benchmark QZS isolator and the X-mount. The advantages of the X-shaped systems are obvious. Firstly, compared with the linear isolator and the QZS, the X-mount shows great suppression effect on the resonant peak and the widest isolation frequency range. The QZS isolator can only be effective when the excitation frequency is larger than unstable frequencies. Most importantly, the X-mount has superior stability compared with the QZS isolator. In the ultra-low frequencies, the QZS isolator appears the multi-steady states and the jump phenomenon which are very dangerous for the application. This unstable state demonstrates the QZS has strong nonlinear property which is sensitive to the initial conditions and the perturbation and leads to the system unsafe in these jump frequency range. While, the X-mount shows a very week nonlinear property which is more stable.

3. EXPERIMENTAL VALIDATION

The experimental setup is shown in Fig. 6(a), the whole X-mount has two layers (n=2) with rod length L=0.075m. An oblique spring with stiffness coefficient K=2300 N m^{-1} is installed in the bottom of the X-mount.

In Fig. 6(b), position A is the initial working angle, position B is the situation when the loading increased to 3N, position C (without contact) is the optimal working position with loading of 5.5N. When the loading continues increasing to 5.6 N, the system reaches to position D (with contact) which is also in the QZS range. In Fig. 7(c), it is clear the resonant frequency shifts to the lower frequency range as the working position is tuned from the initial

position A to the optimal positions (C and D). With the working position C and D, the X-mount has an ultra-low resonant frequency around 1Hz and the transmissibility peak decreases as well. In both positions C and D, the X-mount has ultra-low resonant frequencies and excellent isolation transmissibility performances which effectively confirmed the effectiveness of the enlarged QZS range. Without the special designed oblique spring and the contact stiffness, the QZS range is very narrow and position D will not exist.

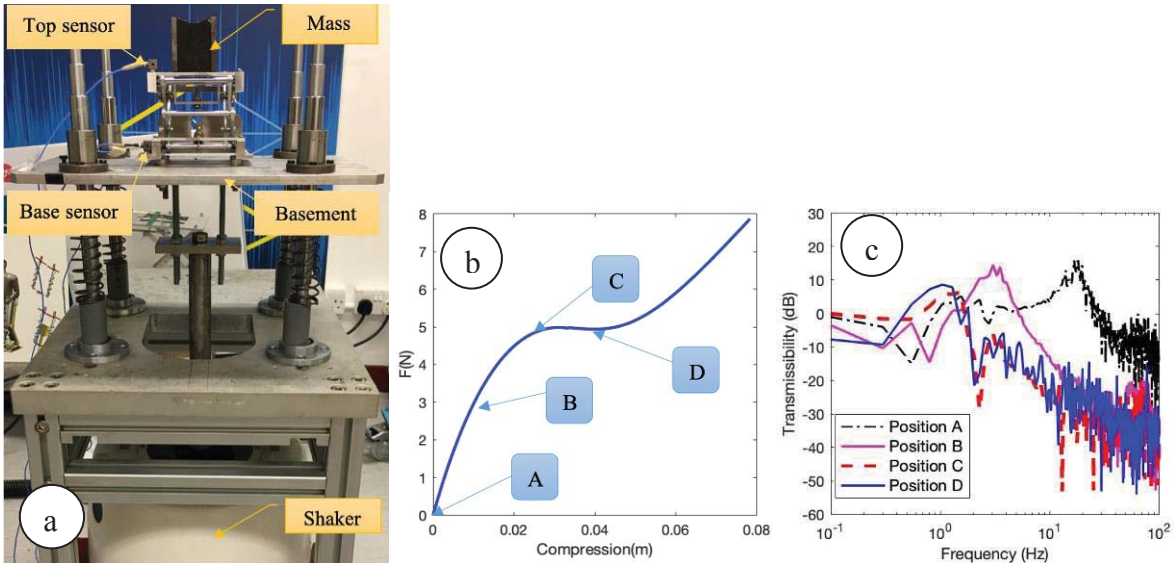

Figure 6. Working position influence: (a)experimental setup, (b) static force curves, (c) transmissibility.

4. CONCLUSIONS

A novel and compact X-mount are designed and investigated in this paper. This X-mount demonstrates beneficial nonlinearities (stiffness and damping), tunable payload and resonant frequency property, and excellent isolation performance with enhanced QZS effect. More specially, the QZS range of this X-mount can be effectively enlarged with a special designed oblique spring via the combination effect of the negative stiffness and the contact stiffness. The X-mount has desirably weak nonlinearities which can achieve superior isolation performance (lower resonant amplitude and wider isolation frequency range) and maintain the stability without the dangerous nonlinear problems, e.g., instability, bifurcation, jump phenomenon and chaos. Therefore, this novel X-mount provides a promising solution for the vibration control and could be conveniently applied in a wide range of engineering practice.

Keywords: Finite element method, Ship hull vibrations, Propeller's excitation, Main engine's excitation

Abstract. *The ship hull vibration has a great impact on the performance, safety of the devices, structures and the sailor's comfort when working on the ship. With increases in ship sizes and speeds, shipboard vibration becomes a significant concern in the design and construction of ships. Therefore, designing a ship without any excessive vibration is an important issue and should be studied through analysis right in the design phase. To ensure minimum vibration in a proposed new design; avoid damage to structures, machinery or equipment (mechanically suitable); meeting the requirements of the crew's living environment and working conditions. The ship's natural and forced vibrations are determined to right from the design stage, which will help ship designers and structures avoid dangerous resonance areas. In the study, a finite element model representing the entire ship hull, including the deckhouse and machinery propulsion system, has been developed using commercial software for vibration analyses of the container ships. The basic elements of a hull vibration system include basic mass, elastic properties as well as damping and exciting forces. In order to control or limit the vibration response, it is necessary to modify the mass and/or elastic properties; by increasing damping; reducing excitation forces or changing the excitation frequency. Increasing damping may be useful in solutions to local structural vibration problems and in some machine and equipment problems but not as a practical solution to reduce hull vibration. The influence of different modeling methods on the obtained calculation results was investigated. The impact of various operating parameters on the vibration level was also analyzed. In particular, the impact of modelling methods, added water mass, loading conditions and sources of excitations, was taken into account. The results are compared with some empirical formulas. As a result, the calculation confidence level was estimated. The calculation results have been verified by comparison with measurement tests carried out on the real ship.*

1 INTRODUCTION

Seagoing ships, particularly those equipped with slow-speed diesel engines, are exposed to excessive vibration of the ship's superstructure and hull [1, 2]. Ship's hull vibrations have a major impact on navigation safety. They have an impact on the marine structures and equipment reliability and on the comfort of maritime crews, which is also connected with navigation safety. In most cases, two main systems of the ship are distinguished: the ship's hull (with superstructure and main engine body) and the power transmission system (crankshaft, main engine shafting, propeller), as shown in figure 1. The ship's adverse dynamic characteristics are very difficult to change once it is built. Therefore, it is very important to correctly determine the expected vibration levels when designing units. All global classification societies require reliable computational analyses (often verified by measurement tests) of dynamic characteristics of the ship's propulsion system and of the propulsion system influence on the seagoing ship's hull and superstructure vibration levels.

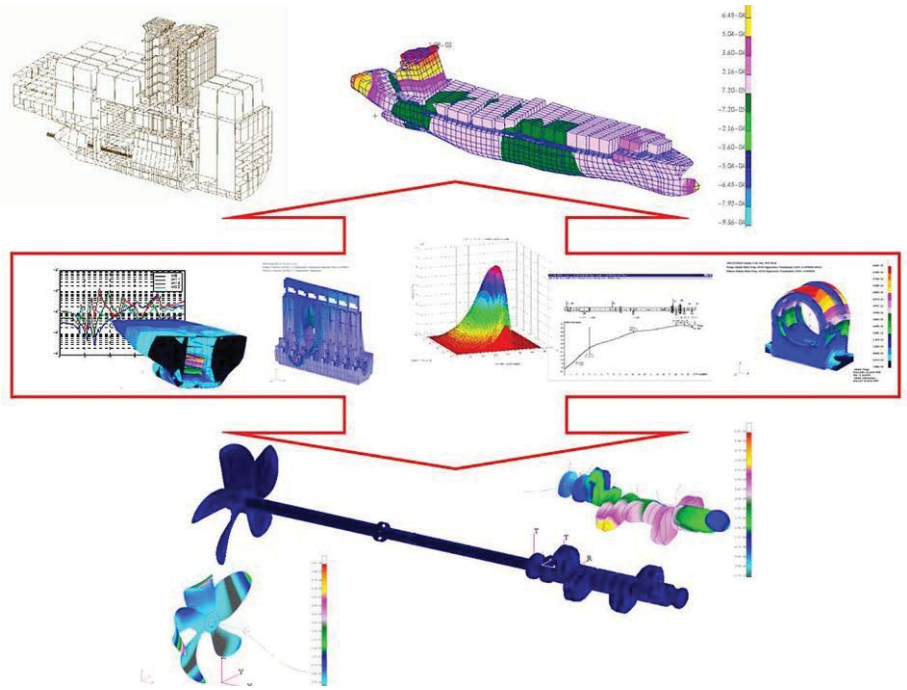

Figure 1: Interactions between the ship's hull and propulsion system through boundary conditions.

Mainly, the power transmission system [3, 4, 5] induces the forces that excite significant vibrations. Environmental impact functions are less important because they do not generate continuous vibration. The purpose of the presented analyses is to identify the main forces, which excite the ship's superstructure and hull vibrations, to test their effects on vibration levels, and to verify the assumptions of the computational methodology. The numerical calculations results have been verified by comparison with the measurement tests.

2 BASIC ASSUMPTIONS

As already mentioned, only propeller excitations and engine excitations will be considered. The rotating propeller is generating six variable components, generalized hydrodynamic forces and a variable field of pressures induced over the propeller on the ship's deck transom. The variable total pressure head causes uncoupled longitudinal vibrations of the power transmission system (main engine shafting + crankshaft), which generate dynamic reactions of the thrust bearing. Transverse hydrodynamic forces generate flexural vibrations of the main en-

gine shafting that result in variable reactions of the radial bearings: the stern bearing and the intermediate bearings. On the other hand, the main engine, and in particular the variable, radial mass and gas forces (from piston-crank system), are the source of unbalanced forces and moments of the main engine. In general, these are also six components: three forces and three force moments. Forces and moments are partially compensated by the correct ignition order choice in the engine cylinders. However, usually not all of them: for selected harmonic components, generalized forcing forces may be non-zero. On the other hand, variable forces cause torsional vibration of the power transmission system. Torsional vibration causes deformation of the crankshaft inside crank, which leads to coupled longitudinal vibrations. Such vibrations are another source of variable thrust bearing reactions.

A list of basic forces exciting vibrations of the hull and superstructure [4, 6, 7] of a ship equipped with a low-speed engine directly driving the propeller is given in figure 2. Drive dynamics analysis is necessary to determine hull vibration correctly; nevertheless, the power transmission system vibration analysis requires knowledge of the boundary conditions, i.e. the hull's stiffness dynamic characteristics. The couplings between the hull and the drive shall be taken into account in any detailed analysis of ship's vibrations.

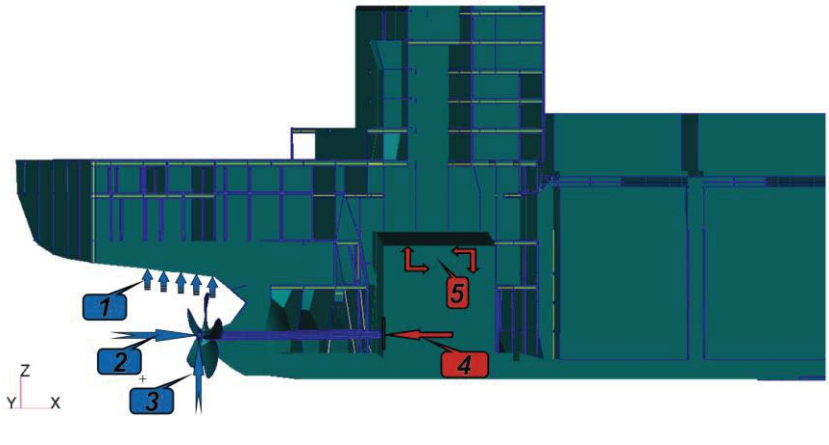

Figure 2: Forces exciting the ship's hull and superstructure vibration.

The dynamic forces indicated schematically in figure 4.25 have the following meanings:

1. pressure pulses induced on the ship's deck transom by the propeller;
2. longitudinal hydrodynamic forces exciting uncoupled longitudinal vibrations of the power transmission system and, consequently, variable reactions of the thrust bearing;
3. transversal hydrodynamic forces and moments causing flexural vibrations of the main engine shafting and, consequently, variable reactions of the transversal radial bearings (stern bearings and intermediate bearings);
4. dynamic reactions of the thrust bearing from coupled longitudinal vibrations of the power transmission system;
5. unbalanced moments (and, possibly, forces) of the main engine coming from the radial gas and mass forces of the piston-crank system.

In the present paper, only the steady-state vibrations, i.e. the ship's vibrations, will be analysed; when all machinery and equipment are operating under the steady operating conditions (constant power and rotational speed). It is assumed that any operation disturbance is small compared to the fixed size. In this case, the mathematical model can be brought into a series of linear differential equations with fixed parameters. The constant and set parameters are both mass and mass moment of inertia, as well as rotational speed, power (moment), forcing

frequency, etc. In addition, in typical marine structures, the vibration damping has a negligible effect on the natural vibrations frequency. In such a case, the finite element method (FEM) that the author uses, applies relatively simple methods of solutions. Therefore, the number of elements (of differential equations) can be very large; the analysed models can be detailed.

The container ship were analysed in the work: a medium-sized, with a capacity of approximately 2700 TEU (standard containers). The ship's length is equal to 207 m, main engine (MAN B&W 8S70MC-C) power: about 25 thousand kW, nominal rotational speed: 91 rpm, and the five-blades propeller. The FEM model for the ship are shown in figure 3.

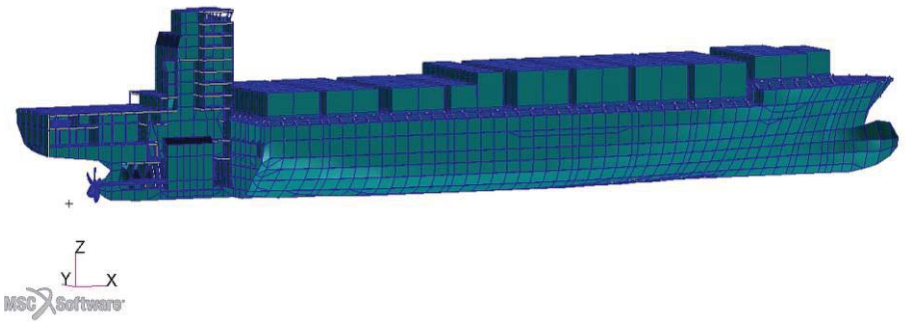

Figure 3: FEM model of a 2700 TEU container ship.

3 NATURAL VIBRATIONS

Free vibrations allow a qualitative assessment of the ship's excessive vibration risk [8]. For example, the position of the ship's hull beam vibration nodes (relative to the position of the main engine) makes it possible to decide on the purchase of the main engine balancing devices (stern and/or bow balancer). The comparison of the forcing frequency with the free vibration frequency of the ship's superstructure allows, yet at the stage of the initial design, to make major structural changes in order to avoid excessive vibrations. For example, low-frequency vibrations of the main engine body may prove its foundation poor or the double bottom too susceptible in the engine room area. When analysing the ship's natural vibration, we can distinguish:

- global vibrations (vertical, horizontal, torsional) of the hull beam,
- main engine body vibrations,
- ship's superstructure vibrations,
- local vibration of decks and other structural elements of the hull.

All of the above types of vibration can be coupled. Figure 4 shows examples of global hull beam vibrations. These are vertical and torsional vibration forms with frequencies from 1.6 to 4.6 Hz. Most often, the "beam-type" forms of the ship's hull free vibrations are benign due to their very low frequencies. They are usually outside the range of the forcing frequency generated by the drive. At a rated speed of 91 rpm, the basic forcing frequency of the 8-cylinder engine is of 12.1 Hz and the basic excitations frequency of 5-blade propeller is of 7.6 Hz. The ship's hull is an example of typical superresonant vibrations with a big offset. Of course, the forcing frequency may be similar to the higher forms of the ship's hull beam free vibrations. For this reason, at least the first dozen free vibration forms should be taken into account when analysing global vibration of ships.

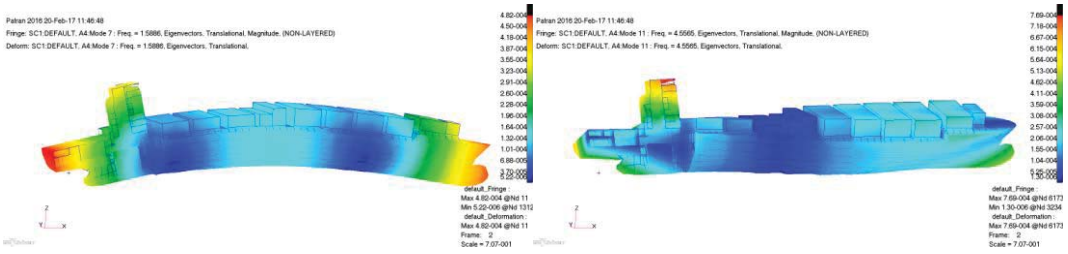

Figure 4: Global natural vibrations of 2700 TEU container ship.

Ship's superstructure vibrations are the most important. They are often coupled with the vibrations of the ship's hull and main engine. Figure 5a shows the forms of the discussed ships' superstructure free vibrations. The main engine body vibrations are also important for two reasons. When excessive, they can be dangerous to the engine reliability, but they can also be a source of forcing other marine structures and equipment. Figure 5b shows the transversal form of the 2700 TEU container ship main engine body natural vibrations.

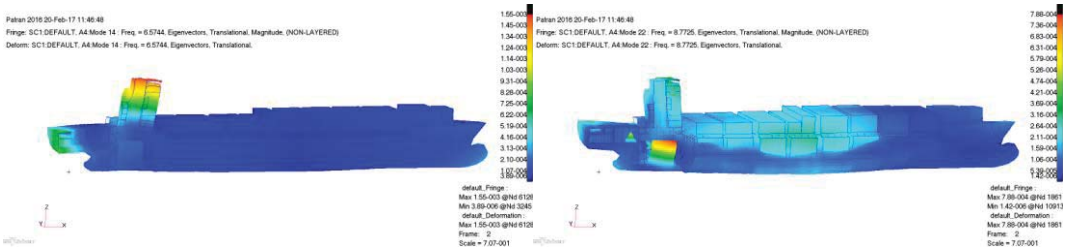

Figure 5: Superstructure and main engine body vibrations of the container ship.

Good consistency between vibration measurements and calculation results is particularly difficult to obtain in marine conditions [4, 9]. Many important design decisions depend on the results of the computational analyses. The reliability and the distribution of the vibration calculation results are a fundamental question in numerical analyses of complex structures. Free vibrations depend only on the stiffness and mass distribution (the damping effect is negligible). Therefore, the confidence level of the free vibration calculation is relatively high. However, the actual level of the forced amplitude may significantly differ from that resulting from the computational analyses. This is due, among others, to poor knowledge of the size of the structural damping in marine conditions. There are no good methods for calculating the damping.

The mass matrix is affected by the ship's performance characteristics. The effect of the ship's loading state on its frequencies and the free vibration forms was examined. The importance of taking into account the masses of associated water that accompanies the hull vibrations was also assessed. If the associated water phenomenon is taken into account, the free vibration frequencies are reduced. The natural vibration frequency decreases by approximately 25%, when the hull wetness is taken into account. This applies mainly to vertical forms with a small number of vibration nodes. The more vibration nodes, the less impact of the associated water. For example, the frequency drop for the 6-node vibration form is of 16%. The hull wetting effect on horizontal vibration is also slightly less, not more than 20%. The addition of the associated water mass also changes the order of the free vibration form occurrence. The effect of the added water on the vibrations of the superstructure and main engine is much lower, it does not exceed 6%. This is because neither the superstructure nor the engine body is directly wetted. This impact is so small that it is acceptable not to include the associated water in analyses focused on these ship's elements.

The effects of cargo condition changes on the free vibration frequencies of both ships are also analysed. As we would expect, the ship's cargo (ballast state -> design cargo state) reduces the hull free vibration frequency. The measured vibration amplitude levels, which are normally checked once a ship is built, during marine tests (ballast condition), may significantly differ from the operational ones (cargo condition). It may be possible to eliminate the excessive vibrations in the superstructure by adding a large effective mass, e.g. by filling a space located high up in the superstructure with sand.

Before calculating forced vibrations, it is necessary to decide on the calculation method. There are two main methods: direct integration and modal superposition. The most common method is the modal superposition of free vibration. In this method, the free vibration forms are added together in an appropriate manner. In this case, we should verify the assumption of the number of free vibration forms included in the summation to forced vibrations. The impact of the quantities of free vibration forms taken into account was verified by analysing the results of the 2700 TEU container ship analyses. Given the nominal speed of the power transfer system (91 rpm) and the fact that the fifth and the eighth harmonic components are the basic forcing force components (number of propeller blades and number of engine cylinders), a maximum frequency of the main forcing forces can be determined at 8 and 12 Hz. The focus was on propeller excitations. For this reason, the key range of excitations is from 0 to 7.6 Hz. A number of variants of forced vibration calculations were carried out, taking into account the different number of free vibration forms. Calculation variants with the following number of free vibration forms included were adopted, from 10 modes (up to 7 Hz - all basic forms of hull and superstructure free vibration forms) to 150 modes (up to 20 Hz - forms with frequencies up to 2.5 times the frequency of the propeller excitations). Figure 6 shows the longitudinal amplitudes of the vibration velocity of the main engine body (MEF—heads on the bow side), the hull in the deck transom area (DTR), and the top of the superstructure (STL—bridge wing), depending on the number of free vibration forms taken into account.

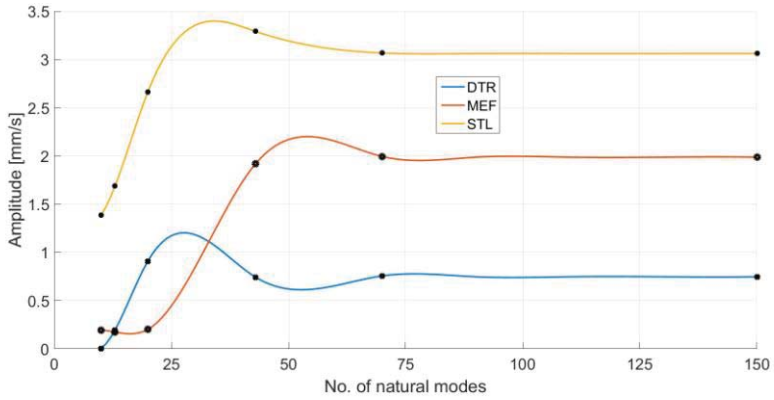

Figure 6: Amplitude of the longitudinal forced vibration velocity depending on the number of natural vibration modes considered.

We should note that if there are not enough free vibration forms to be taken into account, even forced vibration forms might be wrong. For example, the amplitude of the main engine heads longitudinal vibrations, which are more than twice the amplitude of the deck transom. If the free vibration frequency range is from 0 to 9 Hz (20 forms), the calculation results indicate that the heads vibration amplitude is four times less (!) than the deck transom amplitude. Also, the shape of the resonance curves can be changed at an insufficient number of free vibration forms considered. When using the modal superposition method, the band of the free vibration frequencies to be determined should be at least twice as wide as the forcing frequency band so

that the results of the vibration amplitude (velocity) calculations are correct. Forced vibration phases are less sensitive to the number of determined forms of natural vibration. In specific cases, for drives with high-frequency excitations (medium-velocity engines), it is admissible to extend the frequency range of forced vibrations 1.5 times when determining the essential of free vibration forms. In the considered case, taking into account the first 70 free vibration forms (up to 16 Hz) is sufficient.

4 FORCED VIBRATIONS

When calculating the analysed model forced vibrations, the damping matrix must be specified. Damping depends on a large number of factors. The damping is greatly affected by the structure wetting with seawater. It is very difficult to precisely define the damping; practically, it is possible only using experiments. Its values can be found in numerous publications [3, 9]. For steel welded structures, the author believes that vibration increase factor of 20–25 is a good approximation. However, it is very important to verify the calculation analyses using correctly performed measurement tests.

When analysing the hull and superstructure dynamics, two main sources of forcing are to be taken into account: from the propeller and from the main engine [3, 5]. The vibration amplitudes (forcing forces) summation must take into account the time history phase angles between propeller' blades and engine's cranks. In the case of excitations induced by the propeller, the dominant force is the harmonic component associated with the number of propeller blades (for the concerned ship, the 5th component). Engine excitations are represented by a whole spectrum of harmonic components, the most dangerous of which is related to the number of engine cylinders. Power systems with the same number of propeller blades and engine cylinders should not be used in shipbuilding because of the high risk of excessive vibration due to the summation of identical harmonic components. However, even for different numbers of cylinders and propeller blades, harmonic components summation may be unfavourable, as marine low-velocity engines have high collateral harmonic components. For the analysed 8-cylinder engine, the 5th harmonic component is significant. As it has already been stressed, the vibration phases caused by the propeller depend on its blades position, while the vibration phases caused by the main engine depend on the crankshaft crank position. For these reasons, the angular mutual alignment of the propeller and crankshaft may significantly affect the superstructure vibrations level [5].

When minimising vibrations, the selected point vibration amplitude and phase must be determined first, for both sources of excitations. For the main engine excitations, the vibrations caused by the coupled longitudinal vibrations and the vibrations caused by the main engine unbalanced moments are to be added together. Propeller excitations consist of water pressure pulses on the deck transom and of forces induced by drive uncoupled longitudinal vibrations and of the main engine shafting flexural vibrations. Only the 5th harmonic component will be considered in this analysis, as the principal propeller excitations are of the fifth order, and only the same order vibrations can be vectorially added. Figure 7 summarise the longitudinal vibrations levels of the superstructure bridge wing, produced by the propeller and main engine. Summary results by excitations type are presented.

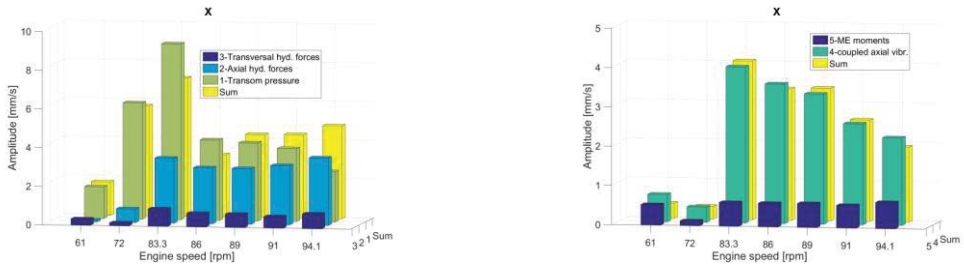

Figure 7: Vibration velocity amplitudes for the container ship in the longitudinal direction on the bridge wing, excited by the propeller and main engine.

Since the total vibrations from the propeller and main engine have similar amplitude levels, it is possible to minimise the vibration by changing the propeller and crankshaft crank angular position. Each vibration direction and each drive rotational speed can be minimised. The admitted optimum angle (the propeller blade optimal translation angle in relation to the first crankshaft crank) is α=-20.3°, it gives a minimum level of superstructure longitudinal vibrations at the nominal engine rotational speed. In reality, the propeller and the crankshaft relative angular position are very often random. Therefore, the distribution of calculation results compared to the measurement tests can be significant. Figure 8 shows the size of distribution, i.e. errors which may result from the accidental propeller and crankshaft phasing for the 5th harmonic component. The reference level is the average of the expected vibration amplitudes.

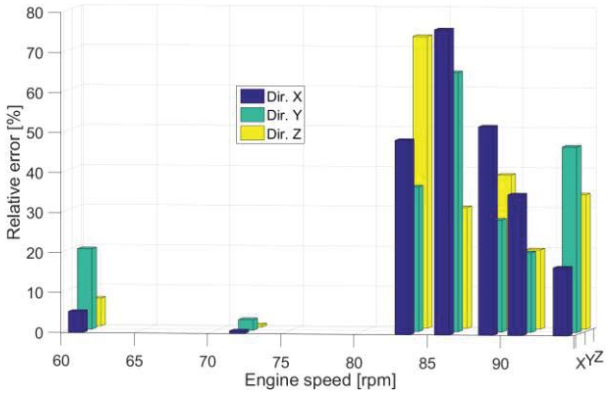

Figure 8: Expected vibration amplitude result distribution of the 5th harmonic component, for the 2700 TEU container ship's variable propeller and engine phasing.

During measurements, total vibrations from all harmonic components are measured and standardised. At rated rotations, the expected 5th harmonic component results distribution is about ±60%. However, the total vibration amplitudes distribution will be smaller. The difference in the 5th harmonic results is to be multiplied by its percentage in the total vibration. It was assumed that the propeller has one dominant harmonic component, i.e. the first blade (5th harmonic).

The measurement tests of the 2700 TEU container has been performed. A comparison of the results of calculations with the results of measuring tests is shown in figure 9. As the measurements results normally give the values of vibration velocity effective amplitude, the calculation analyses results have been recalculated accordingly. The comparison was presented for the most important hull reference points: the superstructure bridge wing.

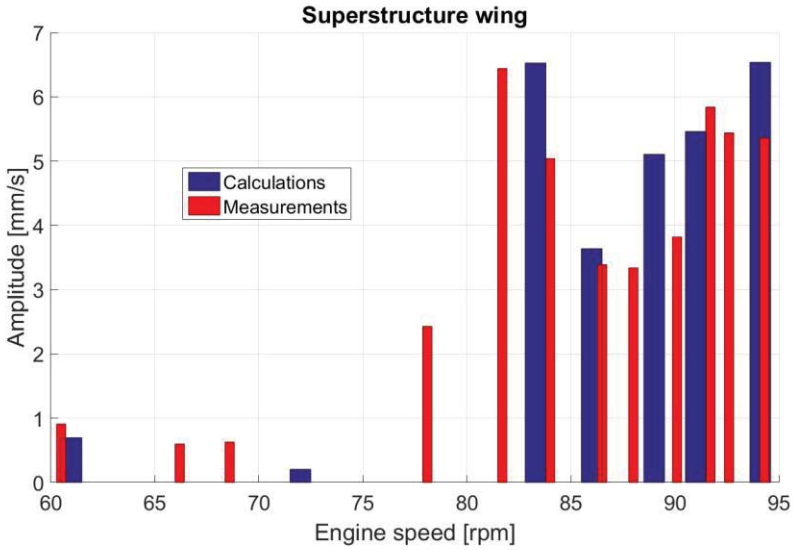

Figure 9: Measurement and calculation verification of the superstructure bridge wing vibrations, for the 2700 TEU container ship, in ballast condition

The presented measurement and calculation verification fully confirmed the validity of the assumptions made and of the used calculation methods. The consistency between the measurement tests and the numerical calculations is highly satisfactory, in the light of the analyses carried out for the expected dispersions and errors in the numerical modelling of a physical object, the hull.

5 CONCLUSIONS

The main engine meaning (in comparison to propeller) varies with its rotational speed, with ship cargo state and the direction of the vibrations to be considered. Therefore, it is impossible to eliminate ships vibrations to levels not noticeable by the crew and passengers. Due to the complexity of the ship structures vibration phenomenon, it is also difficult to reduce them effectively, especially after the ship has been built. For this reason, in-depth calculation analyses of the ship dynamics are extremely important at the design stage. However, it is important to be aware of the inevitable calculation results dispersion (and of measurement tests, also).

Based on the performed analyses, it can be concluded that resonant frequencies should be provided for in calculations with good accuracy. However, even correctly performed calculations of vibration amplitudes may significantly differ from the amplitudes obtained by measurement tests. It should be stressed that measurements, especially those carried out in marine conditions, are also subject to a number of significant errors and dispersions.

Keywords: Pushover analysis, asymmetric buildings, torsionally stiff/flexible buildings, biaxial seismic excitation, nonlinear dynamic analysis, seismic response.

Abstract. *In the present paper a recently developed multimode pushover procedure is evaluated for asymmetric systems with various torsional properties. The procedure is applicable to asymmetric in plan buildings under concurrent action of two horizontal seismic components and its main advantage is that it does not require independent analysis in two orthogonal directions. Thus, the use of simplified directional combination formulae, which is not valid in the nonlinear range, is avoided. The preliminary evaluation of the proposed methodology led to quite satisfactory results. However, the studies conducted up to date are limited to 'torsionally stiff' buildings. Hence, in the present study the procedure is applied to 'torsionally similarly stiff' and 'torsionally flexible' systems too. In particular, a set of nine reinforced concrete buildings are analyzed for 20 earthquake excitations. The values of selected response quantities are compared to those resulting from a conventional pushover analysis variant as well as from nonlinear dynamic analysis. The whole evaluation study leads to the derivation of useful conclusions.*

1 INTRODUCTION

The vast majority of buildings belong to the category of asymmetric in plan structures, i.e. they do not possess any axis of symmetry. The earthquake analysis and design of such buildings should be based on spatial models and should take into account the so-called multi-directional seismic effects, namely the concurrent action of at least the two horizontal seismic components. When linear or nonlinear time history analysis is applied these effects are taken into account directly, by concurrent application of accelerograms along two orthogonal directions. On the other hand, when modal response spectrum or linear static method of analysis are applied a fundamental assumption is adopted. In particular, it is considered that the same design spectrum represents both horizontal seismic components and the analysis is carried out independently for each direction. Then the directional combination is conducted using SRSS (Square Root of the Sum of the Squares) formula or the percentage combination rule. The latter approach is adopted by seismic codes (eg., [1], [2], [3]) even for the implementation of nonlinear static method.

In recent years many researchers investigated the issue of application of pushover analysis to asymmetric buildings under biaxial seismic excitation and presented several relevant methodologies. The majority of them is based also on simplified directional combination formulae. For example, Reyes and Chopra [4], [5] extended the well-known Modal Pushover Analysis [6] in order to include asymmetric buildings under bi-axial seismic excitation. They proposed independent implementation of the procedure along two orthogonal directions and directional combination of the results using SRSS formula. The same approach is also adopted for the extension of N2 method for asymmetric in plan buildings [7], [8], for the Improved Modal Pushover Analysis [9], for the Improved Consecutive Modal Pushover Analysis [10] and for the pushover procedure proposed by Shakeri and Ghorbani [11].

However, the simplified directional combination rules are based on the superposition principle which is not valid in the nonlinear range of behaviour. Thus, the use of such rules is a major shortcoming of the aforementioned methodologies found in literature as well as of those prescribed by seismic codes. In order to overcome this shortcoming Manoukas et al. [12], [13], [14] developed a multimode pushover procedure for asymmetric in plan buildings which does not require independent analysis for each direction, hence directional combination is avoided. The main idea of the procedure is that the seismic response of a multi-degree-of-freedom (MDOF) system under biaxial seismic excitation can be expressed as superposition of the responses of a series of equivalent single-degree-of-freedom (E-SDOF) systems under uniaxial excitation. The properties of the E-SDOF systems (mass, stiffness, damping factor) are calculated using proper formulae which are derived from the equations of motion and take directly into account the concurrent action of the two horizontal seismic components.

The evaluation studies published in the past [12], [13], [14] demonstrated that the proposed procedure provides quite satisfactory results. However, the studies conducted up to date are limited to the so called 'torsionally stiff' buildings. Hence, the scope of the current study is the validation of the procedure for asymmetric in plan systems including 'torsionally similarly stiff' and 'torsionally flexible' buildings [15]. After a brief outline of the procedure, a series of applications to reinforced concrete buildings is presented. In particular, nine multi-storey buildings are analyzed for 20 biaxial seismic excitations. The values of selected response quantities are compared to those resulting from a conventional pushover analysis variant as well as from nonlinear dynamic analysis. The whole study leads to the derivation of useful conclusions.

2 SUMMARY OF THE PROCEDURE

The theoretical background of the proposed procedure has already been presented by Manoukas et al. in previous papers [12], [13], [14]. Hence, in the present study only some key points are briefly outlined. Apart from the well-known assumptions on which all pushover variants are based, an additional one is introduced. In particular, it is considered that the two horizontal seismic components $\ddot{u}_{g(t)X}$ and $\ddot{u}_{g(t)Y}$ are proportional to each other, i.e.:

$$\ddot{u}_{g(t)Y} = \kappa \ddot{u}_{g(t)X} = \kappa \ddot{u}_{g(t)} \tag{1}$$

where κ is a constant factor. Although this is not the case for earthquake excitations, this assumption should be considered as reasonable, since it is in fact equivalent to the common assumption of seismic codes which specify that the same design spectrum represents both horizontal seismic components and the directional combination can be conducted using the percentage combination rule where a factor equal to 0.3 (similar to κ) is applied.

Thanks to the aforementioned assumptions, it has been demonstrated [12], [13], [14] that the motion of an N-DOF system subjected to the seismic excitation given in Eq. (1) is governed by N uncoupled equations, each one corresponding to a 'modal' E-SDOF system:

$$M^*_{XYi}\,\ddot{D}_i + 2\,M^*_{XYi}\,\omega_i\zeta_i\,\dot{D}_i + V_{XYi} = -M^*_{XYi}\,\ddot{u}_g \tag{2}$$

where $D_i = q_i / v_{XYi}$, $\dot{D}_i$, $\ddot{D}_i$ are the displacement, velocity and acceleration of the i^{th} (i = 1…N) E-SDOF system, ω_i, ζ_i and q_i are the natural frequency, the damping ratio and the 'modal' co-ordinate of the elastic vibration mode i and:

$$V_{XYi} = V_{Xi} + \kappa V_{Yi} \tag{3}$$

$$M^*_{XYi} = M^*_{Xi} + \kappa(v_{Xi}\,L_{Yi} + v_{Yi}\,L_{Xi}) + \kappa^2 M^*_{Yi} \tag{4}$$

$$L_{Xi} = \boldsymbol{\delta}_{,X}^T \boldsymbol{M} \boldsymbol{\varphi_i} \tag{5}$$

$$L_{Yi} = \boldsymbol{\delta}_{,Y}^T \boldsymbol{M} \boldsymbol{\varphi_i} \tag{6}$$

$$v_{XYi} = v_{Xi} + \kappa v_{Yi} \tag{7}$$

where $\boldsymbol{M}$ is the NxN mass matrix, $\boldsymbol{\varphi_i}$ is the 'modal' vector of mode i, V_{Xi}, V_{Yi} are the 'modal' base shears parallel to X and Y axes respectively, M^*_{Xi}, M^*_{Yi} and v_{Xi}, v_{Yi} are the effective modal masses and the modal participation factors of mode i due to independent uniaxial excitations, while $\boldsymbol{\delta}_{,X}$, $\boldsymbol{\delta}_{,Y}$ are the influence vectors for independent uniaxial excitations.

Eq. (2) demonstrates that the nonlinear response of an N-degree of freedom system subjected to the seismic excitation given in Eq. (1), can be expressed as the sum of the responses of N SDOF systems under uniaxial excitation, each one corresponding to a vibration 'mode' and having the properties given in Eqs. (3) to (7) and in Table 1. The properties that each E-SDOF would have in case of uniaxial excitation (parallel to X axis) are also tabulated in the second column of Table 1. Notice that the displacements of E-SDOF systems is correlated to the roof displacement u_{Ni}.

The implementation of the proposed methodology should be conducted for the following possible combinations of the horizontal seismic components:

$$\ddot{u}_{gX} + \kappa \ddot{u}_{gY} \tag{8}$$

$$\ddot{u}_{gX} - \kappa \ddot{u}_{gY} \tag{9}$$

$$\ddot{u}_{gY} + \kappa \ddot{u}_{gX} \tag{10}$$

$$\ddot{u}_{gY} - \kappa \ddot{u}_{gX} \tag{11}$$

The properties of the E-SDOF systems should be modified properly for each combination. Consideration of the four combinations with opposite sign (e.g., $-\ddot{u}_{gX} - \kappa\ddot{u}_{gY}$ instead of $\ddot{u}_{gX} + \kappa\ddot{u}_{gY}$) is not necessary because it leads to identical properties for the E-SDOF systems and as a consequence to identical results.

The sequence of steps needed for the implementation of the proposed methodology are shown in the flowchart of Fig.1.

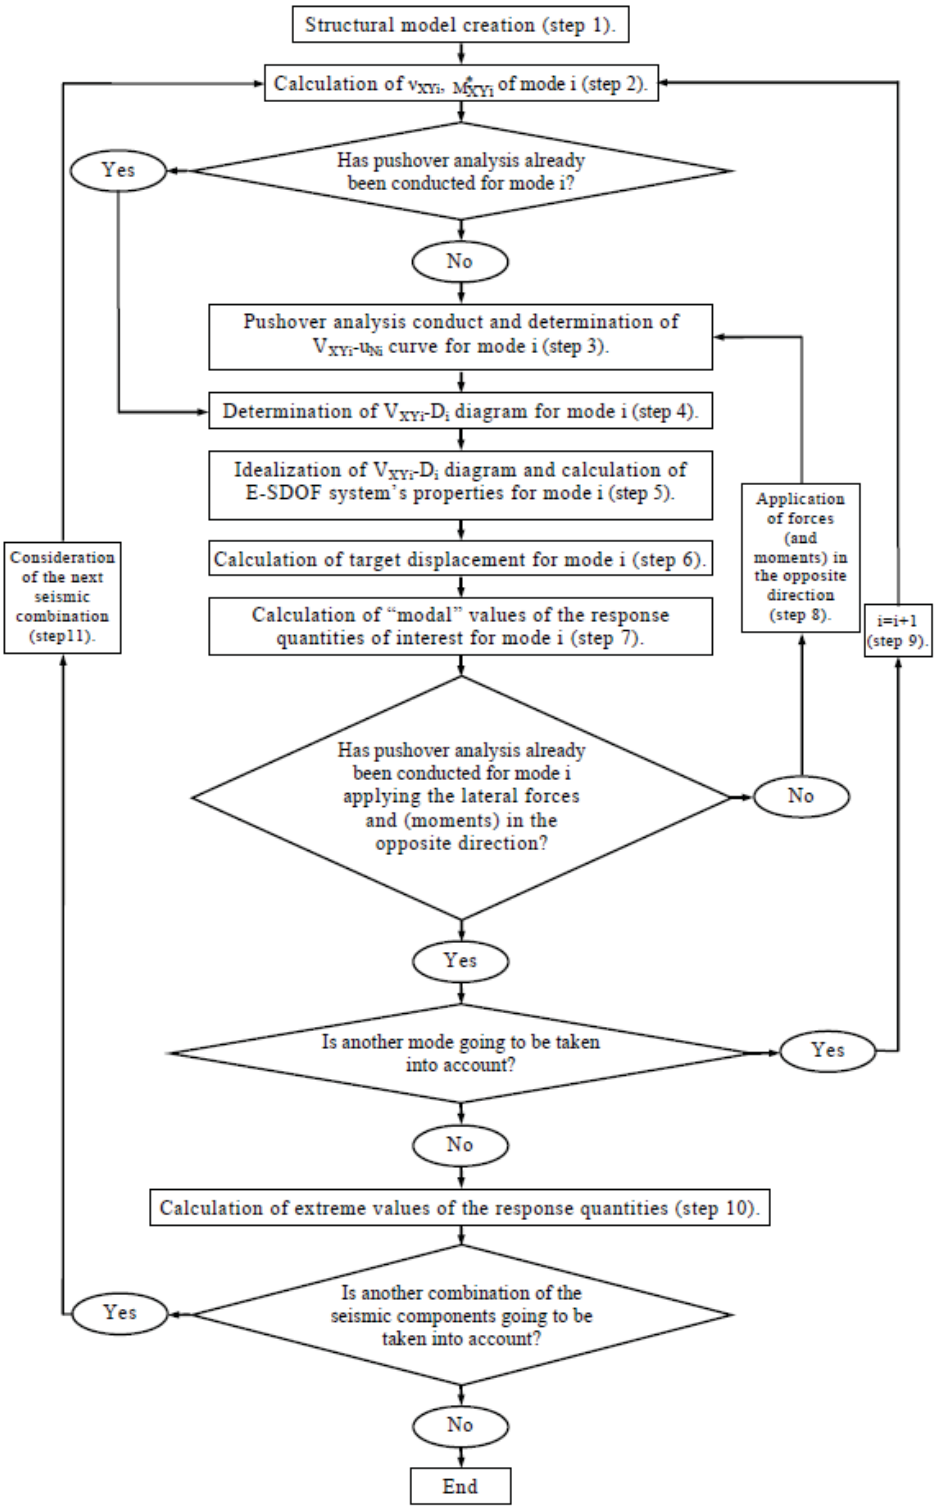

Figure 1: Flowchart of the proposed methodology.

Property	Uniaxial excitation $\ddot{u}_{gX}$	Biaxial excitation $\ddot{u}_{gX} + \kappa\ddot{u}_{gY}$
Mass	M^*_{Xi}	$M^*_{XYi} = M^*_{Xi} + \kappa(v_{Xi} L_{Yi} + v_{Yi} L_{Xi}) + \kappa^2 M^*_{Yi}$
Resisting force	V_{Xi}	$V_{XYi} = V_{Xi} + \kappa V_{Yi}$
Displacement	$D_i = u_{Ni} / v_{Xi} \varphi_{Ni}$ (roof displacement u_{Ni})	$D_i = u_{Ni} / v_{XYi} \varphi_{Ni} = u_{Ni} / (v_{Xi} + \kappa v_{Yi}) \varphi_{Ni}$ (roof displacement u_{Ni})
Damping factor	$2 M^*_{Xi} \omega_i \zeta_i$	$2 M^*_{XYi} \omega_i \zeta_i$

Table 1: Properties of the i^{th} E-SDOF system.

3 EVALUATION STUDY

3.1 Structural modeling and design

It has been demonstrated in previous studies [12], [13], [14] that the proposed methodology produces quite satisfactory results for buildings characterized as 'torsionally stiff' according to the definition given by Chopra and Goel [15] and other researchers. In the framework of the current paper, the procedure is applied to 'torsionally similarly stiff' and 'torsionally flexible' asymmetric in plan buildings too.

In particular, nine multi-storey asymmetric in plan (but regular in elevation) reinforced concrete buildings with various torsional properties are analyzed for 20 seismic excitations. The buildings are characterized by a string symbol comprising 2 or 3 letters and a number indicating the number of storeys (4, 8 or 12). The meaning of the letters is as follows:

- 'ts' ('torsionally stiff'): Asymmetric buildings with plan given in Fig. 2. 'ts' models are characterized as 'torsionally stiff' [15], given that in the first two vibration modes the motion is dominated by lateral displacements.
- 'tss' ('torsionally similarly stiff'): Asymmetric buildings identical to 'ts' models except that the mass moment of inertia of each diaphragm is multiplied by 2. 'tss' models are characterized as 'torsionally similarly stiff' [15], given that in the first two vibration modes lateral and torsional motions are strongly coupled.
- 'tf' ('torsionally flexible'): Buildings identical to 'ts' models except that the mass moment of inertia of each diaphragm is multiplied by 4. 'tf' models are characterized as 'torsionally flexible' [15], given that in the first mode the motion is dominated by torsion.

For example, the symbol tf8 corresponds to a 'torsionally flexible' building with 8 storeys.

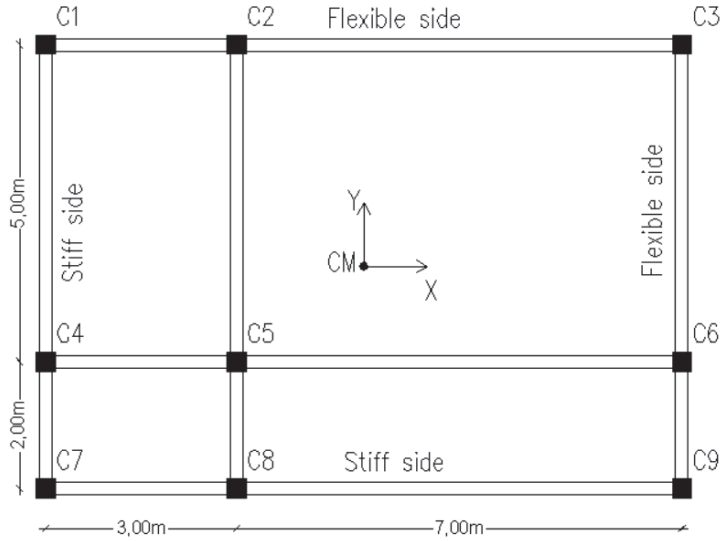

Figure 2: Floor plans of the analyzed buildings.

All buildings are designed using the modal response spectrum method of analysis [3], [16] for Peak Ground Acceleration (PGA) equal to 0.16g. The design is conducted with the aid of the software package NEXT v.2004 which is developed by 'Computec Software' and widely used by engineering professionals in Greece. The mass and the mass moment of inertia of each storey (Table 2) are concentrated to the mass center of the diaphragms. The first six natural periods of the examined models are tabulated in Table 3, while the modal participating mass ratios are shown in Table 4.

The inelastic analyses of the buildings are conducted using the program SAP 2000. The inelastic behavior is represented through plastic hinges possessing elastic-perfectly plastic moments-rotations relations.

3.2 Ground motions

The buildings are analyzed for 20 accelerograms obtained from the PEER database [17] and tabulated in table C-3 of FEMA 440 [18]. The accelerograms are scaled to PGA equal to 0.40g in order to ensure that the analyzed buildings undergo extensive nonlinear deformation. The scaled acceleration response spectra of the 20 seismic excitations along with the mean response spectrum are shown in Fig. 3. Each accelerogram is applied simultaneously along two orthogonal directions with the same intensity.

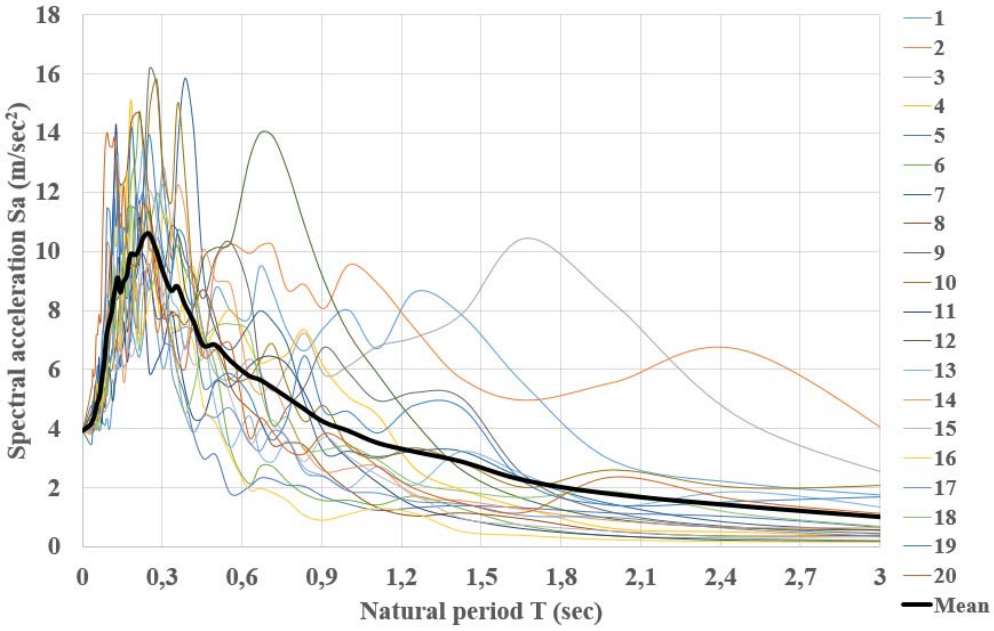

Figure 3: Acceleration response spectra of the 20 seismic excitations.

3.3 Analysis process

Two alternative pushover procedures are implemented:

- The proposed methodology (PM). Due to the simultaneous action of the same earthquake excitation along two horizontal axes, the factor κ (Eq. (1)) is equal to 1. Thus, the combinations of the seismic components (Eqs. (8) to (11)) are limited to two: $\ddot{u}_{gX} + \ddot{u}_{gY}$ (PM+) and $\ddot{u}_{gX} - \ddot{u}_{gY}$ (PM-).
- A conventional procedure (CP) which differs from PM in the following three points: i) CP is applied for independent uniaxial excitations along X and Y axes and the percentage combination rule is used for the calculation of the extreme values of the response parameters (step 10 in Fig. 1), ii) in steps 2 to 4 v_{Xi}, M^*_{Xi}, V_{Xi} or v_{Yi}, M^*_{Yi}, V_{Yi} are used instead of v_{XYi}, M^*_{XYi}, V_{XYi} and iii) step 11 is omitted.

For both procedures the first six vibration modes are taken into account, while the Complete Quadratic Combination (CQC) rule is used for the 'modal' superposition. The target roof displacement for each mode is estimated multiplying by the quantity $v_{XYi}\varphi_{Ni}$ (PM) and $v_{Xi}\varphi_{Ni}$ or $v_{Yi}\varphi_{Ni}$ (CP) the response of the corresponding E-SDOF system. The latter is determined with the aid of nonlinear dynamic analysis. For each building, the floor displacements and the storey drifts at the center of mass (CM), at the flexible side (C3) and at the stiff side (C7) of the plan are calculated.

The values of the response quantities resulting from the two alternative pushover procedures are compared to those obtained by Nonlinear Dynamic Analysis (NDA), which is con-

sidered as 'exact' solution. For each response parameter $R_{j,s}$ calculated by means of pushover analysis for an excitation j, the error with regard to the NDA E_j is determined as follows:

$$E_j\,(\%) = 100\frac{R_{j,s} - R_{j,d}}{R_{j,d}} \tag{12}$$

where $R_{j,d}$ is the value of the relevant parameter resulting from NDA. Furthermore, the mean error *ME* for the 20 excitations is determined using Eq. (13):

$$ME\,(\%) = \frac{1}{20}\sum_{j=1}^{20} E_j = 100\,\frac{1}{20}\sum_{j=1}^{20}\left(\frac{R_{j,s} - R_{j,d}}{R_{j,d}}\right) \tag{13}$$

3.4 Results

In Figs. 4 to 15 the mean errors of the calculated response parameters are shown. The two combinations of PM (PM+ and PM-) provide an upper bound and a lower bound value for each response parameter. The 'exact' value (NDA) for 304 of 432 displacements and for 289 of 432 drifts lies in this range. For the vast majority of response quantities (408 of 432 displacements and 405 of 432 drifts) PM is conservative. This means that the number of modes taken into account is adequate. Non-conservative values are observed mainly for the stiff side of 'torsionally similarly stiff" buildings. The *ME* of the more conservative combination (PM+ or PM-) for displacements range between -13% and 155%, while for drifts between -14% and 211%. In comparison with CP, the absolute values of *ME* resulting from PM are smaller for 384 of 432 displacements and for 357 of 432 drifts. The *ME* of CP range between 0% and 240% for displacements and between 0% and 241% for drifts. Concerning the influence of the torsional properties of the buildings, no remarkable differences in the accuracy of response quantities of the center of mass is identified. However, the proposed procedure tends to highly overestimate both displacements and drifts of the flexible side of 'torsionally similarly stiff" buildings. On the other hand, the mean errors of the response quantities of the stiff side are generally smaller in comparison with 'torsionally stiff' and 'torsionally flexible' buildings. Obviously, this phenomenon may be attributed to the action of torsion. Finally, it is worth noticing that no correlation between the ductility required for each excitation and the corresponding error has been observed.

4 CONCLUSIONS

In the present paper a recently developed multimode pushover procedure is evaluated for asymmetric systems with various torsional properties. The procedure is applicable to asymmetric in plan buildings under concurrent action of two horizontal seismic components and its main advantage is that it does not require independent analysis in two orthogonal directions. Thus, the use of simplified directional combination formulae, which is not valid in the nonlinear range, is avoided. The evaluation study conducted in the present paper leads to the verification of some already derived conclusions [12], [13], [14]:

- The proposed methodology provides for each response parameter an upper limit and a lower limit which in the majority of cases envelope the 'exact' value.
- In general, the mean errors with regard to the nonlinear dynamic analysis results are smaller than those resulting from a conventional procedure based on simplified directional superposition rules.

Furthermore, it seems that the proposed methodology provides more reasonable estimation of the seismic response of 'torsionally stiff' and 'torsionally flexible' in comparison with 'torsionally similarly stiff' buildings.

Keywords: CubeSat, Random Vibration, Optimization, Fatigue Analysis

Abstract. *This paper presents structural analyses and optimization of a student's CubeSat project to be launched in a lower thermosphere orbit. The static and dynamic responses of the primary and secondary structures are simulated, using ANSYS Finite Element Software, being subjected to the mechanical environments of two candidate launchers. The mass of the primary structure is optimized subject to quasi-static loading, during launching phase, given certain constraints on the strength and stiffness imposed by the P-POD provider and the candidate launchers. In addition, random base excitation response, and hence fatigue life estimation, are performed in order to ensure that the primary and secondary structures will safely survive the launching phase. Finally, the structural response of some selected subsystems, modeled in detail and simulated individually, are compared with their lumped mass approximations, which are simulated as part of the whole CubeSat, in order to investigate the outcome of such approximations.*

1 INTRODUCTION

The CubeSat is a modular pico-class-satellites which are early-developed by the Space Systems Design Laboratory at Stanford University. The simplest standardized solution is the 1-Unit CubeSat, a cube-shaped satellite with 100x100x100 mm dimensions and a weight of up to 1,33 kg. This category of satellites, though encapsulated in an Orbital Deployer (P-POD), developed by California Polytechnic State University, is launched as a secondary payload. CubeSat missions are among the most enticing and advanced categories in the space industry, because a cluster of such pico-satellites may easily replace a large cluster. When testing new components and applications, CubeSat missions have proved useful for space-qualified use in future. In addition, these uniform pico-satellites made the university's space technology readily available as a subject in undergraduate and postgraduate programs, where they were originally started. Ampatzoglou et al. [1] designed and tested a 2U nanosatellite, to be launched and working in the lower thermosphere. They developed a hybrid subsystem based on both aluminum and composite materials, fulfilling all design and test requirements and successfully launched into orbit, proving the feasibility of the new design. Barsoum et al. [2] presented hands on experience of the configuration process and strength analyses of a student's CubeSat project. They preformed static and random vibration analysis, and fatigue life analysis in order to the primary structure will safely mechanical environment design will survive the mechanical environments launched safely. Eiswy et al. [3] presented the overall design process of the structure subsystem of 1-U CubeSat mission. they implemented the static and modal analysis using finite element method. Raviprasad et al. [4] they provided the modal, harmonic and random vibration analysis of the nano-satellite mission and findings were compared with the standard mechanical specifications of the CubeSat and launch vehicle providers. Oh et al. [5] introduced a CubeSat mission structure concept, based on the 1U Model, developed by the Chosun University Space Technology Synthesis Laboratory. Furthermore, the validity of their proposed design was investigated through quasi-static and modal analysis. Swartwout [6] Submitted a comprehensive review of the first one hundred CubeSat missions, together with an on-orbit performance assessment while classifying missions by size, origin and mission life. It was found that many design and deployment defects, while correctable, still haunt the CubeSat missions at the university. Furthermore, for this type of missions the P-POD launch container, not the CubeSat model, has proven to be the true supporting technology. Alminde et al. [7] Addressed the educational value of the CubeSat university projects by explaining the overall architecture of the AAU-CubeSat university project launched in space on 30 June 2003. Results from the operation phase were presented, suggesting further work on pico-satellite designs. Noca et al. [8] presented the project organization, mission and satellite description of their first pico-satellite project, Swiss-Cube, developed at the Federal Institute of Technology Space Center in Lausanne. Technical and programmatic lessons were discussed, since the main objective of this project was to provide practical experience of the entire cycle of satellite production. Cote et al. [9] outlined the power, propulsion, and structure subsystems of Worcester Polytechnic Institute's initial endeavor to experiment a CubeSat. Each of the three subsystems teams managed to design and specify a baseline set of components for their subsystem and to perform rudimentary testing. Castello [10] built a MATLAB toolbox to help CubeSat developers understand the limitations of CubeSat, automate their systems, and decrease design development time while meeting initial requirements. Cghan [11] the design analysis of the structure and mechanisms subsystem of their second CubeSat project at the Technical University of Istanbul. Two separate designs were proposed, and the final selection was based on certain target performance parameters. Bürger

et al. [12] Presented static and modal analysis of the structure subsystem of a CubeSat project developed at the Brazilian Aeronautics Technology Institute. Arroyave et al. [13] proposed a design protocol that would help in meeting the unique structural specifications of CubeSat missions. In addition, they evaluated the static and dynamic behaviour of some case studies by performing static, modal, harmonic, and random vibration analyses, subject to special mechanical load conditions. The current work presents structural analyses and optimization of a student's CubeSat project to be launched in a lower thermosphere orbit. The static and dynamic responses of the primary and secondary structures are simulated, using ANSYS Finite Element Software, being subjected to the mechanical environments of two candidate launchers. The mass of the primary structure is optimized subject to static and natural frequency constraints,In addition, random base vibration response, and hence fatigue life are performed in order to ensure that the primary and secondary structures will safely survive the launching phase. Finally, the structural response of some selected subsystems, modeled in detail and simulated individually, and compared with their lumped mass approximations, which are simulated as part of the whole CubeSat, in order to investigate the outcome of such approximations.

2 MODEL OVERVIEW

The current pico-satellite project is a 1-U CubeSat, made for earth observation purposes and is based on commercial of the shelf (COTS) components[18][19]. The primary structure is assembled by four corner rails connected, by stainless steel screws, to four side panels made of Aluminum 6061-T6. Inside the enclosure, four spacer rods, made of brass, where installed to support the Printed Circuit Boards (PCBs) of the different satellite subsystems. Inside the structure, the following components are placed from top to bottom. An optical earth observation camera is installed at the top with its lens penetrating from the top cover. A Communication (COMM) system board responsible for the communication between the CubeSat and the ground station. An On-Board Computer (OBC) board that controls the CubSat based on the commands incoming from the ground station. An Attitude and Directional Control (ADC) unit responsible for the positioning and orientation of the Cubesat. Lastly, an Electrical Power Supply (EPS) unit that powers the CubeSat circuitry. The initial proposed mass budget of the CubeSat, before the optimization, is 1.076 Kg namely: the structure mass 360 g, camera mass 210 g, COMM mass 75 g, OBC mass 75 g, ADC mass 156 g and EPS including its batteries 200 g. Two CubeSat models were investigated throughout the current work; the first one is based on a detailed configuration of the interior and the second one is based on lumped mass representation of the PCBs. Figure 1 shows the proposed detailed layout of the CubeSat with and without the side panels.

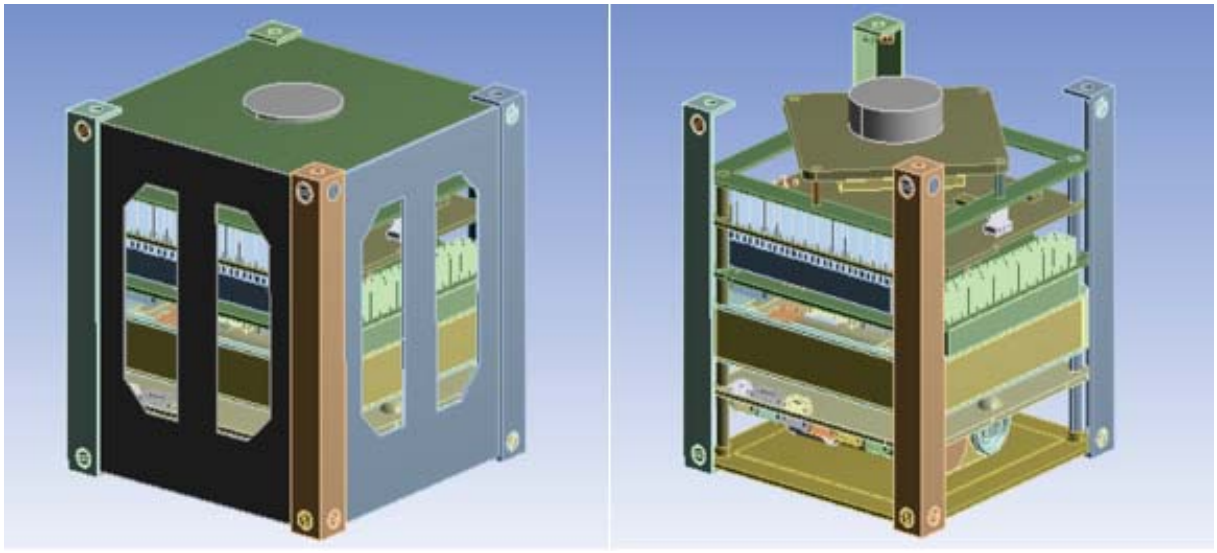

Figure 1: Layout of the proposed primary structure with(left) and without(right) side panels

3 RESULT AND DISCUSSION

3.1 Static analysis of the Assembly

All the analyses presented, hereinafter, are intended to check the static and dynamic behaviour, of the current proposed CubeSat primary structure and its PCBS, in response to the mechanical environment of Soyuz and Dnepr as two candidate launchers. The static response of the satellite structures is simulated while being exposed to a quasi-static acceleration of 13g in the X, Y and Z directions simultaneously. The primary structure is assumed to be clamped through the whole length of the rails [1]. Figures 2 and 3 show the distributions of the equivalent stress and total deformations, respectively, of the lumped mass model. It is shown that the structure experiences maximum stress of 18.786 MPa which is fairly safe in terms of yield stress when compared to the 276 MPa which is the yield stress of the aluminum 6061-T6 and it is seen in Figure 3 that the structure responds with a maximum value of total deflection equals 0.1501 mm which is found very acceptable in terms of the static deflection interference of the different components of the satellite as per the interior static envelop of the proposed configuration. However, for the detailed model shown Figure 4, the equivalent stress increased to 43.127 MPa and the total deformation 0.021066 mm as shown in Figure 5. Taking a closer look at the detailed model, the maximum stress value appeared to be at the pins of the COMM board where these pins are absent in the lumped mass model.

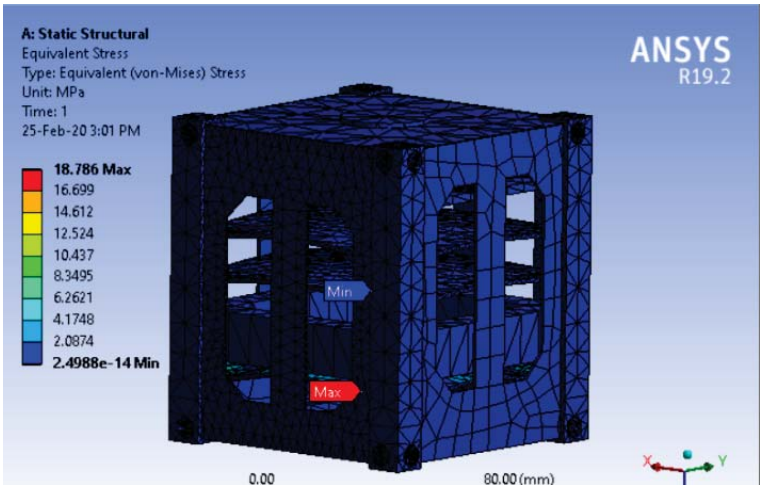

Figure 2: Equivalent Von-Mises stress lumped mass model

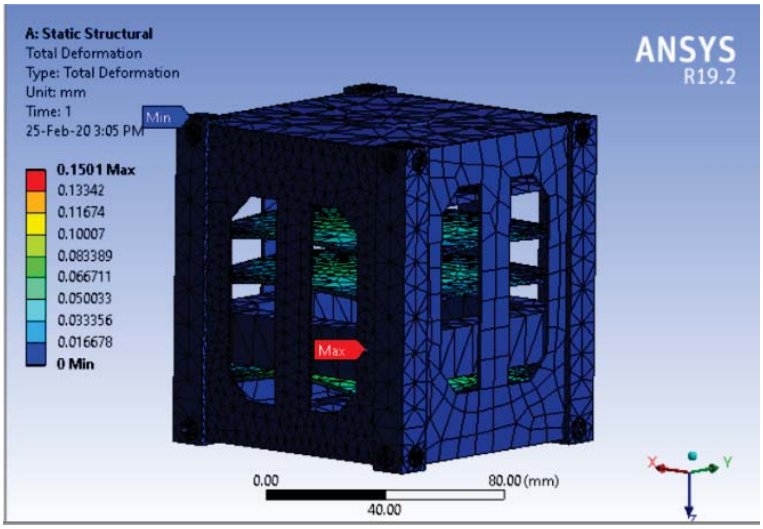

Figure 3: Total Deformation in lumped mass model

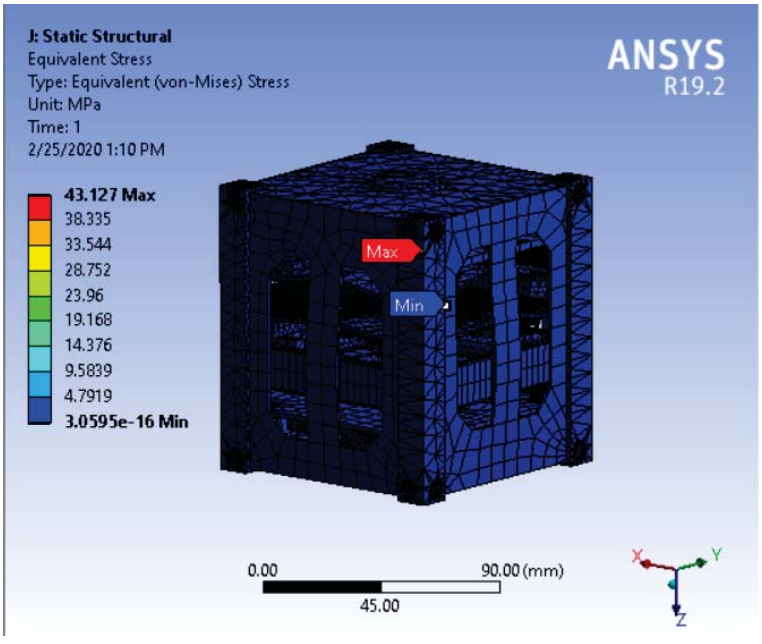

Figure 4: Equivalent Von-Mises stress in fully detailed model

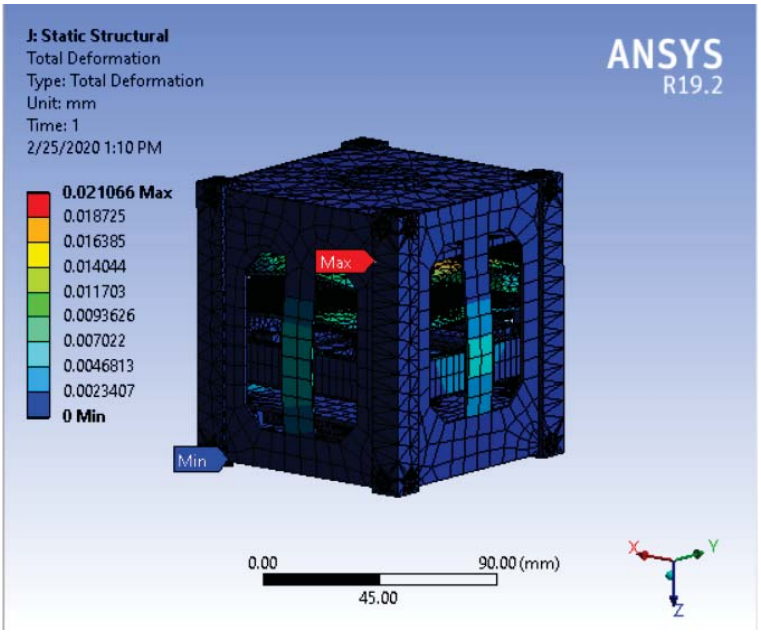

Figure 5. Total Deformation in fully detailed model

3.2 Modal Analysis

Modal analysis was conducted on both, lumped mass and detailed models, for the first six mode shapes as shown in Table 1. It is shown in the results that the first natural frequency of the lumped mass model is 199.81 Hz while in the detailed model the value jumped high to be 562.52 Hz which can be attributed to the more even distribution of the masses on each printed circuit board compared to the lumped mass modeling. The fundamental frequency of both models were found above the lower threshold value of 100 Hz specified by launcher providers.

Mode	Natural Frequencies [Hz]	
	Detailed	Lumped mass
1	562.52	199.81
2	609.68	292.36
3	702.01	304.37
4	785.64	537.79
5	843.19	683.27
6	859.68	686.14

Table 1: Natural frequencies for detailed and lumped mass models

3.3 Static Structural and Modal analyses of PCBs

This section presents the quasi-static response and natural frequencies of each subsystem PCB analyzed separately. There are four commonly used in most CubeSat missions namely: COMM, OBC, ADC and EPS. All of the PCBs are simulated assuming that they are supported from their corner holes. Table 2 shows the static analysis on the COMM board yielding the highest stress value when compared to other PCBs with a value of 50.5 MPa, which is almost similar to the maximum of 43.127 MPa displayed in the analysis of the detailed model and a total deformation of 0.02 mm. Figure 6 shows the maximum stress at the pins of the COMM board same as at the detailed model. In addition, the first mode shape in the detailed model appeared at the COMM board at 562.52 Hz which is approximately the same as the first mode shape of the COMM board which was analyzed separately.

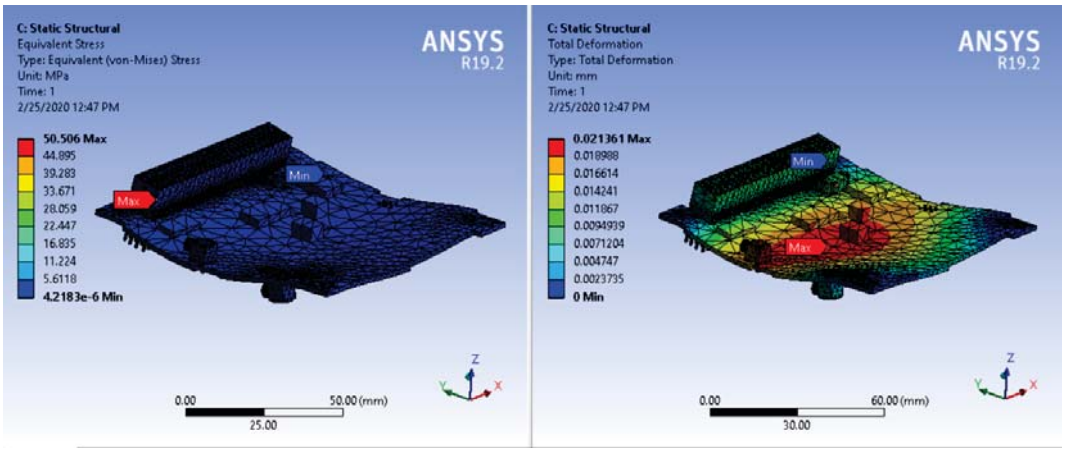

Figure 6: Quasi-static response of COMM PCB: Stress and deformation

Analysis	Value
Von-Mises Stress	50.506 [MPa]
Total Deformation	0.021361 [mm]
Safety Factor	5.5

Table 2: Quasi-static response of COMM PCB

3.4 Optimization

The Objective of the optimization was to minimize the mass of the CubeSat, while keeping it safe under launch loads by limiting the factor of safety of the structure to 2 or more. The mass of the initial proposed design of the CubeSat was 1.076 Kg and the mass of primary structure itself is 0.36012 Kg. After conducting the optimization process, Using surface response optimization method, the CubeSat total mass is dropped to 0.899 Kg which is 16% less than the initial total mass of the CubeSat. To ensure the safety of the structure, static analysis is implemented on the optimized model with the same loading conditions and it yielded nearly same results compared to those prior to the optimization as shown in Figure 7 and 8.

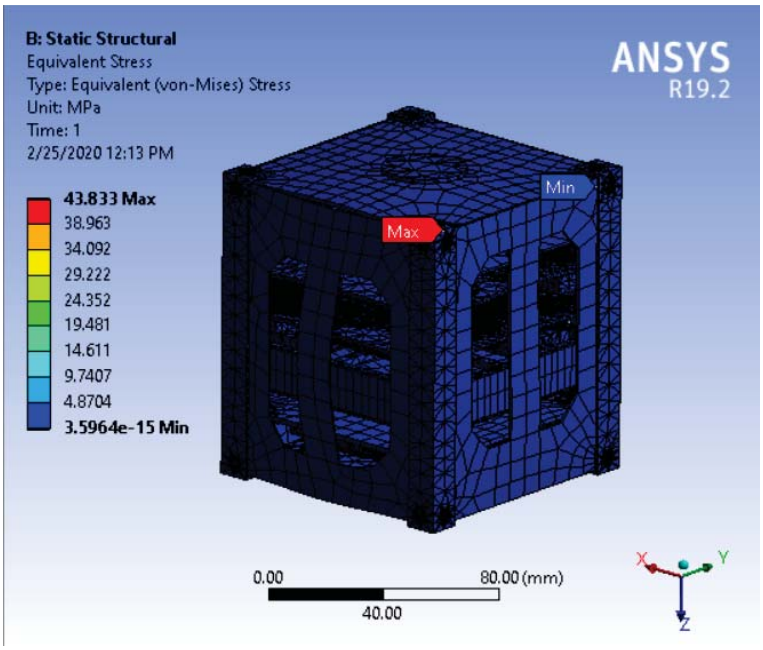

Figure 7: Equivalent Von-Mises for the detailed optimized model

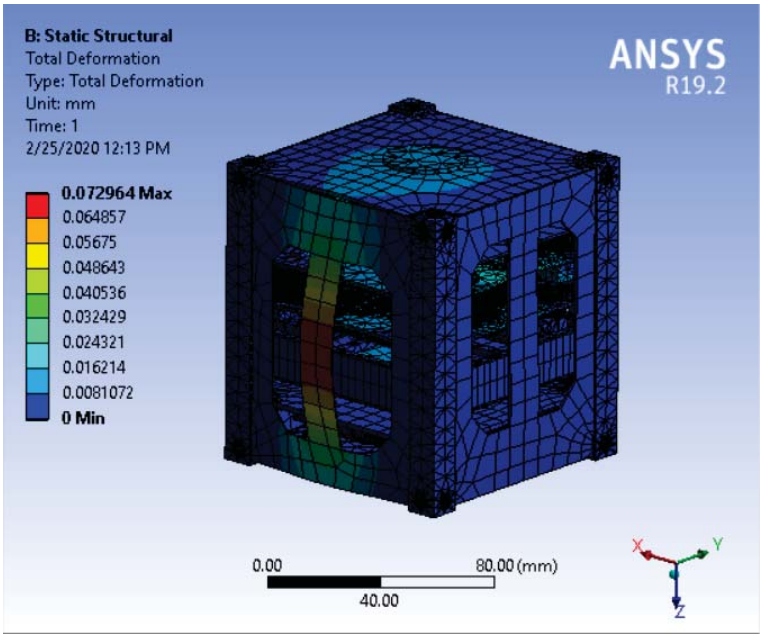

Figure 8: Total Deformation for the detailed optimized model

3.5 Fatigue analysis

This section presents the fatigue analysis of the optimized Cubesat primary structure subjected to random vibration induced by two candidate launchers, namely: Soyuz and Dnepr. The main purpose of preforming this analysis is to identify the stress peak of each launching phase, corresponding to the resonance frequencies of the primary structure to be used later in assessing the effect of cumulative fatigue. Tables 3 and 4 show the PSD (Power Spectral Density) random vibration loading of Soyuz and Dnepr respectively, specifying the expected duration of each launching stage[16][17].

Event	Frequency Band (Hz)						Time (s)
	20-50	50-100	100-200	200-500	500-1000	1000-2000	
	PSD, Power Spectral Density $10^{-3}g^2/HZ$						
1st Stage	5.0	5.0 10.0	10.0 25.0	25.0	25.0 10.0	10.0 5.0	120
2nd & 3rd Stage	2.5	2.5 5.0	5.0 10.0	10.0	10.0 5.0	5.0 2.5	480
Fregat Stage	2.0	2.0	2.0	2.0	2.0-1.0	1.0	1100

Table 3: The limit flight levels of random vibrations of Soyuz launcher [16]

Event	Frequency Band (Hz)							Time (s)
	20-40	40-80	80-160	160-320	320-640	640-1280	1280-2000	
	PSD, Power Spectral Density $10^{-3}g^2/HZ$							
Lift Off,	7.0	7.0	7.0	22.0	35.0	35.0	17.0	35
LV Flight			22.0	35.0		17.0	5.0	
1st Stage Burn	7.0	7.0	7.0	7.0	9.0	9.0	4.5	831
				9.0		4.5		

Table 4: The limit flight levels of random vibrations of Dnepr launcher [17]

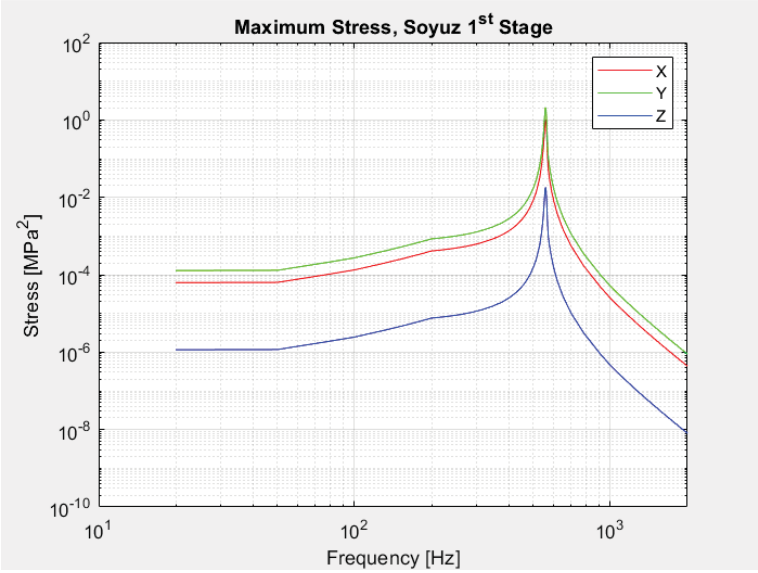

Figure 9: Random vibration response of Soyuz 1^{st} Stage in X, Y and Z (Hz – MPa^2)

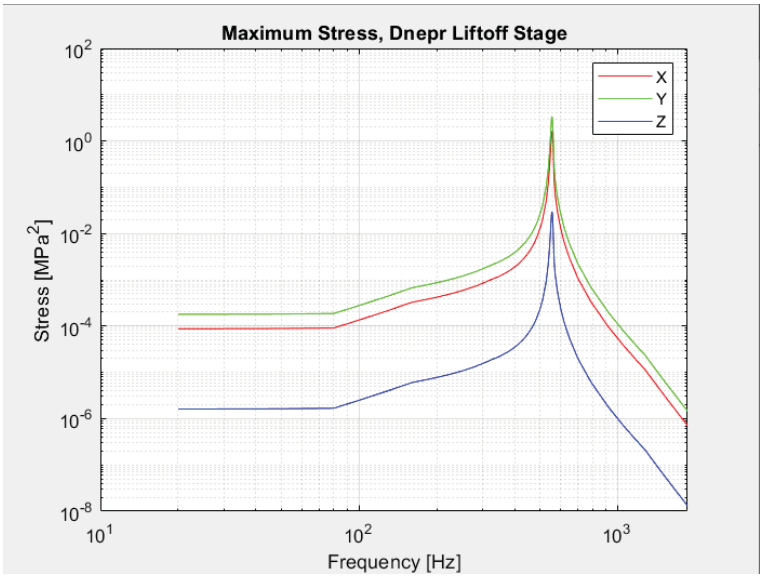

Figure 10: Random vibration response of Dnepr Lift Off, LV Flight in X, Y and Z (Hz – MPa^2)

PSD stress calculated on 24 different points namely, 4 points at the connections between the 4 PCBs and the spacer rods, 4 points at the center of the side panels and 4 points at the middle nodes of the PCBs. From the results of Dnepr simulations, it was found that the liftoff stage yielded the highest stress level, as shown in Figure 10 , which occurred at the point of connection between the spacer rod and the COMM board. It is seen in the Figure 9 that x direction the peak value was 1.02 MPa^2/Hz, y direction was 2.09 MPa^2/Hz and z direction was 1.83E-02 MPa^2/Hz at 557.84 Hz, as in Figure 10 it is seen that x direction the peak value was 1.65 MPa^2/Hz, y direction was 3.39E MPa^2/Hz and z direction was 2.96E-02 MPa^2/Hz at 557.93Hz. As mentioned before the number of stress cycles *ni*, at one frequency found to be most influential, will be calculated while assuming that this frequency will happen to last for the total duration of the given launching stage. Therefore, the frequency peak was found to have the highest (*ni*/*Ni*) value, for the given launching stage, will be considered in calculating the total cumulative effect of all stages.

Referring to the S-N curve of the selected aluminum alloy, it was found that all of the stress levels reported in the previous section fall in the category of high cycle fatigue. Therefore, it would be conservative to use 1E+8 as the number of cycles to fail for all the simulated values of the stress. Miner's law for cumulative fatigue has been implemented for both launcher cases. as shown in table 5 and table 6 number of cycles (*ni*) at stress peak and number of cycles to fail (*Ni*) at each loading phase and then sum the all values to get total cumulative effect of all stages as shown. The total cumulative in launcher Soyuz value is 0.02845 while in launcher Dnepr value is 0.0157.

Loading phase		No. of cycles at 1st stress peak ni	No. of cycles to fail at 1st stress peak Ni	ni/Ni
1st Stage	X	66940.8	1×10^8	0.00067
	Y	66951.6	1×10^8	0.000669516
	Z	66940.8	1×10^8	0.000669408
2nd Stage & 3rd Stage	X	267806.4	1×10^8	0.002678
	Y	267806.4	1×10^8	0.002678
	Z	267806.4	1×10^8	0.002678
Fregat Stage	X	613723	1×10^8	0.006137
	Y	613723	1×10^8	0.006137
	Z	613723	1×10^8	0.0061372
Total cumulative effect of all stages				0.028454214

Table 5: Cumulative fatigue damage analysis subject to Soyuz random load

Loading phase		No. of cycles at 1st stress peak ni	No. of cycles to fail at 1st stress peak Ni	ni/Ni
Lift Off, LV Flight	X	19527.6	1×10^8	0.0002
	Y	19527.55	1×10^8	0.000195276
	Z	19527.55	1×10^8	0.000195276
1st Stage Burn	X	463639.8	1×10^8	0.004636
	Y	267739.2	1×10^8	0.002677
	Z	267806.4	1×10^8	0.002678
Total cumulative effect of all stages				0.010577681

Table 6: Cumulative fatigue damage analysis subject to Dnepr random load

The Modified Goodman-line method was implemented to determine the fatigue factor of safety based on highest stressed location, out of those previously checked using Miner's cumulative fatigue life assessment. The number of stress cycles, of the aforementioned stress location, was calculated using the fundamental frequency and the whole time duration of all launching stages which represent quite conservative assumption. Table (7) shows the stress results of the highest stressed location, which happened to be the maximum out all launching stages, of the two candidate launchers. The fatigue limit of Aluminum 6061-T6 was assumed to be 96.5 MPa as per Yahr [20] for a full reversed cycle, while the maximum stress amplitude was assumed to be 4.5 times the root mean square value (RMS), by converting the random vibration response of the critical launching stage from frequency domain to time domain [21]. It was found that both candidate launchers are fatigue safe with a minimum factor of safety of 2.46, depicted by Dnepr, despite the very conservative assumptions implemented while applying Goodman method compared to those previously used in Miner's cumulative fatigue assessment which proved over safe as well.

Stage	Direction	RMS [MPa]	Stress [MPa]	σ_a	Factor of Safety n
Soyuz 1st Stage	X	3.9211	17.64495	17.64495	5.468986877
	Y	5.6137	25.26165	25.26165	3.820019674
	Z	0.52708	2.37186	2.37186	40.68536929
	Resultant		30.904	30.904	3.122
Dnepr Liftoff	X	4.9712	22.3704	22.3704	4.313736008
	Y	7.1171	32.02695	32.02695	3.013087415
	Z	0.66825	3.007125	3.007125	32.09045184
	Resultant		39.183	39.183	2.46

Table 7 Fatigue life Assessment using Modified Goodman-line factor of safety

4 CONCLUSIONS

This work presented structural analyses and optimization of a student's CubeSat project subject to the mechanical environments of two candidate launchers. The structural response of some selected subsystems, modeled in detail and simulated individually and as part of the whole CubeSat, are simulated and compared with their lumped mass approximations. In terms of the quasi static response due to launcher g-loads, it was found the primary structures of the detailed and lumped mass models displayed similar stress values, in magnitudes and locations. while the some fine details of the subsystems PCBs, which were absent in the lumped mass model, showed stress levels more than two time those of the lumped mass one. Modal analysis results of both models showed that the fundamental frequency of the detailed model higher than the lumped mass one by 281.5% which can be attributed to the much even distribution of component masses of the detailed PCBs model. Therefore, such significant difference in the simulated frequencies could affect the accuracy of the modal assurance coefficient provided to launcher providers. Furthermore, optimization of the primary structure has implemented and the results showed a mass reduction of 16%, which made it 0.899 Kg instead of an initial value of 1.076 Kg.Finally, fatigue life assessments were implemented to the CubeSat primary structure and its PCBs, using Miner's law and Goodman – line method, subject to random vibrations induced by both candidate launders. It was found that both candidate launchers are fatigue safe with a minimum factor of safety of 2.46, depicted by Dnepr, despite the very conservative assumptions implemented while applying Goodman method compared to those previously used in Miner's cumulative fatigue assessment which proved over safe as well.

Keywords: Low-Rise Buildings, Pressure Coefficient, Wind Tunnel, Neighboring structure.

Abstract. *Experimental studies of the wind effects on a low-rise building considering two different turbulent wind speeds and one type of terrain category were carried out at the boundary layer Wind Tunnel operated by the Institute of Engineering of UNAM (IIUNAM). The model considered was a cube made of acrylic, instrumented with 125 taps. Two experimental setups were considered, the first one considered the evaluation of the wind effects on the isolated model (with no obstacles surrounding it), while the second one evaluated the effects of placing a body of identical shape next to the studied model. The second setup considered six different separations between the models. For both experimental setups, wind direction was varied from 0 ° to 180 ° with increments of 10 °, and including the angles of 45 ° and 135 °. Mean, maximum and minimum pressure coefficients were obtained for each arrangement in order to make a comparison between the values obtained in each tap. The results show that the consideration of a neighboring structure has an important impact on the pressure coefficients due mainly to Venturi effects and vortex shedding. It was also observed that the separation between the instrumented model and the obstacle serves as an important parameter to evaluate the increase or decrease of the wind pressures with respect to the isolated model.*

1 INTRODUCTION

In recent years, research on construction and the environment has taken a different direction than the traditional one, trying to minimize the impact on the environment and provide better comfort for the inhabitants. The presence of tall buildings on areas with a high density of low-rise buildings, results in the presence of turbulent wind flows that disturb people's activities. Narrow corridors within an industrial or residential area accelerate flows giving the perception of a greater impact of the wind effect, affecting the activities in these areas.

In some countries, the effects of wind are studied in suburban and urban areas with different building configurations, and their impact on the comfort of people or activities are carried out in predefined spaces [1, 2]. These studies are often developed with Computational Fluid Dynamics (CFD) and later validated with a few wind tunnel tests. These studies are carried out to confirm that the speeds, within spaces confined by neighboring buildings, do not exceed the recommended values for the pleasant stay of the inhabitants. In the event of finding speeds greater than permissible, it is proposed to build barriers that reduce the wind impact and generate greater comfort areas.

In Mexico, the use of any comfort criteria is an unusual practice during the structural design stage, which may lead to serious problems during unfavorable environmental conditions. In this work, experimental studies of the wind effects on a low-rise building by considering two different turbulent wind speeds and one type of terrain category were carried out at the boundary layer Wind Tunnel operated by the Institute of Engineering of UNAM (IIUNAM). The model considered was a cube made of acrylic, instrumented with 125 taps. Two experimental setups were considered, the first one considered the evaluation of the wind effects on the isolated model (with no obstacles surrounding it), while the second one evaluated the effects of placing a body of identical shape next to the studied model. The second setup considered six different separations between the models. For both experimental setups, wind direction was varied from 0 ° to 180 ° with increments of 10 °, including the angles of 45 ° and 135 °. The results show that the consideration of neighboring structures has an important impact on the pressure coefficients due mainly to Venturi effects and vortex shedding.

2 BACKGROUND

The first wind tunnel of UNAM was inaugurated in 1966, in which important projects such as the wind load analysis of the Palace of Sports was studied; however, due to its dimensions, this tool is considered to have significant limitations when addressing current problems of modern wind engineering [3]. Therefore, in 2006, researchers from the Institute of Engineering (IIUNAM) joined efforts to develop a design for a new wind tunnel that was revised and modified by AIOLOS. The new facility was built by a Mexican company and was finally inaugurated in 2015. The boundary layer Wind Tunnel, operated by IIUNAM, is a tool for experimental study of the effects of wind on civil structures through dimensional and similarity analysis in a long-length test section (Figure 1). One of the main dimensional parameters is the geometric scale, which involves not only the scaling of the model, but also the terrain and consequently the scaling of atmospheric conditions.

For practical purposes in civil engineering, within the troposphere there are three main sublayers, the Planetary Boundary Layer (PBL), whose height is associated with a geostrophic height the Atmospheric Boundary Layer (ABL) whose thickness is associated with a gradient height, and the Atmospheric Surface Layer (ASL) which is the closest layer to the ground and usually represents the bottom 10% of the PBL (usually 100 m), its height is mainly defined by vegetation [4]. In the laboratory, ABL is often considered, and ASL is implicitly represented.

The correct simulation of one or the other must adequately replicate the mean velocity and turbulence intensity profiles associated with certain category of terrain based on the logarithmic law or the power law. In order to achieve proper representation in an artificial way, there are several methods, the most commonly used is the Counihan method [5], which uses a barrier, an elliptical needle set and a series of roughness elements distributed throughout the test section, which represent the idealized topography of some terrain. When defining the terrain and model simulation scale, an iterative "test and error" process is required. Based on works by Balendra [6] and Endo [7], in this study the ASL of an urban terrain was adequately represented. The mean wind velocity and turbulence intensity profiles measured were associated with an open country terrain for real velocity values of 13.23 m/s and 21.45 m/s. The geometric scale used was 1:50, while the calculated speed scale was 1:5.

The Silsoe Cube is one of the models that has been tested by various researchers, both on real and reduced laboratory scales. This model has been used for calibration of rigid models and tests of low-rise buildings [8]. It is important to note that this model is usually used for terrain category 2 (open country terrain). Based on the geometric scale mentioned above, the Silsoe Cube was scaled producing a 0.20 m cubic model which was constructed with $4x10^{-3}$m thickness acrylic plates to ensure model rigidity. When the model is oriented to ±45° on the turntable, and when the projected length is greater than 0.20 m, the effective blockade is less than 1% of the cross-sectional area of the tunnel test section 2 (Figure 1). Each face of the model was instrumented with 25 sensors (taps) providing a total number of 125 (Figure 3). The recording of pressure fluctuations and sensor distribution was proposed based on distributions suggested in the literature, as well as on the distribution of pressures obtained by CFD simulations [9, 10]. The sampling rate for the pressure records was 256 Hz and the sampling time was 45 seconds (real-scale observation time is 10 min), obtaining a total of 11,520 samples for each wind direction.

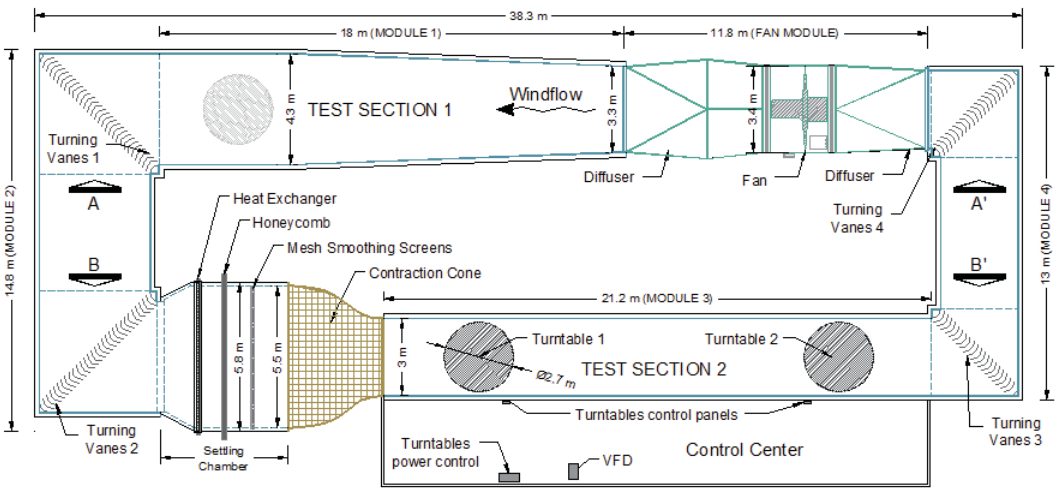

Figure 1. Diagram of the UNAM boundary layer wind tunnel [8]

3 WIND TUNNEL TESTS

Two scaled wind speeds were considered in the tests, the first one was 3.53 m/s and the second one was 5.72 m/s. The previous velocities correspond to mean wind speeds at 10 m height of 13.23 m/s and 21.45 m/s in real scale, respectively. One of the tests consisted in the evaluation of the pressure distribution over the isolated acrylic cube, this test was called Arrangement 0 (Figure 3a). This pressure distribution was used as reference to evaluate the im-

pact of having a structure, with the same geometry as the cube, next to the reference structure. The proposed arrangements for the reference structure with one identical next to it were chosen based on two relevant criteria. Firstly, to get the most common arrangement in the construction of industrial and housing complexes by using satellite images. Figure 2 shows two of these arrangements. The side and aspect ratios (d/b and H/b) of the structures are very similar, where d, b and H represent the length, width, and height of the structure, respectively. Figure 2a shows a minimum separation distance between them, whereas Figure 2b shows that the separation distances are increased. It is noted that variations in the height of bluff bodies in the proximity of the studied model are out of the scope of the present study. This aspect of variations in height requires further investigation.

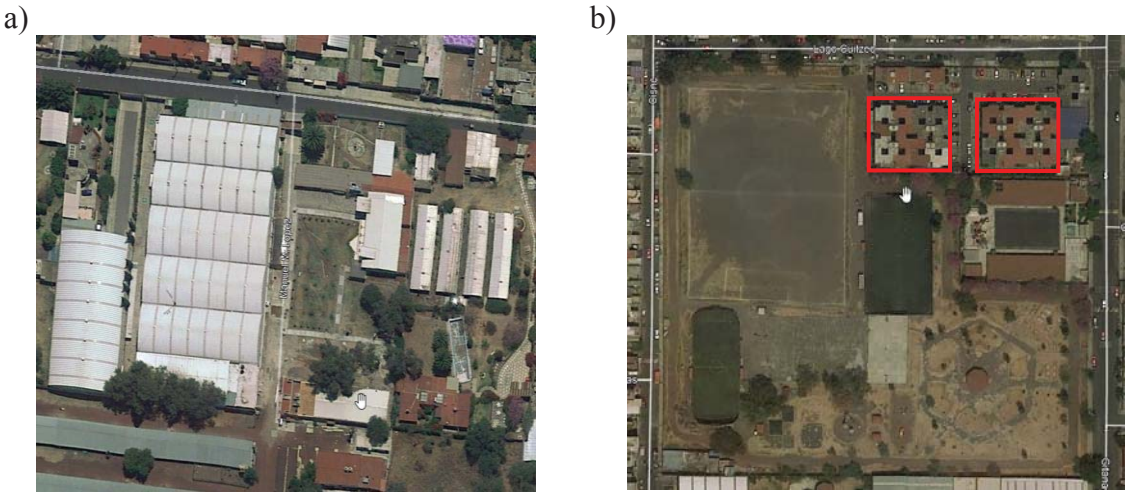

Figure 2. (A) Industrial buildings confined with less separation between them; (b) Two identical buildings in an open terrain with narrow corridors between

Secondly, three of the most important phenomena that can be identify due to the interference of an object in the flow of the wind are:

- Venturi effect. Neighboring buildings, due to their dimensions, shape and orientation, can cause a "bottleneck" effect, accelerating airflow and consequently pressure alterations.
- Wind deviation in vertical direction. When there is a higher body in the leeward zone, the wind flow that affects its windward face is diverted downward increasing the velocities and pressures in areas close to this face. Buildings under this face may have higher pressure coefficients.
- Effects of vortex shedding. One building located at the leeward of another can be significantly affected by the turbulence wake caused by the blockage of the wind flow in windward, which can cause considerable dynamic effects and changes in pressures.

Figure 3b shows Arrangement 1 that consisted in the instrumented acrylic model (Silsoe Cube, [11, 12]), and next to it a wood obstacle placed at a gap that was varied from 0.5H to 3.5H, with 0.5H increments, where H is the total height of the cube (H = 0.20 m). This arrangement was located on turntable 2 (Figure 1), which allows the model to be rotated to simulate different wind directions (θ). The wind directions considered were 0°, 30°, 45°, 60°, 90°, 120°, 135°, 150° and 180°; angles at which it is expected to obtain the most critical external pressures/suctions on the reference model. As mentioned previously, two scaled wind speeds were considered. The wind tunnel tests carried out with these velocities were employed to evaluate if the wind speed affected the values of the External Pressure Coefficients (*EPC*), or

if they could be considered independent of the wind speed when there were obstacles with edges (bluff bodies) in the proximity of the studied model.

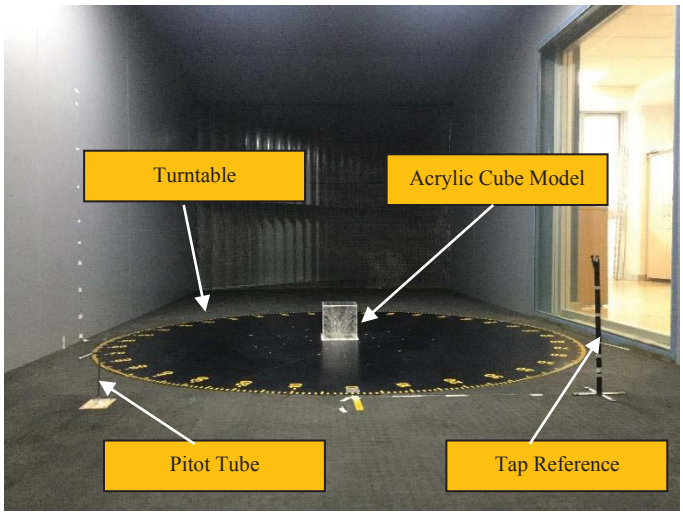

Figure 3a. Arrangement 0. Isolated model

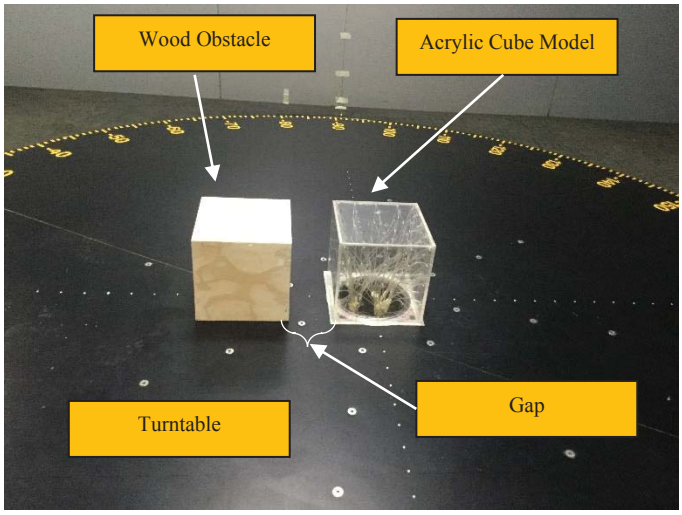

Figure 3b. Arrangement 1. Model with obstacle next to it

4 COMPARISON AND VALIDATION OF RESULTS

Once the pressure records on the different faces of the reference model were acquired, *EPC* were obtained for each tap, this coefficient is defined as the relationship between the pressure difference (ΔP) on a given surface and the dynamic pressure of the undisturbed flow (Pq), see ec. (1):

$$EPC = \frac{\Delta P}{P_q} \tag{1}$$

where:

$$\Delta P = P - p_s \tag{2}$$

$$P_q = P_T - p_s \tag{3}$$

P is the pressure measured on the taps.
p_s is the static pressure of the undisturbed wind flow, measured with a Pitot Tube in the center of the turntable, prior to the tests of the arrangements.
P_T is the total pressure of the undisturbed wind flow, measured with a Pitot tube in the center of the turntable, prior to the tests of the arrangements.

Table 1 shows the average *EPC* values for each face of the cube and each of the arrangements studied for a gap G = 2.0H. Table 1 shows that EPC values increase or decrease on the different surfaces of the model for each of the arrangements, with respect to the isolated model.

Table 1. Mean EPC values

The ratio of the EPC of each arrangement and the isolated model is known as the Interference Factor (F_I), which represents the reduction or increase in pressures and suctions that are acting on the faces of the reference model as a result of the obstacle. This is:

$$F_I = \frac{EPC_{AO}}{EPC_I} \tag{4}$$

where:

EPC_{AO} = External pressure coefficient in isolated model with obstacle.
EPC_I = External pressure coefficient in model.

Ec. (4) was used to determine F_I values for each of the arrays, Table 2 shows the results obtained.

Table 2. Interference Factor

Figure 5 and 6 show the F_I values for arrangement *1* with a gap of *2.0H* between the acrylic model and the wooden obstacle.

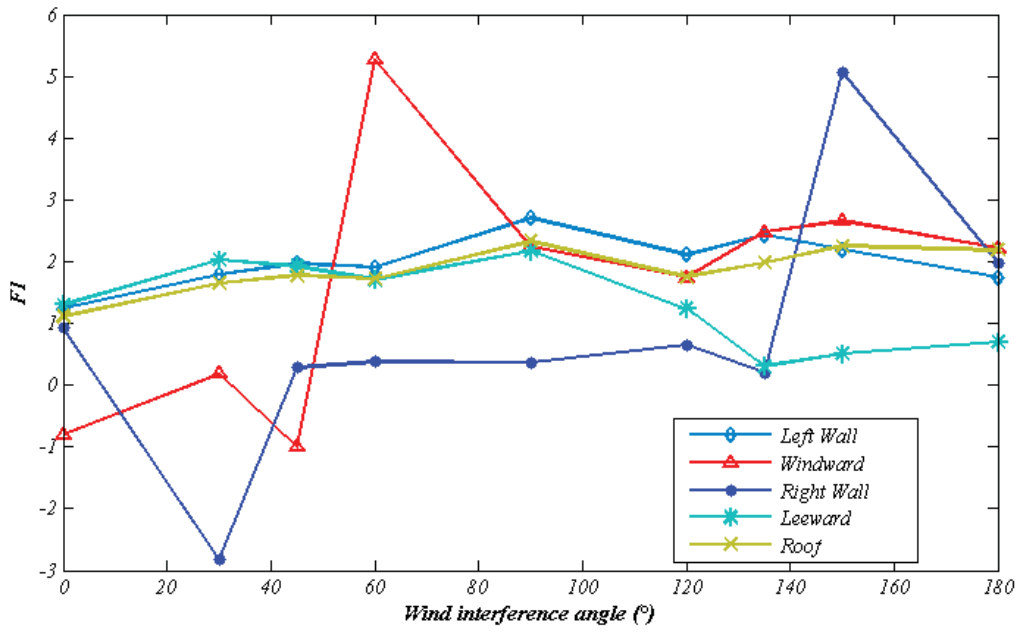

Figure 4. Variation of FI with wind direction for different faces of the reference model. Arrangement 1, V = 3.53 m/s and G = 2.0H

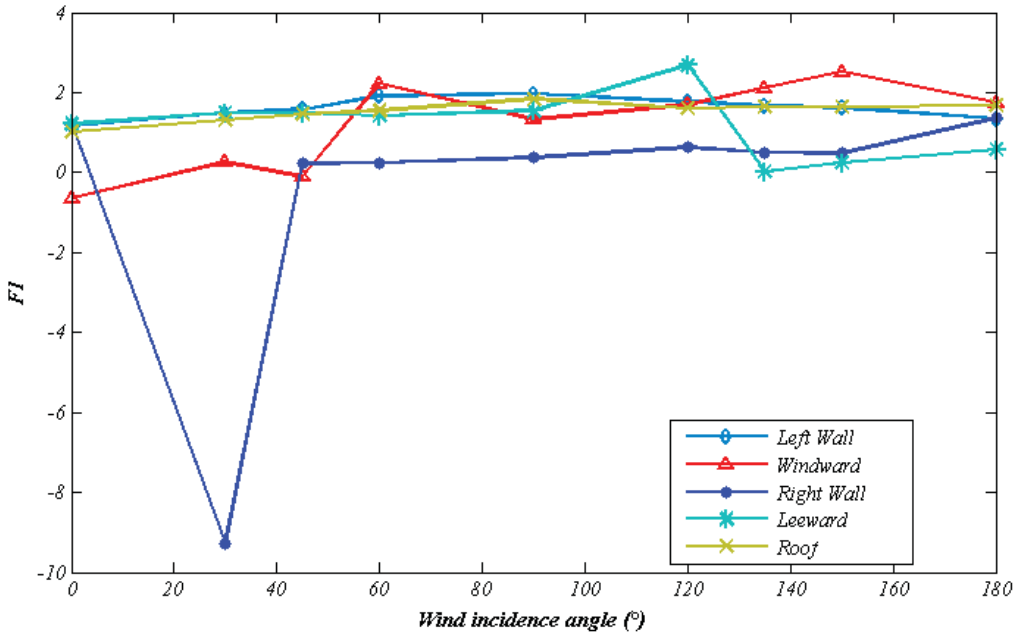

Figure 5. Variation of FI with wind direction on different faces of the reference model. Arrangement 1, V = 5.72 m/s and G = 2.0H

It can be observed from Figures 5 and 6 that F_I varies about 1. If the F_I value is above 1, the pressures or suctions observed in the isolated model are increased, in some cases by more than 100%, in the presence of the obstacles of each arrangement. On the other hand, if the F_I value is below 0, the pressures on the reference model have changed sign and became suctions, or vice versa.

For F_I values between the range of 0 and 1, the pressures or suctions decrease, since the zones are protected by the presence of the obstacle, this is known as the "Shielding Effect".

Figures 7 to 10 present the variation of F_I for other values of wind speed and separation.

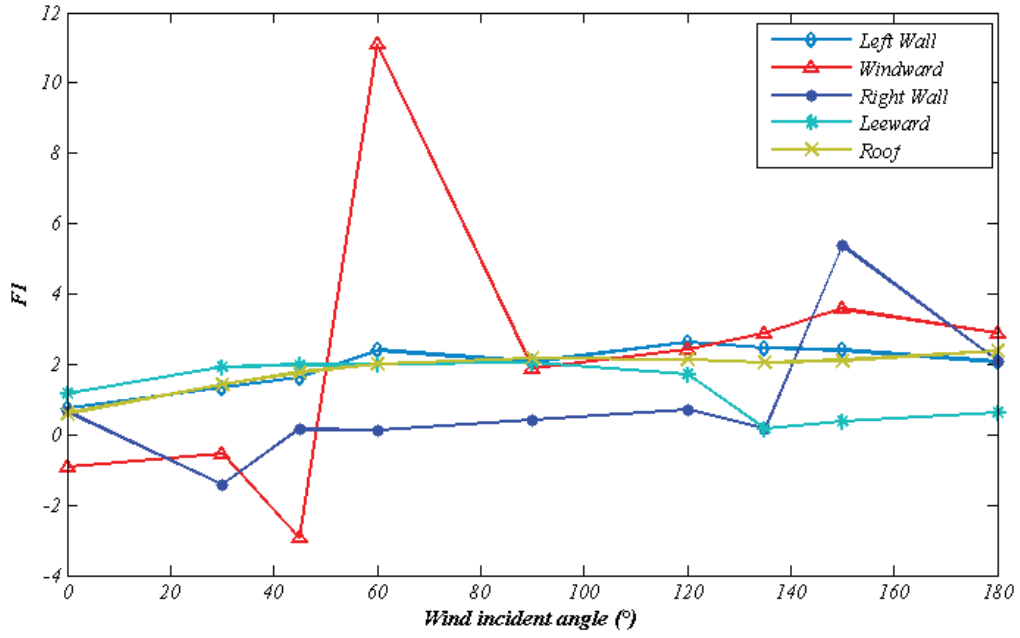

Figure 6. Variation of F_I with wind direction on different faces of the reference model. Arrangement 1, V = 3.53 m/s and G = 0.5H

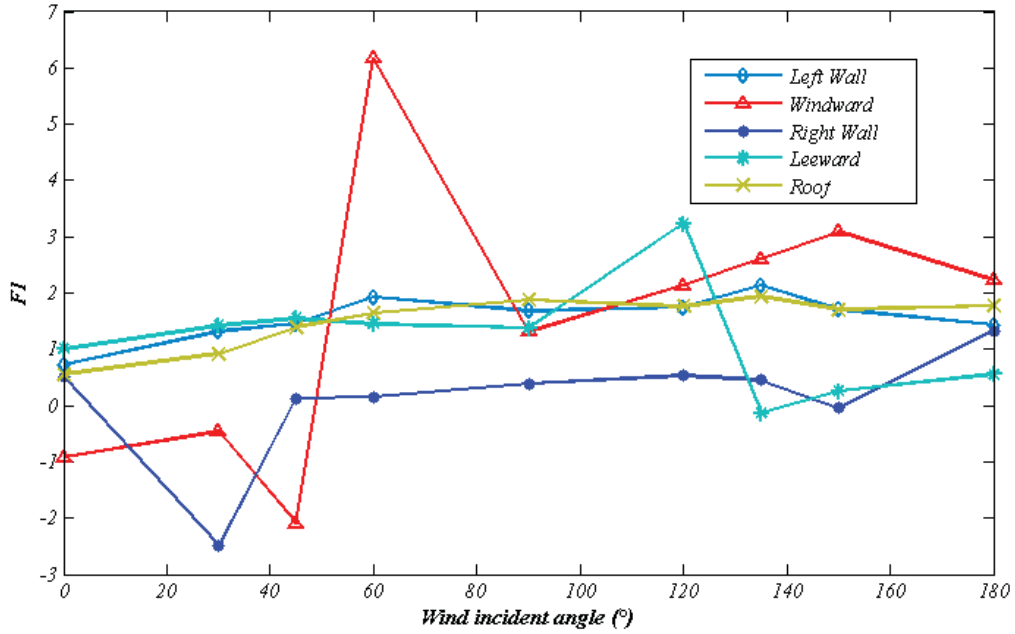

Figure 7. Variation of FI with wind direction on different faces of the reference model. Arrangement 1, V = 5.72 m/s and G = 0.5H

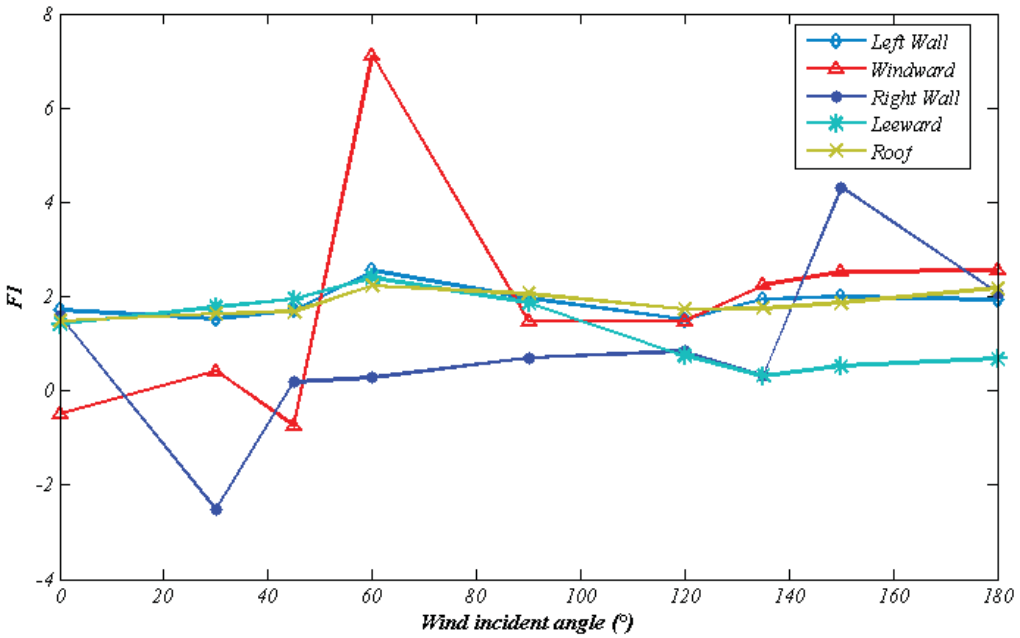

Figure 8. Variation of F_I with wind direction on different faces of the reference model. Arrangement 1, V = 3.53 m/s and G = 3.5H

In all cases, the Left wall and Roof face showed F_I values from 0 to 2. The same applies to the leeward face between the angles of 0° to 110°, then there is a transition at 120°, because at this angle, this face is the one that receives the flow of the wind in a direct way. When V = 3.53 m/s, the F_I at this angle decrease and then is equal almost to zero, while at the speed of V = 5.72 m/s, there is an increase of F_I to 2.5 on average and then descend to values almost to zero.

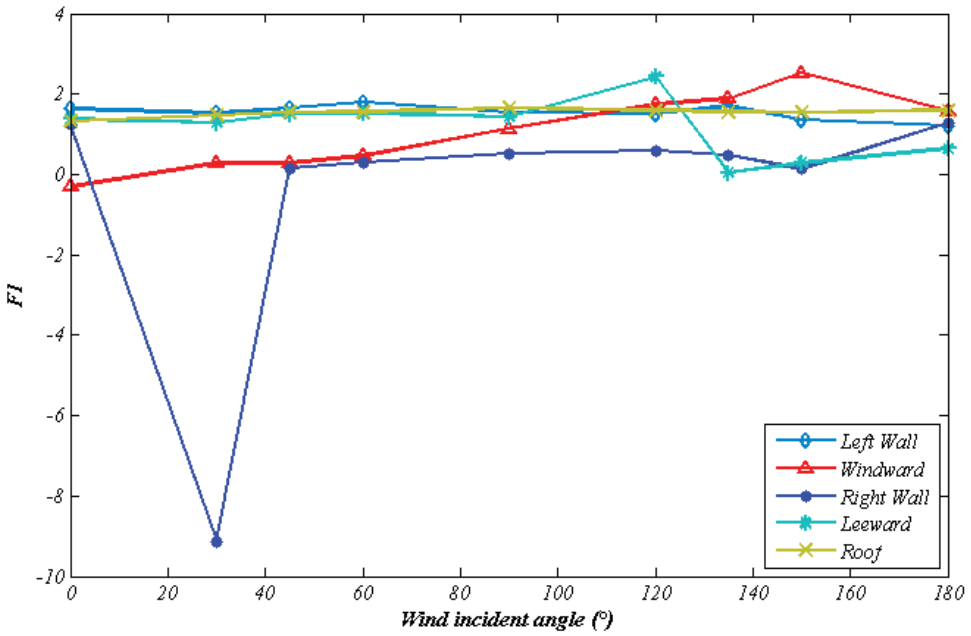

Figure 9. Variation of F_I with wind direction on different faces of the reference model Arrangement 1, V = 5.72 m/s and G = 3.5H

In the case of windward, no great variation between the values of Arrangement 1 for separations of 2.0H and 3.5H are observed (Figures 5 and 9), but by decreasing the gap to 0.5H there is a double F_I increase for the wind direction of 60° (Figure 7). This is probably cause by the combination of Venturi effect and vortex shedding due to the near edge of the obstacle.

Finally, for the right wall there is a considerable increase in the negative values of F_I at the wind incidence of 30° for separations of 2.0H and 3.5H (Figures 6 and 10) for wind speed equal to 5.72 m/s, while for a wind speed of 3.53 m/s the F_I values are almost identical to the other arrangements. Further, for low speeds, the F_I value is increased at 150°wind incidence (Figures 5, 7 and 9).

The shielding effect can be observed on the right wall from 45° to 135° and in the leeward wall about 135° to 180°. This is due to the deviation of the wind flow on the leeward face and the right wall face, reducing the effects of wind pressures.

5 CONCLUSIONS

- The presence of obstacles next to studied structure is an important consideration for wind design.
- The experimental results show that the wind effects caused by obstacles on the neighborhood modify the *EPC*.
- The main mechanisms that cause this variation are the vortex shedding, the reduction of the wind flow area (Venturi effect) and the vertical flow caused by obstacles located in the leeward area.
- The variation of the wind speed affects the interference factors.
- The gap between the reference model and the adjacent obstacle is an important parameter for generating the phenomena described in this work; variation of this measure will be considered for future testing.

Keywords: Steel Fibre Reinforced Concrete, Cyclic loading, Energy dissipation

Abstract. *Steel fibre reinforced concrete (SFRC) is examined experimentally under cyclic loading. The effect of volumetric ratio and type of fibres on the mechanical properties and flexural strength of the SFRC beams are accessed. Multiple prismatic concrete specimens with two different types of steel fibres are fabricated and tested, under four-point bending according to ASTM C1609. Compressive and tensile strength characteristics using cylindrical specimens are determined. The two fibres have similar length to diameter ratio but different size. Two volumetric ratios (0.5% and 1%) are analyzed for each type of fibre. By increasing the volumetric ratio of the fibres, significantly are increased both the tensile and the compressive strengths. Higher post crack peak load and greater cumulative energy dissipation under cyclic loading are attained by increasing the steel fibre content. By adding 1% the volume of concrete, up to 93% the ultimate flexural strength under cyclic loading is enhanced. Although the two fibres have similar aspect ratios, steel fibre type B (larger size) shows higher flexural strength and energy dissipation than steel fibre type A (smaller size).*

1 INTRODUCTION

It is desirable that all existing and new reinforced concrete constructions remain safe and in service or be easily returned to service after a catastrophic event, so as to minimize the socio-economic impact on society. To minimize and/or avoid structural failures a promising approach is to use concrete with better mechanical properties. Among the various mechanical performance improvement techniques for concrete, the steel fibre reinforced concrete developed in the last 20 years, distinguished by its exclusive mechanical properties and durability performance. Steel fibres improve the tensile strength, energy absorption capacity, flexural strength, ductility and flexural toughness of concrete [1]. The fibres either resist the internal stress or transfer to a stable matrix in concrete and limit growth and propagation of cracks. The mechanical properties of steel fibre reinforced concrete (SFRC) are affected by fibre volume fraction, geometry, distribution and the bond strength between fibre and matrix [2, 3].

The volumetric ratio of steel fibres is a key parameter that affects the post-crack flexural performance of SFRC. Previous research [3] investigated the effect of single hooked-end steel fibres content and strain rate in both regular and high strength concretes. The research outcomes indicated that for both regular and high strength concrete, the flexural strength and corresponding deflection increased with the volume fraction of fibres (V_f). Steel fibres with V_f equal to 1.0% and 2.0% in regular concrete increased the ultimate flexural resistance by 13% and 63%, respectively. Likewise, the deflection at the ultimate flexural load significantly improved by the increase in the volume of fibres leading to more ductile failure. However, the 28^{th} day compressive strength and modulus of elasticity of regular concrete are slightly affected by the addition of fibres. The average increase in compressive strength due to the addition of fibres up to 1.5% by volumetric ratio is found to be less than 10% [4].

Previous studies have proved that the aspect ratio (length to diameter ratio, l/d) of fibres has a significant impact on the mechanical properties of SFRC. The common aspect ratios of steel fibres vary between 50 to 100 [5]. The flexural and split tensile strengths of steel fibre reinforced concrete increase with an increase in aspect ratio. This increase in mechanical properties attributes to the improvement of heterogeneous distribution and flocculation of fibres with the increase in aspect ratio [5]. However, fibres could have similar aspect ratio with different length and diameter. The effect of variation in length and diameter without changing the aspect ratio of the fibres on the property of SFRC needs further investigation.

The interfacial bond between fibre and matrix plays a significant role in the capacity of fibres to transfer applied stresses in cracked concrete. Mechanical anchorage is one of the main methods used to improve the bond between matrix and steel fibres. Among the different types of steel fibres, end hook fibres are commonly used due to their advantage to gradually straighten prior to significant slippage [6]. Abdallah and Fan [7] studied the anchorage mechanics of single and double end hooked fibres by conducting pullout tests. The double hooked end fibres showed 50% and 25% higher maximum pullout load and total pullout work, respectively compared to the corresponding single hooked end fibres within normal strength concrete. As a result, these recently developed end hooked fibres are recommended for improved mechanical properties for regular and high strength concrete.

Although the flexural performance of SFRC under monotonic loading has been studied by various researchers, very limited data are found under cyclic loading. Recent developments on high-performance steel fibres also require the evaluation of flexural strength under cyclic loading. This paper presents experimental results on the flexural behaviour of double end hooked steel fibre reinforced concrete under cyclic loading. The effects of volumetric ratio of two double hooked end fibres with similar aspect ratios on the compressive strength, tensile strength and cyclic flexural resistance are investigated. The findings of this study provide a

better understanding of the energy dissipation characteristics under repeated loading and a wider application of the double end hooked fibres, which have been recently provided to the market.

2 EXPERMENTAL PROGRAM

Five different concrete batches are prepared: one control mix without steel fibres and four SFRC with different fibre type and volumetric ratio. The concrete mix design was prepared based on Kosmatka et al. [8] and the mixture composition is presented in Table 1. General use Portland-Limestone (GUL) type cement that meets the standards of the Canadian Standards Association (CSA) A3001 and ASTM C595 and water to cement ratio equal to 0.5 were used. Natural coarse aggregates with a maximum size of 9.5 mm and natural sand fine aggregate were used.

Mixture	Steel fibre		Batch weight (kg/m^3)					SP	Slump
	Type	V_f(%)	Cement	Water	Gravel	Sand	Fibre	(ml)	(mm)
CS	-	-	456	228	768	891.3	-	-	120
FRCA0.5	A	0.50	456	228	764	882.1	39.0	23	130
FRCA1	A	1.00	456	228	760	873.0	78.0	28	125
FRCB0.5	B	0.50	456	228	764	882.1	39.0	23	130
FRCB1	B	1.00	456	228	760	873.0	78.0	28	125

Table 1: Concrete mixture proportion and slump test results.

Figure 1 presents the type and dimensions of the steel fibres. Two types of double hooked end steel fibres with lengths of 35 mm (type A) and 60 mm (type B) were used. Tensile strengths of 1850 MPa and 1600 MPa were reported by the manufacturing company for fibre type A and type B, respectively. Both types of fibres have similar aspect ratio equal to 65. Fiber volume fractions (V_f) of 0% (control specimen), 0.5% and 1.0 % by volume of concrete were investigated. The equivalent amount of fibre were 0, 39.0, and 78.0 kg/m^3 of concrete, respectively. Super plasticizer (SP) was added to improve the workability of the fibre reinforced concrete.

Type A Type B

Figure 1: Types of Steel fibres (type A and type B).

Three prisms with dimensions of 76 x 76 x 292 mm for the flexural test and nine 100 mm x 200 mm cylindrical specimens for both tensile and compressive strength tests were casted for each mixture group. Thus, in total 15 prisms were tested in flexure, 15 cylinders were tested in compression (28 days), 15 cylinders were tested in compression (90 days) and 15 cylinders were tested in tension (28 days). The prisms were tested at the age of 90 days.

2.1 Cyclic flexural test setup

The SFRC prisms were tested under four-point bending according to ASTM C1609 [9] and the test setup is shown in Figure 2(a). A 250 kN testing frame (INSTRON 8802) was used for the flexural tests. Displacement controlled loading with a constant rate of 0.6 mm/min for both loading and unloading was used. The loading protocol contains nine cycles starting at 0.25 mm with an incremental increase of 0.5 mm in each cycle up to 4.25 mm, as shown in Figure 2(b). After completing all 9 cycles, the loading continued until the net deflection hits 6 mm, to determine the residual strength. The prisms were supported by two roller bearings one free to move and the other pinned. An aluminum frame connected to the prism was used to support the bar holding the linear potentiometer (LP) and the net deflection of the prisms was measured relative to the midspan of the specimen.

3 RESULTS AND DISSCUSSION

3.1 Compressive and tensile strengths of SFRC

Table 2 summarizes the compressive and tensile strength results (mean values), where SD represents the standard deviation of the strengths between the specimens of similar mixture composition. Due to the addition of superplasticizer (SP), the SFRC specimens gained strength slower than the corresponding control specimens without SP. Superplasticizers will retard the hydration process when the adsorption of the superplasticizer is greater than hydrated cement [10]. Cement pastes containing superplasticizers are reported to have a slower rate in decreasing porosity over time due to lower hydration rate [11]. As a result, at the 28th day age, most of the fibre reinforced concrete cylinders had slightly lower compressive strength compared to the corresponding control specimens (without fibres). These results coincide

with the experimental findings [12]. However, at the 90th day age, the SFRC had up to 19% higher compressive strength than the control specimen. This increase in compressive strength attributes to the improvement of anchorage between the matrix and fibre as the matrix strength increases with the hydration process.

Mixture	28th day compression		90th day compression		28th day tension	
	$f_c(MPa)$	SD (MPa)	$f_c(MPa)$	SD (MPa)	$f_t(MPa)$	SD (MPa)
CS	38.93	0.43	39.50	0.54	4.32	0.43
FRCA0.5	34.36	1.67	46.14	1.80	5.86	0.06
FRCA1	32.74	3.41	47.14	3.43	6.70	0.09
FRCB0.5	35.65	3.71	47.70	1.99	5.54	0.06
FRCB1	43.03	1.76	44.46	3.15	8.07	0.45

Table 2: Compressive and tensile strength test results.

Figure 3 presents typical compressive stress-strain plots. The steel fibres increase the strain corresponding to the peak compressive stress and this strain increased with the percentage ratio of steel fibre; similar trends have been reported by other researchers [13, 14]. After the peak stress, the SFRC underwent a more ductile failure with extended softening behaviour. The ductility was directly proportional to the fibre content. Regarding the failure mode, multiple cracks were observed on the cylinders with a higher volume of fibres. This was mainly due to the contribution of fibres to produce more ductile failure by bridging cracks. The tensile strength of the SFRC increased as the fibre content increased. As presented in Table 2, by increasing the fibre content from 0.5% to 1.0% by volume of concrete resulted in 35.6% to 55% increase in tensile strength for steel fibre type A and 28.5% to 86.8% for steel fibre type B. The highest tensile strength is recorded for SFRC with 1.0% fibre type B (FRCB1) with a value equal to 8.07 MPa.

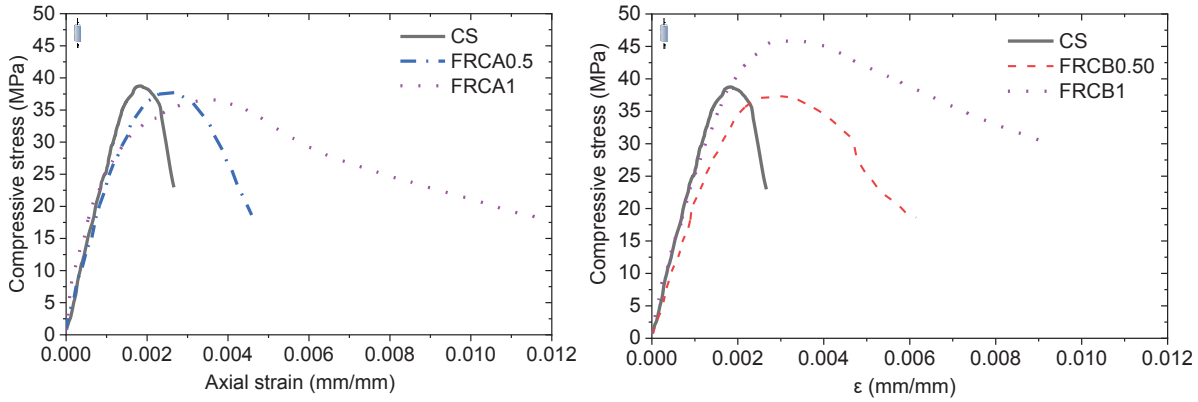

Figure 3: Typical stress-strain response of SFRC cylinders under compression at 28 days age.

3.2 Flexural response under cyclic loading

Typical hysteresis response of the tested specimens under cyclic loading is shown in Figure 4. The fibres became effective following the crack formation and enabled the SFRC to be ductile (Figure 4(a) and Figure 4(b)), while the plain control specimen suddenly failed at a very small deflection (0.123 mm) (Figure 4(c)). At the initial cycles, the SFRC prisms were in the elastic range and the area under the hysteresis was smaller. During the subsequent cycles,

the specimens entered to an elastic-plastic region and the area under the hysteresis increased with the formation of multiple cracks. Then, the material damage started to be progressed and the residual deformation during the unloading appeared. The slope of loading and unloading path decreased with the increased number of cycles, due to the stiffness degradation caused from the material damage [12]. The ultimate flexural strength (f_u, MPa) can be determined using equation 1. In equation 1, P_u denotes the peak load (in N) and L, b, and d denote clear span, width, and depth of the prism in mm.

$$f_u = \frac{P_u L}{bd^2} \tag{1}$$

For both type A and type B fibres, the ultimate flexural strength of SFRC increased with the increase in fibre volumetric ratio. The average ultimate flexural strength versus fibre percentage is shown in Figure 4(d). For the fibre volumetric ratio 0.5% by volume of concrete, the two different fibres show similar response, the ultimate flexural strength is around 11% higher than the control specimen (plain concrete). Although the two fibres have similar aspect ratio, at the 1.0% fibre percentage, the steel fibre type B (longer and thicker fibre) showed superior ultimate flexural strength than the steel fibre type A (shorter and thinner fibre). The recorded ultimate flexural strength at 1.0% fibre volumetric ratio for fibre type A and type B are 41% and 93% higher than the control specimen, respectively.

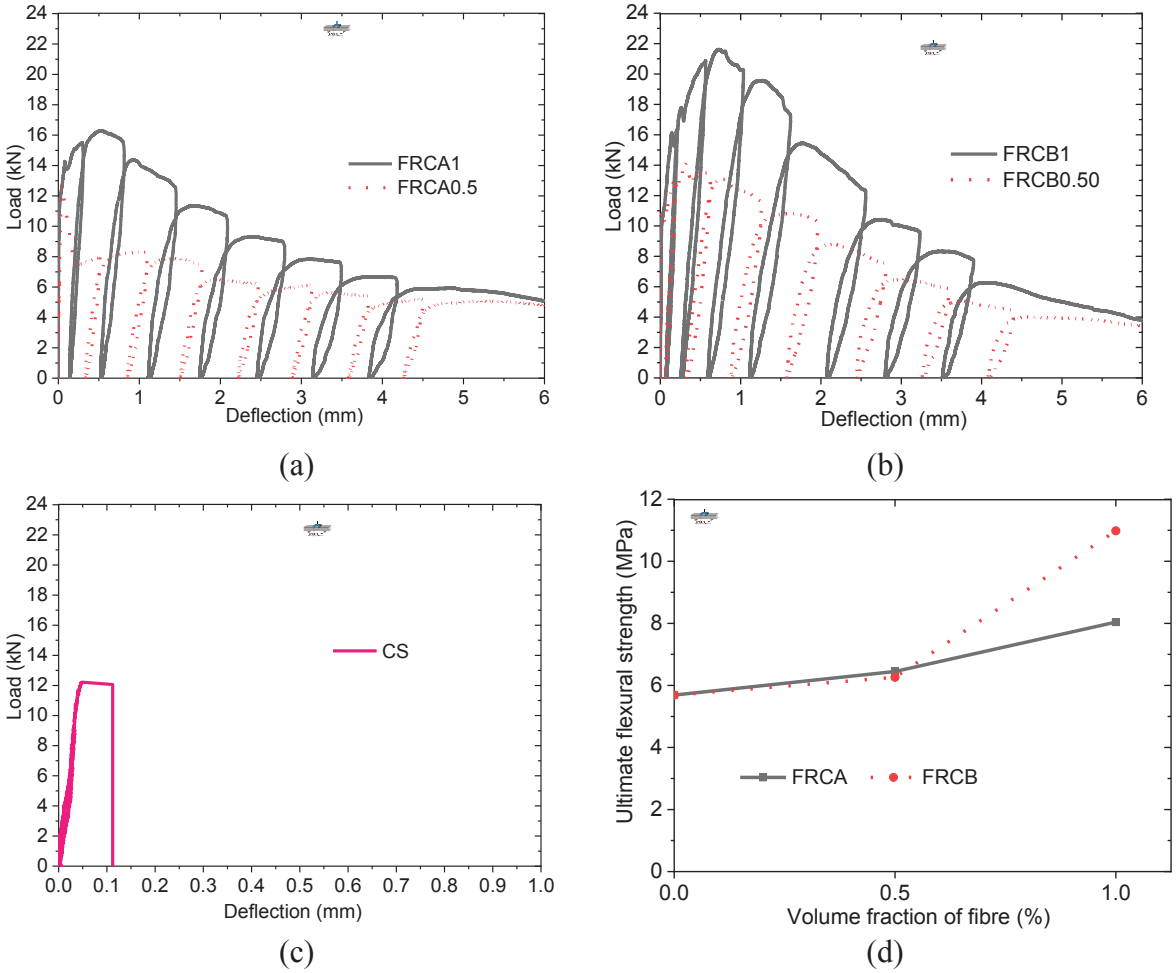

Figure 4: Cyclic flexural test results: (a,b,c) strength versus deflection curves, (d) ultimate flexural strength versus fibre volume fraction.

3.2.1 Energy dissipation

The area under the hysteresis of the load-deflection curve represents the energy dissipated during the loading and unloading cycle [12]. Energy dissipation capacity is essential for structural performance under cyclic loading (e.g., during earthquakes). Structures can survive seismic loads only if they can dissipate the energy exerted by the earthquake [15]. The cumulative energy dissipation versus displacement is plotted in Figure 5. The cumulative energy dissipated by the specimens is calculated by summing up the area under the load-deflection curve before reaching the specified displacement. For both steel fibre types, the cumulative dissipated energy considerably increased with the increase in fibre content. The total energy dissipation at 4.0 mm is 28.66 kNmm and 47.01 kNmm for FRCA0.5 and FRCA1, respectively. Fibre type B showed significantly higher energy dissipation characteristics than fibre type A. The energy dissipation at 1% steel fibre type B (FRCB1) at 4 mm displacement is 34% higher than the fibre type A (FRCA1). This higher energy dissipation characteristic of fibre type B might be due to its better distribution and higher mechanical anchorage from its longer end hook.

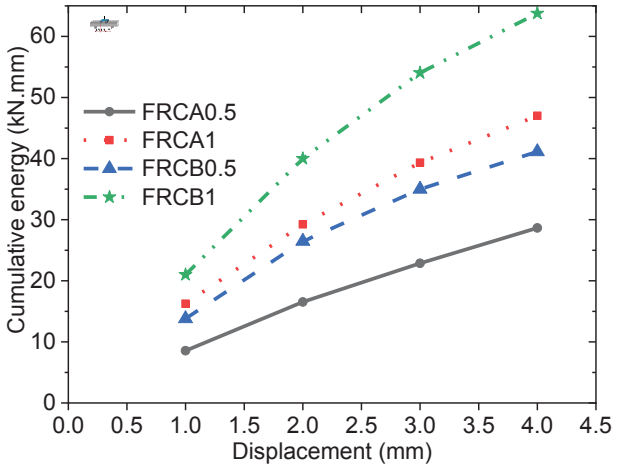

Figure 5: Cumulative energy dissipation of specimens.

4 CONCLUSIONS

The flexural performance of double hooked end steel fibre reinforced concrete prisms tested under cyclic loading was experimentally studied. The following conclusions can be made:

- The steel fibre reinforced concrete (SFRC) specimens showed increased tensile strength, ductility and compressive strength at the 90th day age while slightly reduced compressive strength at the 28th day, when compared to the plain concrete specimens.
- The double hooked end steel fibres enhanced the ductility and ultimate flexural strength of the specimens. The improvement in the flexural strength increased with the increase in the volume fraction of steel fibres. The ultimate flexural strengths of FRCA1 and FRCB1 are 41% and 93% higher than the control plain concrete specimens.
- The cumulative energy dissipation under cyclic loading significantly increased with the increase in fibre content for both steel types.
- Although the two fibres had similar aspect ratios to each other, steel fibre type B (longer and thicker) showed superior flexural strength and energy dissipation characteristics than steel fibre type A (shorter and thinner) showed.

Abstract. *Column capacity design rule is of crucial importance in modern seismic resistant design of moment-frame structures. However, the implementation of this rule in modern codes is still based on an empirical method of design, which lacks the capacity to account for the actual dynamic response of the structure. The lack of column capacity design to completely protect the columns from yielding has been discussed many times in the literature since the '70s. The current study examines the seismic behavior of a large number of moment-frames, using the non-linear dynamic analyses. In total, 20 basic R/C frame configurations (moment frames with 2, 4, 6 and 8 stories, consisting of columns with various strength) are investigated, along with four different masonry infill setups, each one with 12 different infill types (in total 980 different models), against 60 recorded ground motions, scaled to 10 different seismic intensity levels. The results revealed that 2, 4 and 6 story frames designed according to EC-8 failed regularly to fulfill the objectives of the column capacity design. The deformation demand on the columns was found to be systematically higher for frames with fewer stories, and in some cases, even columns overdesigned by a factor of 2 exhibited a deformation demand beyond the yielding point. Subsequently, statistical analysis was used to identify causal relationships between various structural and dynamic properties of the frames and the magnitude of the ductility demand on the columns. Many of these relationships were quantified, and the relevant investigation allowed deriving semi-empirical formulae, that can effectively predict the ductility demand on the columns according to specific characteristics of the structure. On the basis of these findings a brief discussion on the shortcomings of the current method for column capacity design is made, as well as general suggestions for the improovment of its efficiency and effectiveness.*

1 INTRODUCTION

In earthquake resistant design of Reinforced Concret (RC) moment frames capacity design of columns is applied to transfer the demand for inelastic deformation to the beams and to mitigate the risk of story mechanisms. Simple provisions for the so-called “strong column - weak beam” design rule were already incorporated in ACI 318-71 [1]. However, these provisions did not account for the uncertainties involved in the beam and column response, and no overstrength factor was used. Park and Paulay [2] were the first to introduce a rigorous procedure for the column capacity design. They investigated comprehensively the “column sidesway” and “beam sidesway” mechanisms and demonstrated the need for the introduction of a column overstrength factor as high as 2.0 in order to completely protect the columns from yielding. Subsequent work of Paulay (eg. [3,4,5]) laid the basis for the column capacity design rule which, despite the several alternative proposals made by other researchers in the ensuing decades, still remains in use in the modern seismic design codes (e.g. [6,7,8]) with only minor modifications.

Paulay [4] used the non-liner dynamic analysis on 6, 12 and 18-storey frames to evaluate the proposed capacity design method, and found that they exhibited a quite satisfactory seismic performance. Nonetheless, he noticed that the six-story frame suffered greater damage and some column yielding, and ascribed this to the lower overall overstrength factor ($\omega \cdot \Phi_0$) and the lower fundamental period of the six-story frame. Other researchers, however, also found that the capacity design of the columns does not prevent completely the formation of plastic hinges at the columns. For instance, A. Kappos [9] performed a large number of parametric, non-linear dynamic analyses on 10-storey RC frames, in an attempt to evaluate the many already existing criteria for the capacity design of the columns, as well as to verify the efficiency of a new design method, based on non-linear methods of analysis. He found that in order to completely preclude the yielding of columns at the upper storeys an overstrength factor greater than 2 was required, while values greater than 1,5 were required to preclude the formation of column sidesway mechanisms. In another study, Panagiotakos and Fardis [10] used non-linear dynamic analysis to assess the effect of the EC-8 [6] capacity design rules on the seismic performance of 12 RC frame structures of 3, 4 and 12 storeys. The authors found that capacity design does not preclude the yielding of the columns. More interestingly however, the analysis results demonstrate that the average damage of columns increases for the frames with fewer storeys.

In the present study, investigation on the results from a large number of Non-Linear (N/L) dynamic analyses demonstrated clearly that the demand for inelastic deformation on the columns gets grater for frames with fewer storeys. More specifically, 20 basic R/C frame configurations (moment frames of 2, 4, 6 and 8 storeys) were studied, both bare and infilled with 12 different types of UnReinforce Masonry (URM) infills, against 60 recorded ground motions, scaled to 10 different seismic intensity levels. Many of the examined frame types, including the frames designed according to EC-8, exhibited a deformation demand on the columns of the upper stories beyond the yielding point. Statistical analysis on the results allowed the connection between the demand for inelastic response of the columns and certain characteristics of the frames. As a result, semi-empirical formulae were derived, which predict the demand for inelastic deformation on the basis of particular structural characteristics and the intensity of the seismic action.

2 PROBLEM STATEMENT

The basic idea behind the column capacity design rule is most commonly described on the basis of an idealized model of the beam-column joint, which illustrates the desired over-strength of the columns though the moment equilibrium of the joint (Fig. 1a). In this model, it is implied that both columns can contribute with their full bending capacity in order to overcome the sum of the yielding moments of the beams. However, this model is incomplete, as it does not account for the equilibrium of the forces acting on the joint. After taking into account these forces (Fig. 1b), it becomes apparent that it is impossible for the two columns to provide simultaneously their full moment capacity. This problem was already known to Park and Paulay [2], and the "dynamic amplification factor" (ω) was introduced in the New Zealand code (e.g. NZS-3101 - Appendix D [8]) as a remedy to it. Many modern codes overlook the exact nature of the capacity design of the columns, however, it is thought (e.g. [9]) that an accurate description of the problem is the basis for identifying the numerous sources of uncertainties associated with the capacity design of columns.

In principle, the equilibrium of the beam-column node is completely described by the differential equation of dynamics, however, the non-linear nature of the problem does not allow for an analytical solution. Hence, all the methods currently proposed, involve either the use of an amplification factor (such as the aforementioned dynamic amplification factor), whose value is determined empirically or the use of non-linear methods of analysis for the design of the structures. Nevertheless, the ductility demand on the columns, despite being not predictable analytically, is still determined by the underlying laws of dynamics. So, if a large data set of suitable non-linear dynamic analyses were available, distinctive response patterns should emerge, unveiling the deterministic nature of the problem. The present study exploits this idea, and uses statistical analysis on such a data set, in order to establish a quantitative relationship between the ductility demand on the columns and certain dynamic properties of the structure. Such properties are the equivalent seismic forces of each storey and the corresponding base shear, the capacity of each story to withstand lateral loads, and the "Sway-Potential Index" (SPI) initially introduced by Priestley and Calvi [11].

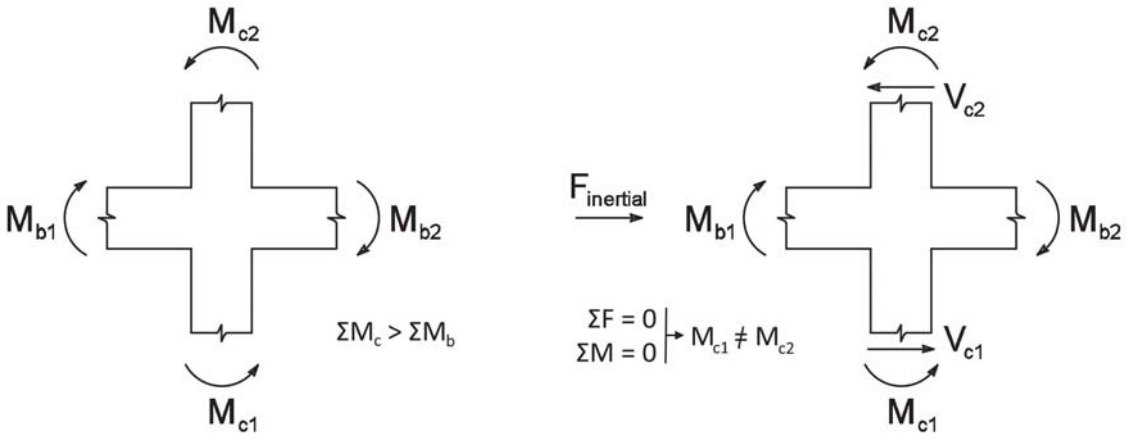

Figure 1: Simplistic (a) and complete (b) model with regard to the column capacity design.

3 INVESTIGATED R/C FRAMES AND N/L ANALYSIS MODELING PARAMETERS

Four groups of frames with a height of two, four, six and eight storeys are investigated. Each group consists of five moment frames with columns of different section size, as follows:

frame type 1: Moment frames designed for a low seismic load, according to the old Greek seismic code.
frame type 2: Moment frames designed according to EC-8[6], without the capacity design of the columns.
frame type 3: Moment frames fully complying with EC-8, with the smallest possible column sections.
frame type 4: Moment frames with overdesigned columns, fully complying with EC-8. The columns in this category have a section depth 50% larger than that of the corresponding columns in category 3.
frame type 5: Moment frames with overdesigned columns, fully complying with EC-8. The column sections in this category have double the depth of the corresponding column sections in category 3.

The seismic load used for designing the frames complies with EC-8[6] and has been calculated in accordance with the greek annex, for soil type "C" and seismic zone II. In all cases, the reinforcing details -and therefore the hysteretic behavior of beams and columns- fulfill the requirements of EC2[12] and EC8. Furthermore, special care was taken not to overdesign the frames of each of the five categories. The design procedure for the frames was based on the linear method of analysis (modal analysis), which was carried out using SAP2000 v19 [13] software. Following the standard practice for tall buildings, the column section size is reduced on the upper floors. However, in these cases, additional models with columns of a constant section across all stories were also investigated, in order to capture the potential effect of the varying column sections to the global response of the structure.

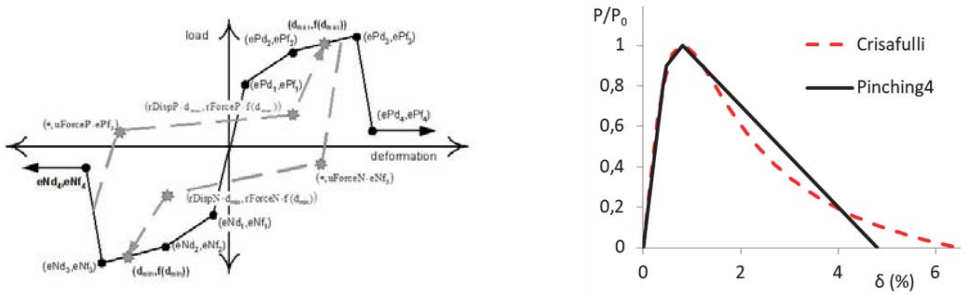
Figure 2. Different types of infill arrangement under investigation (eg. four-story frames).



(a) (b)

Figure 3. Idelized masonry backbone curve (a) and loading/unloading curves for material "pinching4" (b)

To simulate the seismic response of both the bare and the infilled frames, non-linear dynamic analysis is employed using Opensees [14]. For each frame, four cases of different infill arrangements are considered, ranging from the uniform infill distribution to the fully open ground story, as depicted in Fig. 2. For each type of infill arrangement, four different levels of masonry panel strength and three levels of infill ductility were considered (Table 1) in order to cover the most common types of URM infills, including infill walls with openings. The mechanical characteristics of the infill panels are specified in terms of interstorey drift and masonry shear force, and they take the predetermined values of Table 1 for all the frame types, regardless of the frame layout. Additionally, the frame members were carefully modeled in order to preclude secondary characteristics -not included in the investigation- from influencing the analysis results.

Infill Type	Strength category	Plasticity category	Characteristic values for the infill panel			
			V_0 (kN)	V_u (kN)	δ_0 (‰)	δ_u (‰)
1	1	1	33.3	0	4.0	12

Table 1: Overview of the characteristics of the 12 infill types.

The frames are modeled using nonlinear force-based beam-column elements with distributed plasticity [15] and fiber sections, to accurately simulate the post-elastic behavior of the structural elements, as well as the interaction between axial force and bending behaviour. In modeling the floor diaphragmatic action special care was taken to not affect the behavior of the beams by constraining their axial deformation (because of the axial-moment interaction). Uniaxial materials “comcrete01” and “steel4” were adopted for modeling the hysteretic behavior of concrete and reinforcing steel respectively. The infill walls were modeled using the equivalent strut method. Each infill panel was modeled as a pair of diagonal compression-only struts, the mechanical characteristics of which are listed in table 1. The “pinching4” hysteretic law (Fig. 3) was used to define the nonlinear behavior of the struts, as it has been shown to be the most accurate model available in Opensees for implementing the equivalent strut method [16].

The non-linear dynamic analyses were performed using a sample of 60 normalized ground motion records obtained from the PEER strong motion database. The records have been appropriately selected to conform to the elastic spectrum for soil type C according to EC8 (so as to correspond to the design spectrum used in frame design, figure 4). To this end, the geometric mean square error (MSE) between the spectral acceleration of each record and the target spectrum in the range 0.15sec ~ 5.0sec was used as the main selection criterion, while various seismic parameters were utilized to additionally confine the selected set. More specifically the following limiting values were adopted: magnitude M5.5 ~ M8.5, epicentric distance Rjb = 10

km ~ 50 km, mean shear wave velocity at the upper 30 m Vs,30 = 240 m/sec ~ 400 m/sec and significant duration d5-95 = 10 sec ~ 30 sec. The values above were chosen to exclude unlikely events, and also as a means for better matching to the target spectrum. The record suite comprises of both far-fault and near-fault events and covers uniformly a rather wide range of earthquake characteristics with regard to the frequency content and to the most common seismic intensity measures. The scaling of the records was based on the minimization of MSE[17]. Finally, each bare or infilled frame was analyzed for ten different earthquake intensity levels covering a range of 5% to 225% of the intensity corresponding to the seismic design load of the frames. These 10 records comprise a coarse Incremental Dynamic Analysis (IDA) [18], which is used for assessing the change in the seismic response of the frames as the seismic intensity increases.

4 ASSESSMENT OF THE DUCTILITY DEMAND ON THE COLUMNS

The ductility demand on the columns is assessed at the story level, as the average normalized curvature at the top ($\Phi_{av.t}$) and the bottom ($\Phi_{av.b}$) of the storey columns, as follows:

$$\Phi_{av.b} = \sum_{i=1}^{4}\left(\frac{\Phi_{i,b}}{\Phi_{i,y}}\right) \quad , \qquad \Phi_{av.t} = \sum_{i=1}^{4}\left(\frac{\Phi_{i,t}}{\Phi_{i,y}}\right) \tag{1, 2}$$

$\Phi_{i,t}$ and $\Phi_{i,b}$ are the median curvature demand for the 60 time-histories on the top and the bottom section of column i, and $\Phi_{i,y}$ is the yield curvature of the column. The total ductility demand (Φ_{av}) at the story level is subsequently calculated as the average of $\Phi_{av.t}$ and $\Phi_{av.b}$. Φ_i values less than 1 indicate that the bending demand at the respective column section did not surpass the yielding moment of this section in the respective time-history. Accordingly, $\Phi_{av.t}$ and $\Phi_{av.b}$ values less than 1 indicate that on average the maximum bending demand was lower than the bending capacity of the columns' sections (top and bottom section, respectively). $\Phi_{av.t}$ and $\Phi_{av.b}$ are not necessarily concurrent, however statistical analysis on the results of the present study revealed that almost always a story mechanism occurs when both $\Phi_{av.t}$ and $\Phi_{av.b}$ take values larger than 1. Since $\Phi_{av.t}$ is usually lower than $\Phi_{av.b}$, Φ_{av} values slightly larger than 1 do not necessarily imply that both $\Phi_{av.t}$ and $\Phi_{av.b}$ values are larger than 1. However, the difference between $\Phi_{av.t}$ and $\Phi_{av.b}$ is small and of no particular importance, with the only exception of the ground-storey columns.

5 RESULTS AND DISCUSSION

5.1 Bare frames

A large number of structural and dynamic characteristics of the frames were considered as possible factors that determine the ductility demand on the columns. These include the bending capacity of the structural members, the total number of storeys in the frame, the natural period, the seismic intensity etc. In order to estimate the relationship between the ductility demand and these parameters, linear regression analysis was initially employed, without, however, any success. Regression analysis is a powerful statistical method for examining the possible relationship between a set of independent variables and a dependent one, however, it requires to be able to formulate the problem in hand in a polynomial form, and this was found to be impossible in the case of the seismic demand on the columns. Subsequently, an exhaustive examination of the covariance between each independent variable and the ductility demand was performed, and the combination of the most significant of them into formulae that correlate with the response measures was accomplished via trial and error. The following expression is an example of such a formula ($\Phi_{av.i}$ is the Φ_{av} value at storey i, "$\propto$" is the proportionality symbol):

$$\Phi_{av,i} \quad \propto \quad \frac{V_0}{\Sigma M_{c1}} \cdot \left(\frac{F_i}{1.5 \cdot \Sigma M_{ci}} \right)^{2/3} \cdot \frac{\Sigma M_{bi}}{\Sigma M_{ci} + \Sigma M_{ci+1}} \tag{3}$$

The first term ($V_0/\Sigma M_{c1}$) in this expression is a measure of the seismic intensity to the base-shear capacity of the structure ratio. V_0 is the design base shear force calculated as:

$$V_0 = Sa_{(T1)} \cdot m \tag{4}$$

where $Sa_{(T1)}$ is the spectral acceleration according to the design spectrum at T_1, and m is the total mass of all the storeys (T_1 is the fundamental period from the modal analysis). $\Sigma M_{c,1}$ is the sum of the design moment resistance of the ground storey columns, and it is a measure of the actual capacity of the structure to withstand lateral loads. The physical meaning of the first term is that the ductility demand on the columns is proportional to $Sa_{(T1)}$ and inversely proportional to the capacity of the structure to withstand lateral loads.

The second term is a measure of the ratio of the inertial forces acting on storey i (the story for which the ductility demand is calculated) to the capacity of this very storey to withstand lateral loads. F_i (the inertial force) is calculated assuming a triangular distribution of the equivalent lateral load, as follows:

$$F_i = \frac{2 \cdot i}{N \cdot (N+1)} \cdot V_0 \tag{5}$$

where N is the total number of storeys in the frame, i the particular storey counting from the ground, and V_0 the base shear. $\Sigma M_{c,i}$ is the sum of the design moment resistance of the columns of storey i. So, the second term of Equation 3 is a measure of the inertial forces to the lateral force capacity ratio at storey i. Factor 1.5 stands for the shear span of the columns, which is approximately half the height of the storey. The use of the accurate shear span value (according to the modal analysis) was found to result in slightly more reliable results. However, the difference is insignificant, and the approximate value used herein has the advantage of being readily available without the need of any structural analysis of the frame. The physical meaning of the second term is that higher story-level inertial forces -and consequently higher

ductility demand- appears on structures with fewer storeys, as well as on the upper storeys of each structure. This relation however, is not linear, as the exponent ⅔ suggests. Extensive investigation via trial and error lead to the conclusion that the lack of linearity is not a consequence of an incorrect estimation of the distribution of the inertial forces.

The third term is the SPI, initially introduced by Priestley and Calvi [11]. It is the ratio between the sum of the bending resistance of the beams to the sum of the bending resistance of the columns on the respective storey and the storey above it, and serves as a measure of the structure's ability to redistribute the demand for inelastic deformation across multiple stories. SPI, however, was found to be irrelevant to the ductility demand on the columns of the ground story, and so for the ground storey SPI is disregarded.

Equation 3 contains the minimum number of parameters that are absolutely necessary for establishing proportionality to $\Phi_{av.i}$. However, in order to produce a formula that actually fits the data generated by the time-history analyses, a proportionality factor and a constant factor have to be introduced. These factors were defined using regression analysis, resulting in the following equation that best fits the data of the present study:

$$\Phi_{av,i} = 65.8 \cdot \frac{V_0}{\Sigma M_{c1}} \cdot \left(\frac{F_i}{1.5 \cdot \Sigma M_{ci}} \right)^{2/3} \cdot \frac{\Sigma M_{bi}}{\Sigma M_{ci} + \Sigma M_{ci+1}} + 0.495 \quad (6)$$

Finally, this equation can be expanded in order to predict the ductility demand for seismic intensity levels other than the seismic intensity of the design earthquake, by multiplying with the ratio of the ground acceleration of the supposed seismic action to the design ground acceleration (α_g/α_{gd}), with an exponent of 1.5:

$$\Phi_{av,i} = \left(\frac{\alpha_g}{\alpha_{gd}} \right)^{3/2} \cdot \left[35.85 \cdot \frac{V_0}{\Sigma M_{c1}} \cdot \left(\frac{F_i}{1.5 \cdot \Sigma M_{ci}} \right)^{2/3} \cdot \frac{\Sigma M_{bi}}{\Sigma M_{ci} + \Sigma M_{ci+1}} + 0.495 \right] \quad (7)$$

Equation 7 fits the data with a considerably high coefficient of determination (R^2). In Fig. 5a the results for seismic intensity level 5 are ploted, while Fig. 5b displays aggregated results for seismic intensity levels 4~7 (75% ~ 150% of the design earthquake). It should be noted that $\Phi_{av.t}$ also correlates well with Equation 7 (R^2=0.907 for seismic intensity level 5), while $\Phi_{av.b}$ correlates more loosely (R^2=0.780 for seismic intensity level 5). In all three cases, however, the coefficient of determination can get significantly higher if outliers are omitted (for example, frame types 1 and 5). The reliability of Equation 7 can also be improved by using more accurate data (for example T_1 and column shear span). However, the purpose of Equation 7 is not to serve as an accurate predictor of the ductility demand of the columns, but rather to demonstrate that the ductility demand is unambiguously determined by certain properties of the structure. Equation 7 may not fit well other data sets (for example results from frames with a different aspect ratio or mass distribution), while Equation 3 -which is not quantified- underlines a potentially more universal principle about the proportionality of the ductility demand to specific characteristics of the structure. Obviously, however, more research is needed in order to confirm that Equation 3 is indeed generally valid.

The unexpected discovery during the above investigation was that the ductility demand on the columns depends on the number of storeys of the frame, as well as on the actual storey under examination, as indicated by the term $F_i/(1.5 \cdot \Sigma M_{ci})$. This means that low-rise structures are more vulnerable to the formation of a storey mechanism, regardless of the regulatory framework they comply with. Besides, higher storeys in bare frames are also more vulnerable (though in the common practice the presence of infill walls may eliminate the additional risk). Another issue being highlighted by Equation 3 is that a small increase in the column strength

can have a significant effect on the protection against the formation of a story mechanism, since the bending resistance of the columns contributes to the denominator of all the three terms of Equation 3. However, this also implies that the resistance of modern buildings to the formation of story mechanism may arise from other factors leading to over-strengthened columns (for example the minimum reinforcement requirement), which also affect the first two terms of Equation 3, and not necessarily from the column capacity design (which in principle affects only the 3rd term).

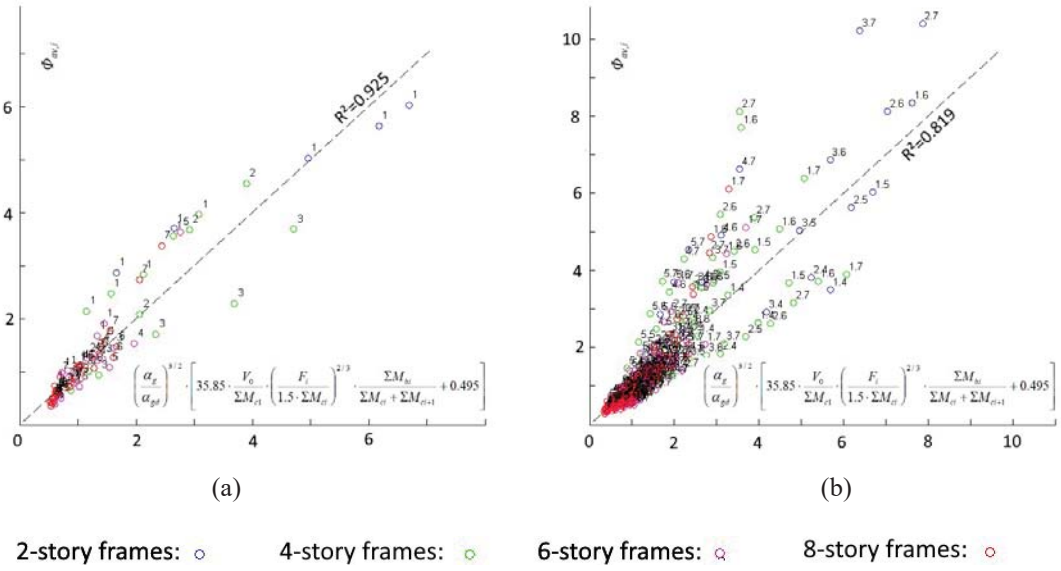

Figure 5: Prediction of the ductility demand on the columns on the basis of Equation 7. a: for seismic intensity level 5 (the numbers indicate the storey number). b: for seismic intensity levels 4~7 (the numbers indicate the frame type and the intensity level).

5.2 Infilled frames

Adding strong infill walls to the frames leads in concentration of the demand for inelastic deformation to fewer storeys, which effectively protects the rest storeys from large post-elastic deformation. The change in the distribution of the ductility demand along the height of the frames (from that of the bare frame to the one of the frames with strong infill walls) happens progressively as the infill strength increases, in a complicated, difficult to quantify manner. Nevertheless, as the infill strength increases, the maximum ductility demand on the columns tends to appear on the storey sustaining the maximum damage (usually one of the lower storeys), while the columns of the other storeys remain near -or within- the elastic response domain. As a result of this behavour, the term $(F_i/1.5\cdot M_{ci})^{2/3}$ which describes the distribution of the ductility demand along the frames' height in the case of the bare frames, does not apply to the infilled frames.

The behavior of the infilled frames is further complicated because the infill walls dissipate seismic energy and provide resistance to lateral loads, an effect that has a different impact on frames with a different number of storeys and different layout. So, Equation 3 is completely inadequate for describing the ductility demand on the columns of the infilled frames. Moreover, due to the many more parameters simultaneously affecting the seismic response of the infilled frames, it proved impossible to derive a universal formula for predicting the ductility demand. Nevertheless, the influence of each parameter on the seismic response is still recognizable, and some of them can be still jointed in formulae that partially describe the seismic response of the structure.

As an example, Equation 8 utilizes the strength of the structural elements and the infill walls of the first and the second storey, to predict $\Phi_{av.t}$ at the ground storey:

$$\Phi_{av,t} = \left(\frac{1600-\Sigma V_{inf2}}{80}\right)\cdot\frac{V_0-(0.8-d)\cdot 0.65\cdot\Sigma V_{inf1}}{\Sigma M_{c1}}\cdot\frac{\Sigma M_{bi}}{\Sigma M_{c1}+\Sigma M_{c2}+0.2\cdot\Sigma V_{inf1}}\cdot\frac{\Sigma M_{c2}+\Sigma V_{inf2}}{\Sigma M_{c1}+0.5\cdot\Sigma V_{inf1}} \quad (8)$$

The first term $[(1600\text{-}\Sigma V_{inf1})/80]$ is a general factor for the detrimental infill effect (gets higher as the infill strength increases). ΣV_{inf2} is the sum of the shear strength of the infill walls on the second storey.

The second term accounts for the contribution of the infill in withstanding seismic loads and dissipating seismic energy. This contribution was found to depend on the stiffness of the frame, which is roughly represented by the depth (d) of the column sections. ΣV_{inf1} is the sum of the shear strength of the infill walls on the ground storey. V_0 is the design base shear force calculated on the basis of the design spectrum, as already described.

The third term is a version of the SPI, modified due to the presence of infill walls. Finally, the fourth factor accounts for the irregularities induced by the infill. This factor reflects the unfavorable effect of even the uniformly distributed infill, due to the damage concentration.

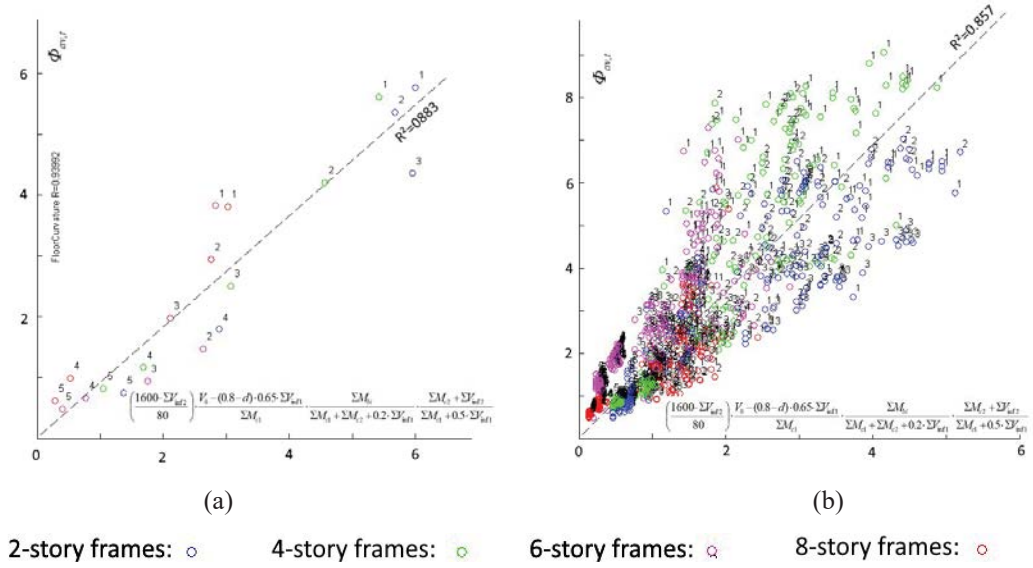

Figure 6: Prediction of the ductility demand on the columns on the basis of Equation 8, for seismic intensity level 5 (the numbers indicate the frame type). a: for the bare frames. b: for all the infilled frames (48 different infill types of uniform and non-uniform arraignment).

The many empirical constant factors utilized in equation 8 were defined either by trial and error or by partial regression analyses, in order to best fit the empirical data. Figure 6 depicts the relation between the values predicted by Equation 8 and the actual $\Phi_{av.t}$ values for seismic intensity level 5 (the design earthquake). As already mentioned, it has been impossible so far to derive a formula accounting for all the parameters that affect the ductility demand on the columns of the infilled frames. Moreover, partial formulae like the one in Equation 8 are purely empirical and, due to the large number of the arbitrary factors involved, they lack the robustness of Equation 3. Moreover, Equation 8 has a lower correlation with the actual empirical data than Equation 3. Nevertheless, Equation 8 still provides an insight into the mechanisms being activated by the addition of infill walls, and this insight is particularly useful in the context of the capacity design of the columns. Further research may allow drawing

more reliable and definitive conclusions about the infill effect on the ductility demand on the columns.

6 CONCLUSIONS

Historically, the view that the column capacity design is not necessary to completely preclude yielding of the columns has prevailed in the relevant research. However, to this day different seismic design codes call for different protection levels against the formation of story mechanisms, by utilizing different column overstrength factors. Moreover, the predominant method for the column capacity design is still based on the simplistic model of Fig. 1a. and utilizes a single general overstrength factor. While this method has been in use for decades now successfully, the present study demonstrates that it cannot ensure a uniform level of protection against the formation of a story mechanism for all the different structures or even for all the columns within the same structure. Based on the current results, the following conclusions may be drawn:

- Most seismic design codes formulate the column capacity design methodology on the base of the simplified beam-column joint model. However, this model is fundamentally incomplete. It misleads the designer about the nature of the column capacity design and has been many times criticized in the literature. The adoption of an accurate model, fully accounting for the equilibrium of the lateral forces acting on the beam-column joint, is of paramount importance for implementing an effective and efficient method for the column capacity design.
- In order to provide a uniform level of protection for all the columns within the structure, as well as for every different structure, the column capacity design should account for the number of stories of the building, the specific story being checked, and the presence of infill walls. More specifically, the results of the present study demonstrated that low- to mid-rise buildings are more vulnerable to the column sidesway mechanism. Higher storeys of bare frames were also found to be more vulnerable; however, the presence of infill was found to effectively mitigate the additional risk at the upper storeys of the investigated frames.
- Since infill walls are not considered load resisting members in R/C structures, the introduction of an additional general level of protection accounting for a minimum nominal level of adverse infill effect seems to be a reasonable choice.
- A more effective and efficient method for column capacity design can be established on the basis of formulae like Equation 3 or even Equation 8. Such a method could ensure a uniform level of protection both for all the columns in a structure, and all the different structures. A method like this can still be based on a general criterion, which however, will have the form of an ultimate acceptable ductility demand, rather than that of an arbitrary overstrength factor.

7 AKNOWLEGMENTS

Results presented in this work have been produced using the AUTH Compute Infrastructure and Resources. The earthquake records were obtained from the Pacific Earthquake Engineering Research Center (PEER) database. Time-history analyses were performed using OPENSEES software developed at Berkley University.

Abstract. *The elastic axis of multistory buildings is defined as the intersection of two vertical principal bending planes which are perpendicular. The elastic axis intersects each story at a point which has the property of the rigidity center. Single-story and special classes of multi-story buildings, such as isotropic ones possess an elastic axis. Taking into account the dynamic nature of earthquake excitation the following question arises: under the action of a torsional earthquake component, is it possible to locate a stable vertical axis around which the structural system will be rotated under any torsional ground motion? For this purpose, monosymmetric single-story and isotropic monosymmetric multi-story buildings are studied analytically. The equation of motion is expressed in the time domain and transferred by Fast Fourier Transform in the frequency domain. Mathematical expressions of the coordinates of the torsional axis at each story level are produced, taking into account that each floor behaves as a rigid in-plane diaphragm. The derived equations indicate that the dynamic torsional axis depends not only on the geometrical and mechanical characteristics of the system but also on mass, damping and excitation frequency. Numerical examples are included for enhancing the comprehension of the derived equations. The divergence of the coordinates of the static and dynamic definition of elastic axis is discussed.*

Keywords: elastic axis, earthquake torsional effects, isotropic buildings, monosymmetric buildings

1 INTRODUCTION

The damage state of the structural facilities following an earthquake excitation usually discloses: (i) the torsional nature of buildings behavior; and (ii) the significance of torsional ground motion [1-4]. The main causes of torsion are the following: (i) stiffness eccentricity, which is attributed to the asymmetric distribution of load bearing elements; (ii) inertial eccentricity, which is attributed to the asymmetric distribution of masses and live loads [5]; (iii) torsional earthquake component, which is attributed to the wave passage effect [6-7] or the incoherency of ground motion [8]; various parameters that are not considered in the design phase, such as non-structural elements, yield strength of bearing elements, differences between actual values of mechanical parameters and computed ones. Thus, multi-story buildings presenting asymmetries in plan are submitted in a coupled lateral-torsional motion during earthquake excitation. The most vulnerable in terms of risk of collapse elements are those that are located in the perimeter of a structure due to significant swaying caused by twisting [9].

According to the aforementioned, the necessity to take into account torsional effects during the design phase arises. Therefore, the notion of eccentricity is introduced by various codes [10] and two types of it are defined: (i) structural eccentricity which is the distance between the center of mass (CM) and the center of rigidity (CR), is attributed to the lack of symmetry in plan and is responsible for the natural or inherent torsional moment; (ii) accidental eccentricity, which is attributed to uncertainty in determination of center of mass, uncertainty in location of center of rigidity and the possible influence of torsional ground motion input. It is expressed with the aid of the structure's dimensions in plan [5, 11].

The center of rigidity (CR) can be easily determined in single-story buildings [10], is usually denoted as CR, called elastic center and is accompanied by two axes denoted I,II, called principal directions [12]. The properties of the elastic center (CR, I, II) are the following: (i) the static response of a single-story building can be defined by two pure bending states along I, II axes and one pure torsional state about CR; (ii) Only translational motion is produced when arbitrary horizontal forces are applied along principal directions. In this case, CR corresponds to the bending center (BC) and axes I, II correspond to the translational planes; (iii) Only rotation is produced when arbitrary torsional moment is applied at the story level. In this case, CR corresponds to the center of twist or torsion (TC); (iv) If arbitrary horizontal force is applied at the story level, the resultant of internal shear forces passes through CR, only under the condition that the rotation of the story is restrained. In this case, CR corresponds to the shear center (SC). The aforementioned properties are independent of the applied loads and depend only on the structural geometry and mechanical characteristics [13].

The definition and existence of the elastic axis in multi-story buildings presents some difficulties [11] and has been investigated by various researchers [13-18]. However, there is a certain multi-story buildings category that the elastic axis and the principal bending planes can be defined. In this case, the elastic axis is a unique vertical axis that the rigidity center of each story belongs and is independent of the load distribution along the vertical direction as well [10]. The aforementioned category corresponds to buildings that consist of homotropic vertical elements [13]. Homotropicity is expressed by the same elastic deformation law for all vertical elements under horizontal loading, and therefore the horizontal stiffness matrices of the aforementioned elements are proportional [19-22]. Homotropic buildings can be divided in the following categories: (i) isotropic, all elements follow the same homotropicity rule and their horizontal stiffness matrices receive the following form: $\mathbf{K}_n = k_n \cdot \mathbf{K}_o$, where k_n is the proportionality constant and $\mathbf{K}_o$ is the characteristic stiffness matrix; (ii) orthotropic, elements along X, and Y directions follow different homotropicity rules and their horizontal stiffness matrices

receive the following forms: $\mathbf{K}_{\mathrm{xn}} = \mathrm{k}_{\mathrm{xn}} \cdot \mathbf{K_{ox}}$, $\mathbf{K}_{\mathrm{yn}} = \mathrm{k}_{\mathrm{yn}} \cdot \mathbf{K_{oy}}$, where $\mathrm{k}_{\mathrm{xn}}, \mathrm{k}_{\mathrm{yn}}$ are the proportionality constants and $\mathbf{K_{ox}}$, $\mathbf{K_{oy}}$ are the characteristic stiffness matrices; (iii) complex isotropic-coaxial, the vertical elements can be divided into two or more subsystems that belong to type (i) or (ii) [13].

All the aforementioned studies refer to the definition of elastic axis under the application of static horizontal forces or moments. Since the torsional effects are attributed to a purely dynamic phenomenon the two-fold question that arises is the following: (i) Is it possible to define a dynamic elastic axis under the application of transient horizontal forces or moments?; (ii) Will this axis be different than the elastic axis defined by the static loading? The present paper utilizes the notion of twist center which coincides with the center of rigidity in order to define the dynamic elastic axis. In particular, monosymmetric single-story and monosymmetric isotropic multistory buildings are excited by a torsional ground motion and the center of twist of each story is determined. Once the centers of twist line up in a vertical axis, the dynamic elastic axis is possible to be defined. The position of the dynamic axis is compared with the position of the known elastic axis.

2 MATHEMATICAL FORMULATION

The equation of motion of any structural system is the following:

$$\boldsymbol{M} \cdot \ddot{\boldsymbol{U}}(t) + \boldsymbol{C} \cdot \dot{\boldsymbol{U}}(t) + \boldsymbol{K} \cdot \boldsymbol{U}(t) = \boldsymbol{F}(t) \tag{1}$$

where $\mathrm{M}, \mathrm{C}, \mathrm{K}$ are the mass, damping and stiffness matrices respectively. $\mathrm{U(t)}$ and $\mathrm{F(t)}$ are the displacement and force vectors respectively. The damping matrix, $\boldsymbol{C}$ is represented by Rayleing damping by the following expression [23]:

$$\boldsymbol{C} = a \cdot \boldsymbol{M} + b \cdot \boldsymbol{K} \tag{2}$$

where the constants a, b are related to the modal damping ratio, ζ by the following expressions:

$$a = \frac{2 \cdot \zeta \cdot \omega_i \cdot \omega_j}{\omega_i + \omega_j} \qquad b = \frac{2 \cdot \zeta}{\omega_i + \omega_j} \tag{3}$$

where ω_i, ω_j are the eigenfrequencies of the ith and jth eigenmode respectively.

The equation of motion (1) in the time domain is coupled due to the participation of accelerations, $\ddot{U}(t)$; velocities, $\dot{U}(t)$; and displacements, $U(t)$. Therefore, the Fast Fourier Transform is applied to both parts of equation (1).

$$(\boldsymbol{K} - \Omega^2 \cdot \boldsymbol{M} + i \cdot \Omega \cdot \boldsymbol{C}) \cdot \boldsymbol{U}(\Omega) = FFT(\boldsymbol{F}(t)) \tag{4}$$

It is assumed that each story plate behaves as an in-plane rigid diaphragm. Therefore, each story has three degrees of freedom: (i) translation at X axis, u_x; (ii) translation at Y axis, u_y; (iii) rotation around Z axis, θ_z. The constraint equations between two points $i(x_i, y_i)$ and $j(x_j, y_j)$ that belong to the diaphragm are the following [24].

$$\begin{aligned} u_{xj} &= u_{xi} - \Delta y_{ij} \cdot \theta_z, \ \Delta y_{ji} = y_i - y_j \\ u_{yj} &= u_{yi} + \Delta x_{ij} \cdot \theta_z, \ \Delta x_{ji} = x_i - x_j \end{aligned} \tag{5}$$

Furthermore, it is assumed that the masses of the individual vertical resisting elements are negligible and the mass distribution is uniform at the floor levels. Therefore, the center of mass, CM coincides with the geometric center of the diaphragm. The center of mass of a system is

the point on the diaphragm through which the resultant of the inertial forces of the diaphragm is passing through.

2.1 Single-story symmetric buildings

A single-story building which is symmetric at the X axis is depicted in Fig. 1. The structure has three degrees of freedom: (i) translation at X axis, u_x; (ii) translation at Y axis, u_y; (iii) rotation around Z axis, θ_z. Furthermore, the inertial characteristics of the single-story are: the translational mass, m; and the mass moment of inertia, J_m.

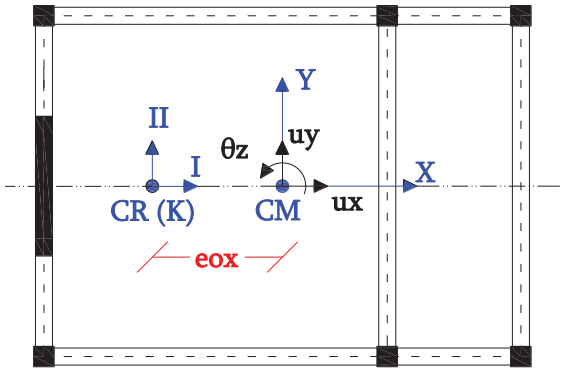

Figure 1: Single-story building symmetric at X axis.

The mass, stiffness and damping matrices of the system under study are represented by the following equations.

$$\boldsymbol{M} = \begin{bmatrix} m & 0 & 0 \\ 0 & m & 0 \\ 0 & 0 & J_m \end{bmatrix}$$

$$\boldsymbol{K} = \begin{bmatrix} k_{xx} & 0 & 0 \\ 0 & k_{yy} & k_{yz} \\ 0 & k_{yz} & k_{zz} \end{bmatrix} \qquad \boldsymbol{C} = \begin{bmatrix} c_{xx} & 0 & 0 \\ 0 & c_{yy} & c_{yz} \\ 0 & c_{yz} & c_{zz} \end{bmatrix} \tag{6}$$

The displacement and force vector are expressed by the following relationships in time domain.

$$\boldsymbol{U}(t)^T = [u_x(t) \quad u_y(t) \quad \theta_z(t)] \qquad \boldsymbol{F}(t)^T = [0 \quad 0 \quad -J_m \cdot \ddot{\theta}_g(t)] \tag{7}$$

where $\ddot{\theta}_g(t)$ is the rotational base excitation. The aforementioned vectors receive the following expressions in the frequency domain.

$$\boldsymbol{U}(\Omega)^T = [u_x(\Omega) \quad u_y(\Omega) \quad \theta_z(\Omega)] \qquad \boldsymbol{F}(\Omega)^T = [0 \quad 0 \quad FFZ] \tag{8}$$

where FFZ is the Fast Fourier Transform of the rotational moment, $-J_m \cdot \ddot{\theta}_g(t)$.

Finally, the equation of motion for the single-story building, which is symmetric with respect to X axis is expressed as follows:

$$\begin{bmatrix} k_{xx} - \Omega^2 \cdot m + i \cdot \Omega \cdot c_{xx} & 0 & 0 \\ 0 & k_{yy} - \Omega^2 \cdot m + i \cdot \Omega \cdot c_{yy} & k_{yz} + i \cdot \Omega \cdot c_{yz} \\ 0 & k_{yz} + i \cdot \Omega \cdot c_{yz} & k_{zz} - \Omega^2 \cdot J_m + i \cdot \Omega \cdot c_{zz} \end{bmatrix} \cdot \begin{bmatrix} u_x(\Omega) \\ u_y(\Omega) \\ \theta_z(\Omega) \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ FFZ \end{bmatrix} \tag{9}$$

The dynamic elastic center can be defined as the point which belongs to the diaphragm, and that under a rotational base excitation is only rotated without being translated at all. Therefore,

using the diaphragm's constraint equations (5), the coordinates of the dynamic elastic center can be defined as follows:

$$x_K = -\frac{u_y(\Omega)}{\theta_z(\Omega)} \qquad y_K = \frac{u_x(\Omega)}{\theta_z(\Omega)} \tag{10}$$

By solving equation (9) and replacing the expressions of the displacements at CM in equation (10), the coordinates of the dynamic elastic center receive the following form.

$$x_K = \frac{k_{yz} + i \cdot \Omega \cdot c_{yz}}{k_{yy} - \Omega^2 \cdot m + i \cdot \Omega \cdot c_{yy}} \qquad y_K = 0 \tag{11}$$

From Equation 11 the following observations can be made.

- The coordinates depend on: (i) stiffness terms (k_{yy}, k_{yz}) related to the translational degree of freedom, Y which is perpendicular to the axis of symmetry, X; (ii) translational mass, m ; (iii) damping terms (c_{yy}, c_{yz}); and (iv) frequency of excitation, Ω.
- The coordinates do not depend on the rotational earthquake component ($\ddot{\theta}_g(t)$).
- The coordinates do not depend on the mass moment of inertia, J_m.
- The coordinates as expressed in the frequency domain, are complex numbers. Their imaginary part is attributed to the damping terms exclusively.
- In case that the dynamic terms, such as mass and damping, are ignored or the excitation frequency is very small ($\Omega \approx 0$) the coordinates of the dynamic elastic center coincide with the coordinates of the elastic center as defined by the application of a static moment ($x_K = k_{yz}/k_{yy}$).
- The deviation of the static values of the coordinates is expected at the high frequency range. This is important taking into account that the rotational earthquake accelerations are dominated by frequencies higher than the corresponding translational accelerations [8].

2.2 Two-story isotropic monosymmetric buildings

Fig. 2 depicts the plan view of an isotropic monosymmetric building. The main assumption regarding the inertial characteristics is that they remain the same at each story level. Furthermore, the centers of mass of all stories belong on the same vertical axis. Each story level has a translational mass, m and a mass moment of inertia, J_m. The vector of displacements for all six degrees of freedom and the mass matrix of the two-story isotropic building are given by following Equation 12.

$$\boldsymbol{u} = \begin{bmatrix} u_{x1} \\ u_{x2} \\ u_{y1} \\ u_{y2} \\ \theta_1 \\ \theta_2 \end{bmatrix}, \qquad \boldsymbol{M} = \begin{bmatrix} m & 0 & 0 & 0 & 0 & 0 \\ 0 & m & 0 & 0 & 0 & 0 \\ 0 & 0 & m & 0 & 0 & 0 \\ 0 & 0 & 0 & m & 0 & 0 \\ 0 & 0 & 0 & 0 & J_m & 0 \\ 0 & 0 & 0 & 0 & 0 & J_m \end{bmatrix} \tag{12}$$

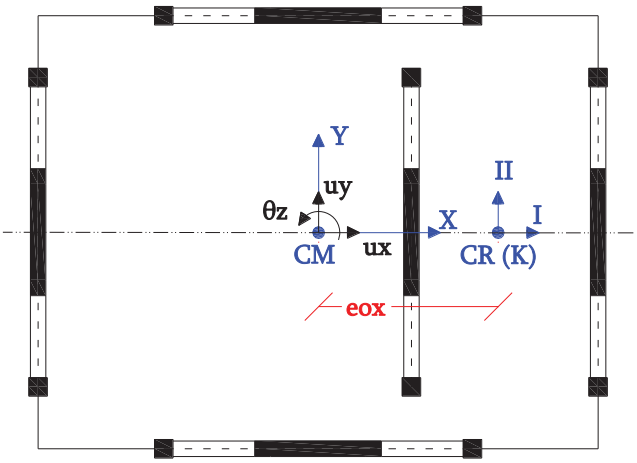

Figure 2: Plan view of isotropic building.

Furthermore, the main characteristic of the isotropic buildings behavior is that all the planar frames participating in the structural system, have proportional stiffness matrices. The frames may consist of mixed-type resisting elements, such as for example moment frames coupled with shear walls. Therefore, the following equation is valid [25].

$$\boldsymbol{K}_i = k_i \cdot \boldsymbol{K}_o \tag{13}$$

where $\boldsymbol{K}_i$ is the stiffness matrix of each frame participating in the structural system, K_o is the characteristic stiffness matrix and k_i is the proportionality constant. The stiffness matrix of the two-story structure is expressed by the following relationships [20].

$$\boldsymbol{K} = \begin{bmatrix} k_{xx} \cdot \boldsymbol{K_o} & 0 & 0 \\ 0 & k_{yy} \cdot \boldsymbol{K_o} & k_{yz} \cdot \boldsymbol{K_o} \\ 0 & k_{yz} \cdot \boldsymbol{K_o} & k_{zz} \cdot \boldsymbol{K_o} \end{bmatrix} \qquad \boldsymbol{K_o} = \begin{bmatrix} K_{o1} & K_{o2} \\ K_{o2} & K_{o3} \end{bmatrix} \tag{14}$$

The damping matrix is expressed by Rayleigh damping and it is given by equation (2).

The displacement and force vector are given by the following relationships, expressed in the frequency domain.

$$\boldsymbol{U}(\Omega)^T = [u_{x1}(\Omega) \quad u_{x2}(\Omega) \quad u_{y1}(\Omega) \quad u_{y2}(\Omega) \quad \theta_{z1}(\Omega) \quad \theta_{z2}(\Omega)]$$
$$FFT(\boldsymbol{F}(t))^T = [0 \quad 0 \quad 0 \quad 0 \quad FFZ_1 \quad FFZ_2] \tag{15}$$

where the indices 1,2 denote the first and second floor respectively and FFZ is the Fast Fourier Transform of the moment $-J_m \cdot \ddot{\theta}_g(t)$.

After performing some mathematical calculations (see Appendix), the complex matrix which is multiplied by the displacement vector receives the following form.

$$\boldsymbol{K_{comp}} = \begin{bmatrix} k_{xx} \cdot \boldsymbol{K_{ox}} & 0 & 0 \\ & k_{yy} \cdot \boldsymbol{K_{oy}} & k_{yz} \cdot \boldsymbol{K_{o,imag}} \\ symm. & & k_{zz} \cdot \boldsymbol{K_{oz}} \end{bmatrix} \tag{16}$$

where the 2x2 submatrices receive the following expressions (see A8, A10, A14):

$$\boldsymbol{K_{0x}} = \begin{bmatrix} (K_{o1} - \Omega^2 \cdot m/k_{xx} + i \cdot \Omega \cdot \alpha \cdot K_{o1} + i \cdot \Omega \cdot b \cdot m/k_{xx}) & K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\ K_{o2} \cdot (1 + i \cdot \Omega \cdot a) & (K_{o3} - \Omega^2 \cdot m/k_{xx} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot m/k_{xx}) \end{bmatrix} \tag{17}$$

$$\boldsymbol{K_{0y}} = \begin{bmatrix} \left(K_{o1} - \Omega^2 \cdot m/k_{yy} + i \cdot \Omega \cdot \alpha \cdot K_{o1} + i \cdot \Omega \cdot b \cdot m/k_{yy}\right) & K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\ K_{o2} \cdot (1 + i \cdot \Omega \cdot a) & \left(K_{o3} - \Omega^2 \cdot m/k_{yy} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot m/k_{yy}\right) \end{bmatrix}$$

$$\boldsymbol{K_{0z}} = \begin{bmatrix} (K_{o1} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{o1} + i \cdot \Omega \cdot b \cdot J_m/k_{zz}) & K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\ K_{o2} \cdot (1 + i \cdot \Omega \cdot a) & (K_{o3} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot J_m/k_{zz}) \end{bmatrix}$$

$$\boldsymbol{K_{0,imag}} = (1 + i \cdot \Omega \cdot a) \cdot \boldsymbol{K_0}$$

Finally, the equation of motion of the two-story isotropic building can be written as follows.

$$\boldsymbol{K_{comp}} \cdot \begin{bmatrix} \boldsymbol{u_x}(\Omega) \\ \boldsymbol{u_y}(\Omega) \\ \boldsymbol{\theta_z}(\Omega) \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \boldsymbol{FFZ}(\Omega) \end{bmatrix} \tag{18}$$

where $\boldsymbol{u_x}(\Omega), \boldsymbol{u_y}(\Omega), \boldsymbol{\theta_z}(\Omega)$ are 2-dimensional vectors of translations $u_{x1}(\Omega), u_{x2}(\Omega), u_{y1}(\Omega), u_{y2}(\Omega)$ and rotations $\theta_{z1}(\Omega), \theta_{z2}(\Omega)$ at each story level; $\mathbf{0}$ is a 2-dimensional zero force vector; and $\boldsymbol{FFZ}(\Omega)$ is a 2-dimensional moment vector of FFZ_1, FFZ_2.

The coordinates of the dynamic elastic axis are determined using equations (5) and receive the following forms.

$$\begin{gathered} \boldsymbol{X_{Ko}} = \left(\boldsymbol{K_{oy}} \cdot k_{yy}\right)^{-1} \cdot \left(\boldsymbol{K_{o,imag}} \cdot k_{yz}\right) \\ \boldsymbol{Y_{Ko}} = \mathbf{0} \end{gathered} \tag{19}$$

where $\boldsymbol{X}_{Ko}, \boldsymbol{Y}_{Ko}$ are square matrices. In this particular case of symmetry, the matrix $\boldsymbol{Y}_{Ko}$ contains zero terms. Therefore, the elastic axis is located on X axis, the axis of symmetry. The diagonal terms of matrix $\boldsymbol{X}_{Ko}$ denote the coordinates of the elastic center at each story-level. The off-diagonal terms must be zero. In case that the off-diagonal terms are not zero then the elastic axis does not exist.

2.3 n-story monosymmetric isotropic buildings

A typical plan view of N-story isotropic building which is symmetric with respect to X axis is depicted in Fig. 2. The plate of each story behaves as a rigid in-plane diaphragm. Therefore, each story has three degrees of freedom: two translations at the X, Y axes and one rotation around Z axis.

The displacement and force vector are given by the following relationships, expressed in the frequency domain.

$$\begin{gathered} \boldsymbol{U}(\Omega)^T = [u_{x1}(\Omega) \quad u_{x2}(\Omega) \quad \ldots \quad u_{y1}(\Omega) \quad u_{y2}(\Omega) \quad \ldots \quad \theta_{z(n-1)}(\Omega) \quad \theta_{zn}(\Omega)] \\ FFT(\boldsymbol{F}(t))^T = [0 \quad 0 \quad \ldots \quad 0 \quad 0 \quad \ldots \quad FFZ_{(n-1)} \quad FFZ_n] \end{gathered} \tag{20}$$

where the indices 1,2,…,n denote the first, second and nth floor respectively and FFZ is the Fast Fourier Transform of the moment $-J_m \cdot \ddot{\theta}_g(t)$.

The inertial characteristics are the same for each story. In particular, each story has a translational mass, m and a mass moment of inertia, J_m. Therefore, the mass matrix of the n-story isotropic building is a 3n-dimensional matrix and it can be written as follows.

$$\boldsymbol{M} = \begin{bmatrix} m & 0 & 0 & 0 & . & . & 0 & 0 \\ 0 & m & 0 & 0 & . & . & 0 & 0 \\ 0 & 0 & m & 0 & . & . & 0 & 0 \\ 0 & 0 & 0 & m & . & . & 0 & 0 \\ .. & . & . & . & . & . & . & . \\ . & . & . & . & . & . & . & . \\ 0 & 0 & 0 & 0 & . & . & J_m & 0 \\ 0 & 0 & 0 & 0 & . & . & 0 & J_m \end{bmatrix} \tag{21}$$

Taking into account the proportionality of the stiffness matrices of the planar frames and the symmetry with respect to X axis, the stiffness matrix, $\boldsymbol{K}$ of the n-story building is a 3n-dimensional matrix and can be expressed by equation (14). However, the characteristic stiffness matrix, $\boldsymbol{K_o}$ is an n-dimensional matrix and receives the following form:

$$\boldsymbol{K_0} = \begin{bmatrix} K_{o11} & K_{o12} & K_{o13} & K_{o14} & \dots & \dots & K_{o1(n-1)} & K_{o1n} \\ & K_{o22} & K_{o23} & K_{o24} & \dots & \dots & K_{o2(n-1)} & K_{o2n} \\ & & K_{o33} & K_{o34} & \dots & \dots & K_{o3(n-1)} & K_{o3n} \\ & & & K_{o44} & \dots & \dots & K_{o4(n-1)} & K_{o4n} \\ & & & & \ddots & \dots & \vdots & \vdots \\ & & symm. & & & \ddots & \vdots & \vdots \\ & & & & & & K_{o(n-1)(n-1)} & K_{o(n-1)n} \\ & & & & & & & K_{onn} \end{bmatrix} \tag{22}$$

The damping matrix is expressed by Rayleigh damping, it is expressed by equation (2).

Following the same notion as in the case of the two-story building, the complex matrix which is multiplied by the displacement vector can be expressed by equation (16). However, the diagonal terms of each submatrix, $\boldsymbol{K_{ox}}, \boldsymbol{K_{oy}}, \boldsymbol{K_{oz}}$ receive the following forms.

$$\begin{aligned} \boldsymbol{K_{0x(ij)}} &= K_{oij} - \Omega^2 \cdot m/k_{xx} + i \cdot \Omega \cdot \alpha \cdot K_{oij} + i \cdot \Omega \cdot b \cdot m/k_{xx} \\ \boldsymbol{K_{0y(ij)}} &= K_{oij} - \Omega^2 \cdot m/k_{yy} + i \cdot \Omega \cdot \alpha \cdot K_{oij} + i \cdot \Omega \cdot b \cdot m/k_{yy} \\ \boldsymbol{K_{0z(ij)}} &= K_{oij} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{oij} + i \cdot \Omega \cdot b \cdot J_m/k_z \end{aligned} \tag{23}$$

where $i = j = 1{:}\,1{:}\,n$

The off-diagonal terms of each submatrix, $\boldsymbol{K_{ox}}, \boldsymbol{K_{oy}}, \boldsymbol{K_{oz}}$ are the same and receive the following forms.

$$\boldsymbol{K_{0(ij)}} = K_{oij} \cdot (1 + i \cdot \Omega \cdot a) \tag{24}$$

where $i \neq j$.

The imaginary matrix, $\boldsymbol{K_{0,imag}}$ is represented by equation (17).

The equation of motion in the frequency domain is represented by equation (18). However, $\boldsymbol{u_x}(\Omega), \boldsymbol{u_y}(\Omega), \boldsymbol{\theta_z}(\Omega)$ are n-dimensional vectors of translations rotations at each story level; $\mathbf{0}$ is a n-dimensional zero force vector; and $\boldsymbol{FFZ}(\Omega)$ is a n-dimensional moment vector of FFZ_i.

Finally, the coordinates of the dynamic elastic axis can be calculated by equations (19) where $\boldsymbol{X_{Ko}}, \boldsymbol{Y_{Ko}}$ are n-dimensional matrices. The diagonal terms of each matrix denote the coordinates of the elastic center at each story-level. The off-diagonal terms must be zero. In case that the off-diagonal terms are not zero then the elastic axis does not exist.

3 NUMERICAL APPLICATIONS

In the present section a characteristic numerical example for each structural formulation is presented. A MATLAB code has been written in order to apply the final equations for the estimation of the coordinates of the elastic center or axis [26]. The code also performs a modal analysis, in order to estimate the eigenfrequencies and calculate further the Rayleigh damping components, a, b. The Rayleigh damping matrix takes into account all the eigenfrequencies in the case of single-story buildings. In the case of multi-story building the MATLAB code has the capability to take into account more than three eigenfrequencies. The stiffness matrix is calculated by the application of the Finite Element Method while the mass matrix is calculated according to the inertial data.

3.1 Single-story symmetric building

Fig. 3 depicts a single-story building which is symmetric with regard to X axis.

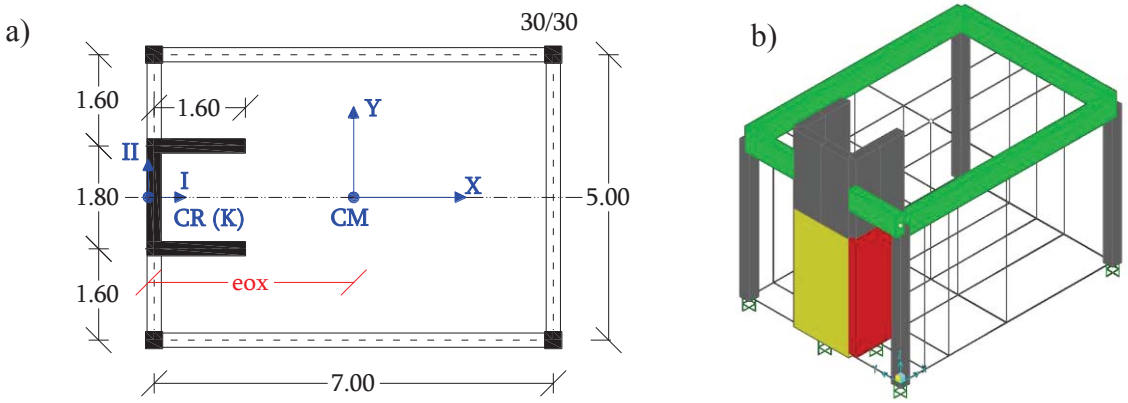

Figure 3: Single-story symmetric building: a) plan view; b) finite element model.

The vertical supporting elements consist of four columns (30/30) and a C shaped shear wall. The horizontal supporting elements consist of a rectangular plate which behaves as a rigid in plane diaphragm and five beams (20/60), which are located at the perimeter of the plate. The height of the building equals 4.5m. The material characteristics are: E=2.8e7kN/m^2; v=0.2. The uniform vertical load of the plate equals to 12kN/m^2 and the modal damping ratio equals 5%. Fig.3 also depicts the structure's finite element model. The simulation of the C shaped shear wall follows the notion of the equivalent frame model.

Taking into account the geometry of the plate and the vertical uniform load, the mass matrix can be calculated under the assumption of diaphragmatic function. In the following equations the stiffness matrix, mass and damping characteristics are given.

$$K = \begin{bmatrix} 238720.458 & 0 & 0 \\ 0 & 214041.096 & -770547.945 \\ 0 & -770547.945 & 3329528.158 \end{bmatrix} \quad m = 42.813\text{tn} \quad a = 2.0894$$

$$J_m = 264.016\text{tnm}^2 \quad b = 6.442 \cdot 10^{-4}$$

Fig.4 depicts the real and imaginary parts of the coordinates of the elastic center, which are calculated according to equation (11). The following two cases are studied: (i) $\zeta = 5\%$; (ii) $\zeta = 0\%$. The real parts of the coordinates coincide with the static values $(x_k = -3.6m, y_k = 0)$ while the imaginary parts are zero, except for very small values of periods or for very large values of frequencies.

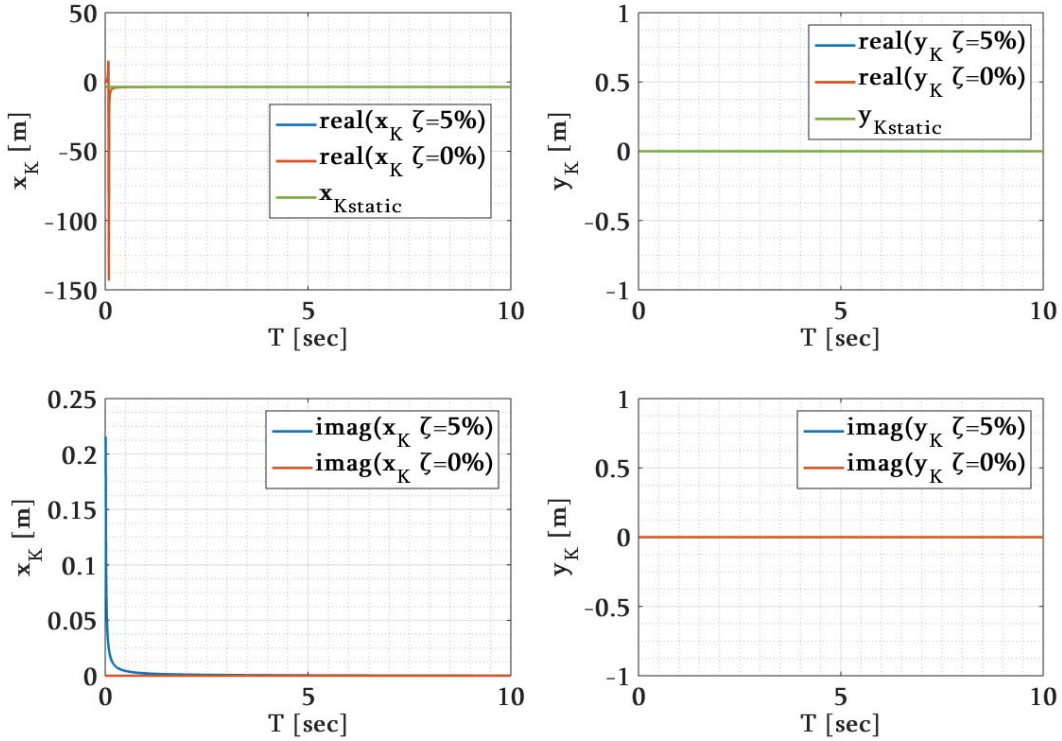

Figure 4: Coordinates of elastic center for a single-story building symmetric with regard to X axis.

3.2 Two-story isotropic symmetric building

Fig.5 depicts a two-story isotropic building. The vertical supporting elements are three walls of 200/25 dimensions and two walls of 160/25 dimensions. The horizontal supporting element is a plate of 3m x 6m which behaves as a rigid in plane diaphragm. The height of each story equals 3.5m. The material characteristics are: E=2.9e7kN/m^2; v=0.2. The inertial characteristics at each story are: translational mass equal to 18tn and polar moment of inertia equal to 67.5tnm^2. The modal damping ratio equals 5%. Fig.5 also depicts the structure's finite element model.

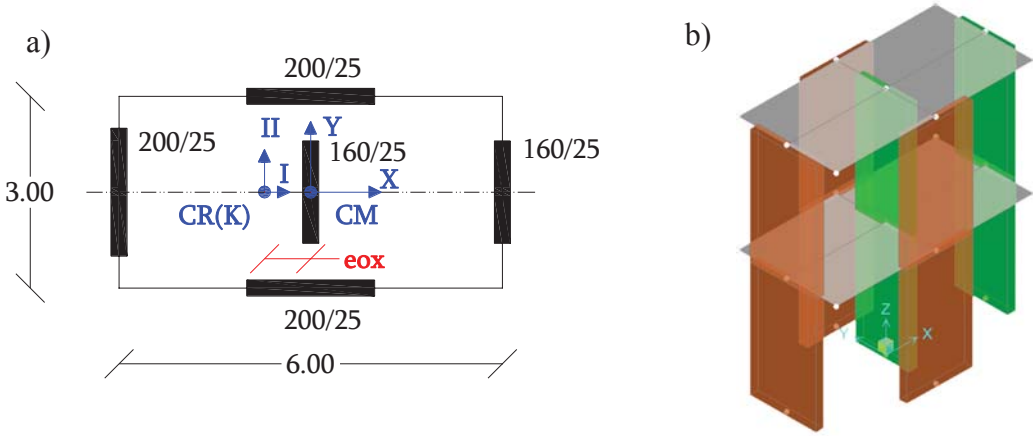

Figure 5: Two-story isotropic building: a) plan view; b) finite element model.

The terms participating in the stiffness matrices according to equations (16, 17) and the coefficients of Rayleigh damping matrix taking into account the first three eigenfrequencies are given in the following.

$$k_{xx} = 361993.161\,,\ k_{yy} = 465153.413$$
$$k_{yz} = -336159.689,\ k_{zz} = 3529724.779$$
$$\boldsymbol{K_o} = \begin{bmatrix} 8 & -2.5 \\ -2.5 & 1 \end{bmatrix} \qquad a = 3.947 \qquad b = 5.944 \cdot 10^{-4}$$

Using well known equations the coordinates of the static elastic axis are determined [25]: $XX_{static} = -0.7227\text{m}$; $YY_{static} = 0\text{m}$. Fig.6 depicts the values of the matrix of the dynamic elastic axis. The coordinate values in X axis deviate from the stable values for the case of zero damping, which is unrealistic and in the small period or high frequency range. This is attributed solely to the presence of inertia according to equation (17). The off-diagonal terms receive zero values for the case that the damping ratio of the structure equals 5%. Furthermore, the coordinate values in Y axis receive zero values. Therefore, the real dynamic elastic axis exists and coincides with the static elastic axis.

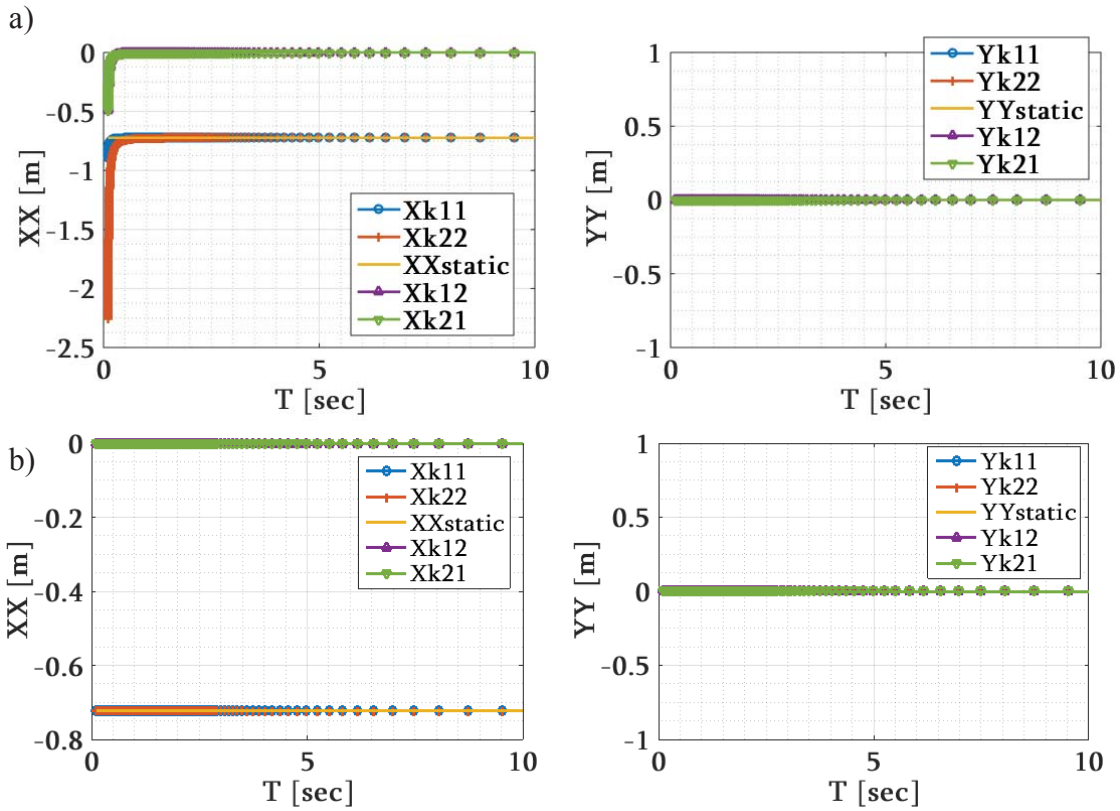

Figure 6: Coordinates of elastic axis for a two-story isotropic building: a) ζ =0%; b) ζ =5%.

3.3 Five-story isotropic building

Fig.7 depicts the plan view of a five-story isotropic building which is symmetric with respect to X axis.

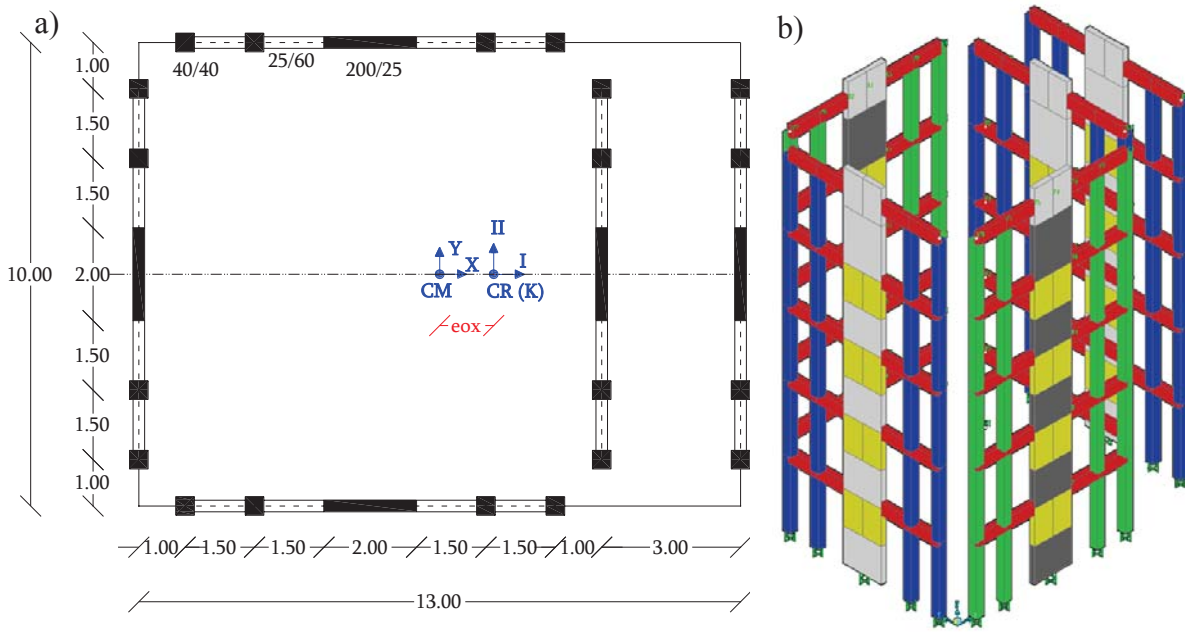

Figure 7: Five-story isotropic building: a) plan view; b) finite element model.

The vertical supporting elements consist of 20 columns (40/40) and five walls (200/25). The horizontal supporting elements consist of a square plate (13mx10m) which behaves as a rigid diaphragm and twenty beams (25/60). The height of each story equals to 3.5m. The material characteristics are: E=2.9e7kN/m^2; v=0.2. The inertial characteristics of each story are: translational mass equal to 200tn and mass moment of inertia equal to 4483.33tnm^2. The modal damping ratio equals 5%. Fig.7 also depicts the structure's finite element model.

The terms participating in the stiffness matrices according to equation (18) are:

$$k_{xx} = 2, k_{yy} = 3$$

$$k_{yz} = 3.5,$$

$$k_{zz} = 146.75$$

$$\boldsymbol{K}_o = \begin{bmatrix} 135.686 & -76.379 & 16.963 & -1.457 & 0.112 \\ & 118.982 & -74.930 & 16.747 & -1.253 \\ & & 118.767 & -73.955 & 14.608 \\ & symm. & & 107.895 & -49.359 \\ & & & & 35.903 \end{bmatrix} \cdot 1e4$$

The coefficients of Rayleigh damping matrix taking into account the first three eigenfrequencies (damping case 1) and the first six eigenfrequencies (damping case 2) are given in the following.

$$a_{3eigen} = 0.9153 \qquad a_{6eigen} = 1.2104$$

$$b_{3eigen} = 0.0025 \qquad b_{6eigen} = 0.001$$

Fig.8 a) and c) depicts the diagonal terms for the two damping cases. A deviation from the static values of the elastic axis is observed at short period range. However, the deviation refers to the third decimal place, and therefore it can be ignored. The increase of the number of eigenfrequencies that participate in the Rayleigh damping matrix, reduces the aforementioned deviation but in small percentage. Fig.8 b) and d) depicts the off-diagonal terms for the two damping cases as well. The values of the terms are considered to be negligible and equal to zero. Therefore, the dynamic elastic axis as defined by the rotational excitation of the structure coincides with the static elastic axis.

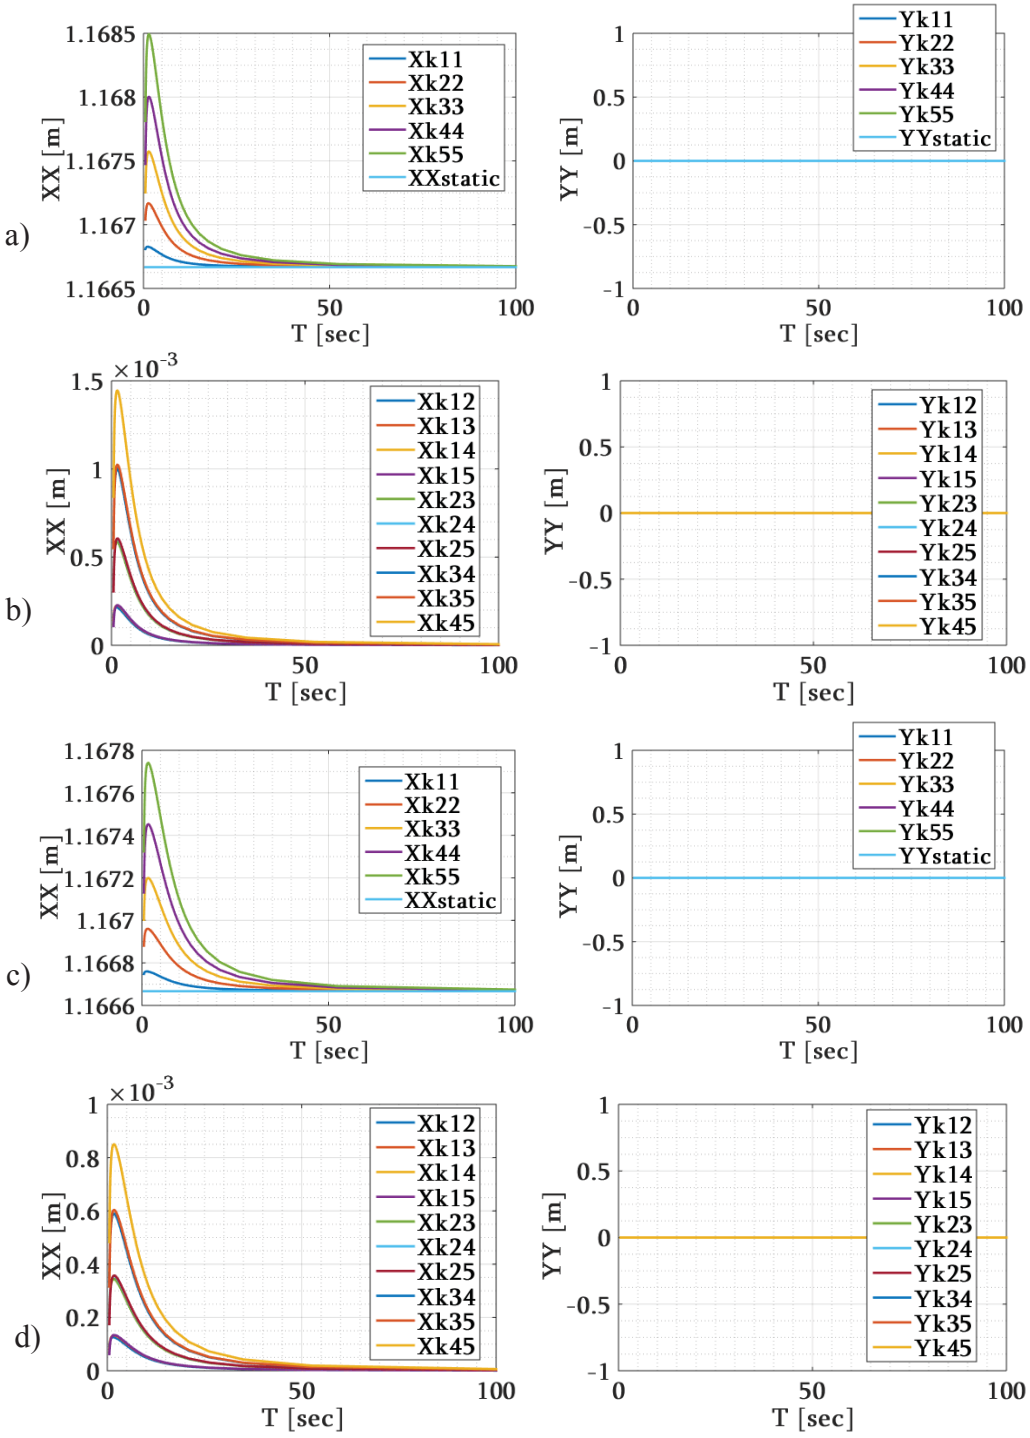

Figure 8: Coordinates of elastic axis for a five-story isotropic building: a) diagonal terms, damping case 1; b) off-diagonal terms, damping case 1; c) diagonal terms, damping case 2; d) off- diagonal terms, damping case 2.

4 CONCLUSIONS

The investigation of the existence of a torsion axis under the action of torsional seismic load has led to the development of analytical formulae for the determination of the torsional axis

under torsional excitation in single story monosymmetric and in multistory isotropic monosymmetric buildings. The determination of the torsional axis has led to the following conclusions:

- A torsional axis can be defined under dynamic excitation in single story monosymmetric and isotropic monosymmetric buildings.
- The location of the torsional axis under dynamic loading depends not only on the geometrical and mechanical characteristics of the structural systems, as the static elastic axis but also on the translational mass and damping characteristics.
- The location of the dynamic torsional axis is independent of the torsional earthquake component and the mass moment of inertia of each story-level.
- The deviation of the coordinates between the static and the dynamic definition of the elastic axis is observed in the high frequency range.
- Characteristic numerical examples are presented for each case under study. Especially for the case of multistory isotropic buildings, the deviation of the elastic axis coordinates from the static values is reduced if more eigenfrequencies are taken into account during the calculation of damping matrix.

The investigation is continued in other types of buildings: asymmetric isotropic buildings and mixed type R/C buildings.

APPENDIX

Two-story isotropic symmetric building

The equation of motion in the frequency domain receives the following form.

$$(\boldsymbol{K} - \Omega^2 \cdot \boldsymbol{M} + i \cdot \Omega \cdot \boldsymbol{C}) \cdot U(\Omega) = FFT(\boldsymbol{F}(t)) \tag{A1}$$

The displacement and force vector in frequency domain, receive the following forms.

$$\boldsymbol{U}(\Omega)^T = [u_{x1}(\Omega) \quad u_{x2}(\Omega) \quad u_{y1}(\Omega) \quad u_{y2}(\Omega) \quad \theta_{z1}(\Omega) \quad \theta_{z2}(\Omega)]$$
$$FFT(\boldsymbol{F}(t))^T = [0 \quad 0 \quad 0 \quad 0 \quad FFZ_1 \quad FFZ_2] \tag{A2}$$

The stiffness matrix of the two-story isotropic building is expressed by the following form

$$\boldsymbol{K}=\begin{bmatrix} k_{xx}\cdot\boldsymbol{K_o} & 0 & 0 \\ 0 & k_{yy}\cdot\boldsymbol{K_o} & k_{yz}\cdot\boldsymbol{K_o} \\ 0 & k_{yz}\cdot\boldsymbol{K_o} & k_{zz}\cdot\boldsymbol{K_o} \end{bmatrix} \qquad \boldsymbol{K_o}=\begin{bmatrix} K_{o1} & K_{o2} \\ K_{o2} & K_{o3} \end{bmatrix}$$

$$\boldsymbol{K}=\begin{bmatrix} k_{xx}\cdot K_{o1} & k_{xx}\cdot K_{o2} & 0 & 0 & 0 & 0 \\ k_{xx}\cdot K_{o2} & k_{xx}\cdot K_{o3} & 0 & 0 & 0 & 0 \\ 0 & 0 & k_{yy}\cdot K_{o1} & k_{yy}\cdot K_{o2} & k_{yz}\cdot K_{o1} & k_{yz}\cdot K_{o2} \\ 0 & 0 & k_{yy}\cdot K_{o2} & k_{yy}\cdot K_{o3} & k_{yz}\cdot K_{o2} & k_{yz}\cdot K_{o3} \\ 0 & 0 & k_{yz}\cdot K_{o1} & k_{yz}\cdot K_{o2} & k_{zz}\cdot K_{o1} & k_{zz}\cdot K_{o2} \\ 0 & 0 & k_{yz}\cdot K_{o2} & k_{yz}\cdot K_{o3} & k_{zz}\cdot K_{o2} & k_{zz}\cdot K_{o3} \end{bmatrix} \tag{A3}$$

The mass matrix is expressed by the following equation

$$\boldsymbol{M}=\begin{bmatrix} m & 0 & 0 & 0 & 0 & 0 \\ 0 & m & 0 & 0 & 0 & 0 \\ 0 & 0 & m & 0 & 0 & 0 \\ 0 & 0 & 0 & m & 0 & 0 \\ 0 & 0 & 0 & 0 & J_m & 0 \\ 0 & 0 & 0 & 0 & 0 & J_m \end{bmatrix} \tag{A4}$$

The damping matrix following the notion of Rayleigh damping.

$$\boldsymbol{C}=a\cdot\boldsymbol{K}+b\cdot\boldsymbol{M}$$

$$\boldsymbol{C}=\begin{bmatrix} a\cdot k_{xx}\cdot K_{o1}+b\cdot m & a\cdot k_{xx}\cdot K_{o2} & 0 & 0 & 0 & 0 \\ a\cdot k_{xx}\cdot K_{o2} & a\cdot k_{xx}\cdot K_{o3}+b\cdot m & 0 & 0 & 0 & 0 \\ 0 & 0 & a\cdot k_{yy}\cdot K_{o1}+b\cdot m & a\cdot k_{yy}\cdot K_{o2} & a\cdot k_{yz}\cdot K_{o1} & a\cdot k_{yz}\cdot K_{o2} \\ 0 & 0 & a\cdot k_{yy}\cdot K_{o2} & a\cdot k_{yy}\cdot K_{o3}+b\cdot m & a\cdot k_{yz}\cdot K_{o2} & a\cdot k_{yz}\cdot K_{o3} \\ 0 & 0 & a\cdot k_{yz}\cdot K_{o1} & a\cdot k_{yz}\cdot K_{o2} & a\cdot k_{zz}\cdot K_{o1}+b\cdot J_m & a\cdot k_{zz}\cdot K_{o2} \\ 0 & 0 & a\cdot k_{yz}\cdot K_{o2} & a\cdot k_{yz}\cdot K_{o3} & a\cdot k_{zz}\cdot K_{o2} & a\cdot k_{zz}\cdot K_{o3}+b\cdot J_m \end{bmatrix} \tag{A5}$$

The complex matrix, which is multiplied by the displacement vector is calculated by the following expression.

$$\boldsymbol{K_{comp}}=(\boldsymbol{K}-\Omega^2\cdot\boldsymbol{M}+i\cdot\Omega\cdot a\cdot\boldsymbol{K}+i\cdot\Omega\cdot b\cdot\boldsymbol{M})$$

$$\boldsymbol{K_{comp}}=\left[\begin{array}{cc:cc:cc} K_{comp}(1,1) & K_{comp}(1,2) & 0 & 0 & 0 & 0 \\ & K_{comp}(2,2) & 0 & 0 & 0 & 0 \\ \hdashline & & K_{comp}(3,3) & K_{comp}(3,4) & K_{comp}(3,5) & K_{comp}(3,6) \\ & & & K_{comp}(4,4) & K_{comp}(4,5) & K_{comp}(4,6) \\ \hdashline & symm. & & & K_{comp}(5,5) & K_{comp}(5,6) \\ & & & & & K_{comp}(6,6) \end{array}\right] \tag{A6}$$

$$\boldsymbol{K_{comp}}=\begin{bmatrix} \boldsymbol{K_{comp,1}} & \boldsymbol{0} & \boldsymbol{0} \\ & \boldsymbol{K_{comp,2}} & \boldsymbol{K_{comp,3}} \\ symm. & & \boldsymbol{K_{comp,4}} \end{bmatrix}$$

The complex matrix can be divided at six 2-dimensional symmetric matrices. The terms of the first submatrix are calculated in the following.

$$\begin{aligned} &K_{comp}(1,1)=k_{xx}\cdot K_{o1}-\Omega^2\cdot m+i\cdot\Omega\cdot a\cdot k_{xx}\cdot K_{o1}+i\cdot\Omega\cdot b\cdot m\Rightarrow \\ &K_{comp}(1,1)=k_{xx}\cdot(K_{o1}-\Omega^2\cdot m/k_{xx}+i\cdot\Omega\cdot\alpha\cdot K_{o1}+i\cdot\Omega\cdot b\cdot m/k_{xx}) \\ &K_{comp}(1,2)=k_{xx}\cdot K_{o2}+i\cdot\Omega\cdot a\cdot k_{xx}\cdot K_{o2}=k_{xx}\cdot K_{o2}\cdot(1+i\cdot\Omega\cdot a)=K_{comp}(2,1) \\ &K_{comp}(2,2)=k_{xx}\cdot K_{o3}-\Omega^2\cdot m+i\cdot\Omega\cdot a\cdot k_{xx}\cdot K_{o3}+i\cdot\Omega\cdot b\cdot m\Rightarrow \\ &K_{comp}(2,2)=k_{xx}\cdot(K_{o3}-\Omega^2\cdot m/k_{xx}+i\cdot\Omega\cdot\alpha\cdot K_{o3}+i\cdot\Omega\cdot b\cdot m/k_{xx}) \end{aligned} \tag{A7}$$

Therefore, the first submatrix can be written as:

$$\boldsymbol{K_{comp,1}}=\begin{bmatrix} k_{xx}\cdot(K_{o1}-\Omega^2\cdot m/k_{xx}+i\cdot\Omega\cdot\alpha\cdot K_{o1}+i\cdot\Omega\cdot b\cdot m/k_{xx}) & k_{xx}\cdot K_{o2}\cdot(1+i\cdot\Omega\cdot a) \\ k_{xx}\cdot K_{o2}\cdot(1+i\cdot\Omega\cdot a) & k_{xx}\cdot(K_{o3}-\Omega^2\cdot m/k_{xx}+i\cdot\Omega\cdot\alpha\cdot K_{o3}+i\cdot\Omega\cdot b\cdot m/k_{xx}) \end{bmatrix}$$

$$\boldsymbol{K_{comp,1}}=k_{xx}\cdot\boldsymbol{K_{0x}} \tag{A8}$$

$$\boldsymbol{K_{0x}}=\begin{bmatrix} (K_{o1}-\Omega^2\cdot m/k_{xx}+i\cdot\Omega\cdot\alpha\cdot K_{o1}+i\cdot\Omega\cdot b\cdot m/k_{xx}) & K_{o2}\cdot(1+i\cdot\Omega\cdot a) \\ K_{o2}\cdot(1+i\cdot\Omega\cdot a) & (K_{o3}-\Omega^2\cdot m/k_{xx}+i\cdot\Omega\cdot\alpha\cdot K_{o3}+i\cdot\Omega\cdot b\cdot m/k_{xx}) \end{bmatrix}$$

The terms of the second submatrix are calculated in the following.

$$K_{comp}(3,3)=k_{yy}\cdot\left(K_{o1}-\Omega^2\cdot m/k_{yy}+i\cdot\Omega\cdot\alpha\cdot K_{o1}+i\cdot\Omega\cdot b\cdot m/k_{yy}\right)$$

$$
\begin{aligned}
K_{comp}(3,4) &= k_{yy} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\
K_{comp}(4,3) &= K_{comp}(3,4) \\
K_{comp}(4,4) &= k_{yy} \cdot \left(K_{o3} - \Omega^2 \cdot m/k_{yy} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot m/k_{yy}\right)
\end{aligned} \tag{A9}
$$

Therefore, the second submatrix can be written as:

$$
\boldsymbol{K_{comp,2}} = \begin{bmatrix} k_{yy} \cdot \left(K_{o1} - \Omega^2 \cdot m/k_{yy} + i \cdot \Omega \cdot \alpha \cdot K_{o1} + i \cdot \Omega \cdot b \cdot m/k_{yy}\right) & k_{yy} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\ k_{yy} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) & k_{yy} \cdot \left(K_{o3} - \Omega^2 \cdot m/k_{yy} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot m/k_{yy}\right) \end{bmatrix}
$$

$$
\boldsymbol{K_{comp,2}} = k_{yy} \cdot \boldsymbol{K_{0y}} \tag{A10}
$$

$$
\boldsymbol{K_{0y}} = \begin{bmatrix} \left(K_{o1} - \Omega^2 \cdot m/k_{yy} + i \cdot \Omega \cdot \alpha \cdot K_{o1} + i \cdot \Omega \cdot b \cdot m/k_{yy}\right) & K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\ K_{o2} \cdot (1 + i \cdot \Omega \cdot a) & \left(K_{o3} - \Omega^2 \cdot m/k_{yy} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot m/k_{yy}\right) \end{bmatrix}
$$

The terms of the third submatrix are calculated in the following.

$$
\begin{aligned}
K_{comp}(3,5) &= k_{yz} \cdot K_{o1} \cdot (1 + i \cdot \Omega \cdot a) \\
K_{comp}(3,6) &= k_{yz} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\
K_{comp}(4,5) &= K_{comp}(3,6) \\
K_{comp}(4,6) &= k_{yz} \cdot K_{o3} \cdot (1 + i \cdot \Omega \cdot a)
\end{aligned} \tag{A11}
$$

Therefore, the third submatrix can be written as:

$$
\boldsymbol{K_{comp,3}} = \begin{bmatrix} k_{yz} \cdot K_{o1} \cdot (1 + i \cdot \Omega \cdot a) & k_{yz} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\ k_{yz} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) & k_{yz} \cdot K_{o3} \cdot (1 + i \cdot \Omega \cdot a) \end{bmatrix}
$$

$$
\boldsymbol{K_{comp,3}} = k_{yz} \cdot \boldsymbol{K_{0,imag}} \tag{A12}
$$

The terms of the fourth submatrix are calculated in the following.

$$
\begin{aligned}
K_{comp}(5,5) &= k_{zz} \cdot (K_{o1} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{o1} + i \cdot \Omega \cdot b \cdot J_m/k_{zz}) \\
K_{comp}(5,6) &= k_{zz} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\
K_{comp}(6,5) &= K_{comp}(5,6) \\
K_{comp}(6,6) &= k_{zz} \cdot (K_{o3} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot J_m/k_{zz})
\end{aligned} \tag{A13}
$$

Therefore, the fourth submatrix can be written as:

$$
\boldsymbol{K_{comp,4}} = \begin{bmatrix} k_{zz} \cdot (K_{o1} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{o1} + i \cdot \Omega \cdot b \cdot J_m/k_{zz}) & k_{zz} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\ k_{zz} \cdot K_{o2} \cdot (1 + i \cdot \Omega \cdot a) & k_{zz} \cdot (K_{o3} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot J_m/k_{zz}) \end{bmatrix}
$$

$$
\boldsymbol{K_{comp,4}} = k_{zz} \cdot \boldsymbol{K_{0z}} \tag{A14}
$$

$$
\boldsymbol{K_{0z}} = \begin{bmatrix} (K_{o1} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{o1} + i \cdot \Omega \cdot b \cdot J_m/k_{zz}) & K_{o2} \cdot (1 + i \cdot \Omega \cdot a) \\ K_{o2} \cdot (1 + i \cdot \Omega \cdot a) & (K_{o3} - \Omega^2 \cdot J_m/k_{zz} + i \cdot \Omega \cdot \alpha \cdot K_{o3} + i \cdot \Omega \cdot b \cdot J_m/k_{zz}) \end{bmatrix}
$$

Finally, the 6-dimensional complex matrix can be written in the following form.

$$
\boldsymbol{K_{comp}} = \begin{bmatrix} k_{xx} \cdot \boldsymbol{K_{ox}} & 0 & 0 \\ & k_{yy} \cdot \boldsymbol{K_{oy}} & k_{yz} \cdot \boldsymbol{K_{o,imag}} \\ symm. & & k_{zz} \cdot \boldsymbol{K_{oz}} \end{bmatrix} \tag{A15}
$$

Keywords: Railway viaduct, resonance, fatigue test, RC member, PPC member

Abstract. *Resonance phenomenon during train passing has been observed because of the increased in train operation speed in high-speed railway, the spread of low stiffness girder such as PPC and SRC girder, and the advances in measurement technology. An example has been reported in which significant resonance is generated, which is caused by a decrease in stiffness due to the progress of cracks in concrete members. The stiffness of members must be evaluated in consideration of the action hysteresis during the design life time, i.e. the magnitude and the cyclic number of the load. The aim of this paper is to evaluate the vibration characteristics of RC and PPC beam members in operating condition and the variation of stiffness and damping of the beam after repeated loads of about 2 million times was evaluated based on fatigue tests of 4 specimens. Static loading tests made it clear that the effective stiffness of RC members decreases with respect to increasing load magnitude and it is consistent with the previous evaluation formula. On the other hand, the effective stiffness of the PPC member is overestimated in the case of the previous evaluation formula, and is consistent with Branson's cubic law. From the fatigue tests, the effective stiffness decreases by about 6 to 16% for RC members and 10 to 33% for PPC members after 2 million cyclic loading. The equivalent damping is from 4.0% for RC members, according to the load magnitude and decreases to about 0.5%, and 1.5% to 0.5% for PPC members after 2 million cyclic loading. This means that the repeated loading accompanying the train pass contributes to increasing the dynamic response, especially with a large degree of influence on the PPC members. Finally, dynamic analyses implementing the experimental results implied that excessive response can occur after millions of train passage, especially in the case of PPC members, even if it were not observed in the initial stage of operations.*

1 INTRODUCTION

The phenomenon of vibrational resonance during train passing has been confirmed following the enhanced operational speeds of high-speed railways, the spread of low-stiffness girder such as the PPC and SRC girders, and the advances in measurement technology [1]. For example, there was a study reporting that significant resonance was generated from a decrease in stiffness of concrete members owing to crack progression. As such, further refinement of the impact coefficient is required in the dynamic response evaluation of such members, largely depending on their natural frequencies or their rigidities [2]. In view of this, the stiffness of concrete members must be evaluated in consideration of their experience during the design lifetime, i.e. the magnitude and cyclic number of the repeated loads. Thus, the stiffness of RC members was evaluated herein, under the assumption of an operational condition [3]. Moreover, the hysteresis characteristics of PPC members were evaluated under the same use condition, whereas in the past such characteristics were partially studied in the architectural field, under the occurrence of earthquakes [4, 5, 6].

This paper aims to evaluate the vibration characteristics of RC and PPC beam members under a specific operational condition in beam stiffness and damping variations after a fatigue test of approximately two million times of repeated loading.

2 EXPERIMENT

2.1 Specimen

Figure 1 shows the design details of the specimens, which consists of both RC and PPC members, of which the latter has become widely popular in railway structures in recent years. Herein, the ratio of tensile rebars and the amount of introduced pre-stress were assumed by reference to specifications of general railway bridges. The tensile reinforcement ratio of RC and PPC member are 1% and 0.6%, respectively. The prestressing coefficient of PPC member λ is 0.71.

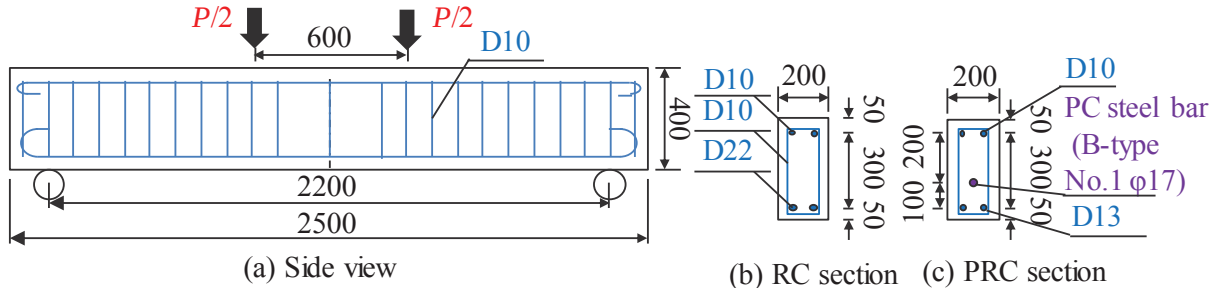

Figure 1: Design details of specimens

2.2 Loading pattern

Figure 2 illustrates the static cyclic loading test for evaluating the basic hysteresis characteristics of the members, with increments of 20kN in the load control through the tensile rebar's yield point and 2 mm as displacement control after yield. At each increasing load level, the number of repetitions was three times. Moreover, a 5-kN load was maintained during unloading.

In the dynamic loading test, the upper limit load was increased to 70, 120 and 170kN, with assumed 50-kN reinforcement stress (of approximately 100 MPa) of dead load based on a 5-Hz excitation frequency. In this test, the number of repetitions at each load level was two million.

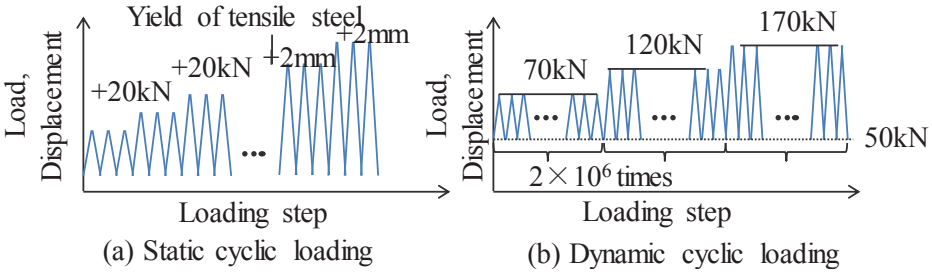

Figure 2: Loading pattern

2.3 Static load-displacement relationship

Figure 3 shows the load–displacement relationship obtained from the static and dynamic loading test. Apparently, the stiffness (effective stiffness K_{eq}) at unloading and reloading decreased in the region where cracks occurred, whereas it decreased on the skeleton curve (after δ_c in the figure). Moreover, the residual displacement at unloading in the RC members increased with respect to increasing load as compared to the PPC members. The hysteresis characteristics of PPC members exhibited a stronger tendency to point towards the origin during unloading when compared with those of the RC members; as the residual displacement decreased, the effective stiffness showed decreasing tendency. That is, the prestress introduced for the purpose of reducing the crack width was found to influence reduction in the stiffness of the entire beam system.

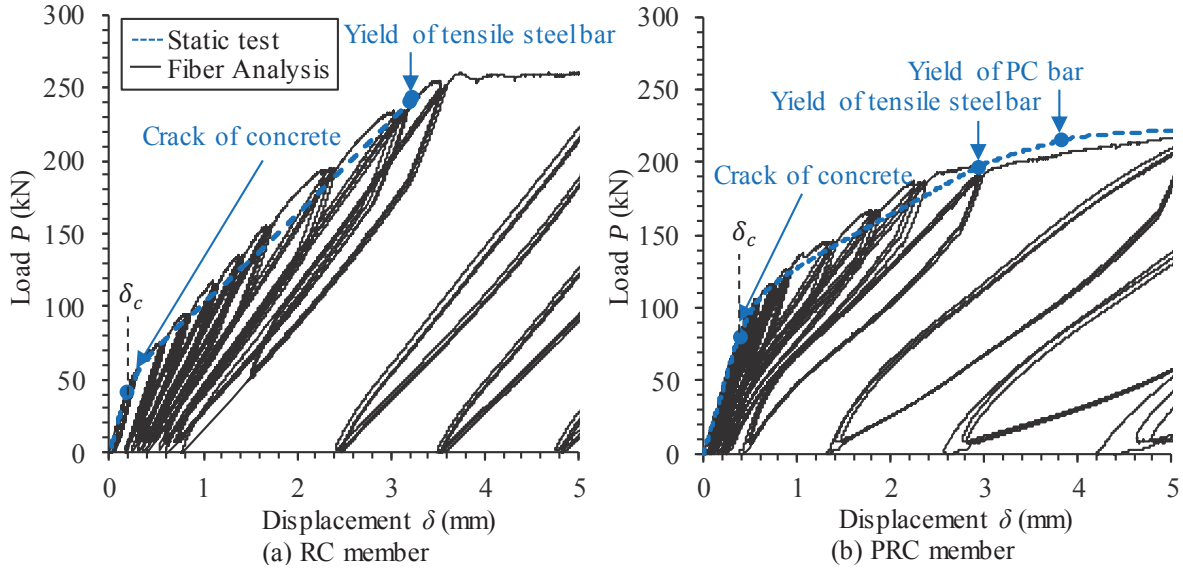

Figure 3: Load-displacement relationship obtained from static and dynamic loadings

2.4 Dynamic characteristics variation due to cyclic loading

Figures 4 shows the effective stiffness and equivalent damping of RC members obtained from the static and dynamic loading tests. Displacement of the horizontal axis was the maximum displacement experienced in the past at each loading step. On one hand, effective stiffness was the active stiffness connecting the maximum and minimum load points of the loop on the load–displacement relationship under cyclic loading. On the other hand, equivalent damping ratio was the equivalent viscous damping of the hysteresis damping calculated from the area of the same loop.

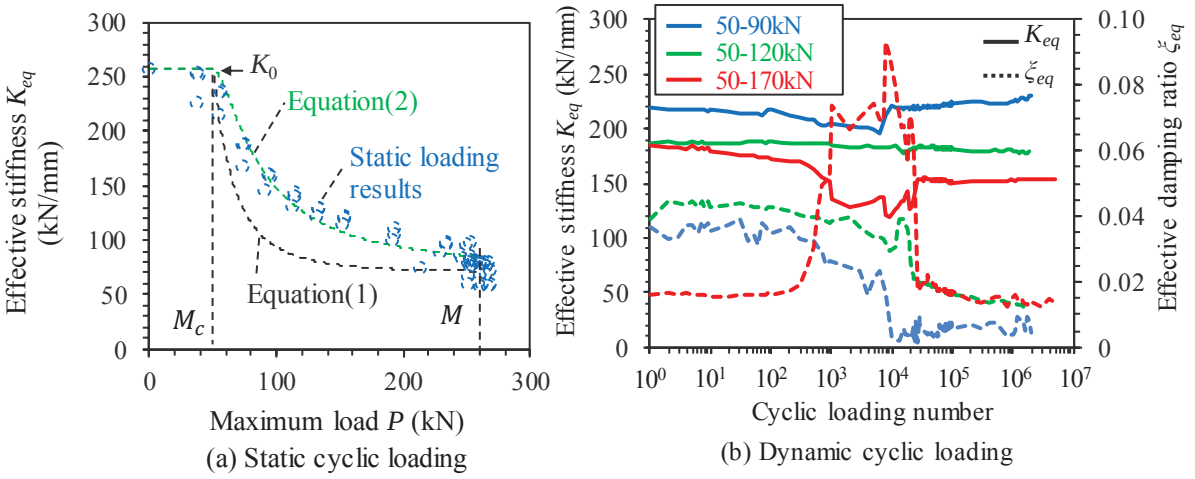

Figure 4: Effective stiffness and equivalent damping of RC members

The ACI 318-08 [7] technique is based on the method proposed by Branson [8, 9], which uses the effective stiffness K_e,

$$K_e = \left(\frac{M_{cr}}{M_{max}}\right)^3 K_0 + \left\{1 - \left(\frac{M_{cr}}{M_{max}}\right)^3\right\} K_{cr} \tag{1}$$

where K_0 is the gross sectional stiffness (uncracked concrete section); K_{cr} the sectional stiffness of the fully cracked section; M_{max} the applied maximum bending moment; M_{cr} the cracking moment. In practical designs, the secant stiffness is calculated by Eq. (1) (Railway Technical Research Institute 2004).

Wakui et al. (1996) proposed a method to predict the flexural stiffness at reloading by using the following equation.

$$K_{s,RC} = \left(\frac{M_{cr}}{M_{max}}\right)^{1.6} K_0 + \left\{1 - \left(\frac{M_{cr}}{M_{max}}\right)^{1.6}\right\} K_e \tag{2}$$

Hereafter, test results are compared with above two equations for the sake of conforming the applicability especially for PPC members under cyclic loading condition.

For the RC member, the static loading test results confirmed that the effective stiffness decreases with an increase of loading amplitude after δ_c. The obtained effective stiffness K_{eq} of the RC member was consistent with stiffness $K_{s,RC}$ during reloading by the static cyclic loading test.

Results of the fatigue test by dynamic loading indicated that the RC members achieved K_{eq} of approximately 220kN/mm to about 11% at 50–90kN and approximately 189kN/mm to nearly 6% at 50-120kN in 50–90kN. At 170-kN load, K_{eq} decreased from 184kN/mm to approximately 16%. Moreover, ξ_{eq} showed the tendency to increase with increasing load and to decrease with increasing number of repeated loads. Specifically, it decreased from 4.0% to 0.5% at 50–90kN and from 167kN/mm to within 4.5%–1.2% at 50–120kN. The change was small at nearly 1.5% at 50-170kN. K_{eq} exhibited a sharp decline of roughly 25% while ξ_{eq} increased rapidly from approximately 1.5% to 9% at repetitions of almost 500 to 20,000 times at 50–170kN. Crack width and residual displacement in this region increased simultaneously, indicating that there is a possibility of deterioration of aggregate mesh in the concrete at the cracked area. Nonetheless, the mesh was improved by repeated loading thereafter, where K_{eq}, ξ_{eq} must have settled to the value prior to 500 times of repeated loadings.

For the PPC member, the effective stiffness decreases with respect to increasing loading amplitude after δ_c. These results were consistent with the stiffness K_e obtained by using Branson's law, with overestimated $K_{s,RC}$.

Figures 5 shows the effective stiffness and equivalent damping of PPC members obtained from the static and dynamic loading tests. For the PPC members, results for the dynamic loading test indicated that K_{eq} decreased almost 10% from the initial stiffness 275kN/mm when the cyclic loading amplitude is 50-90kN loading. It decreased almost 33% from 240kN/mm when the loading amplitude is 50-120kN and almost 20% from 167kN /mm when the loading amplitude is 50-170kN. These results show the stiffness of PPC member significantly decreases when compared to RC members due to cyclic loading. ξ_{eq} exhibited a tendency to increase with respect to increasing loading amplitude and to decrease with increasing frequency of repeated loads. Particularly, it ranged within 0.5% and 1.5% when the cyclic loading amplitude is 50-90kN. It decreased from 1.5% to 0.5% when the amplitude is between 50 and 120kN and from 2.3% to 1.2% when the amplitude is between 50 and 120kN. Both RC and PPC members showed a tendency of stiffness reduction and damping reduction by the repeated loading, towards a greater or a lesser extent. Especially for PPC members, the dynamic response is expected to shift to the direction of increase due to repeated loading accompanying the train passing.

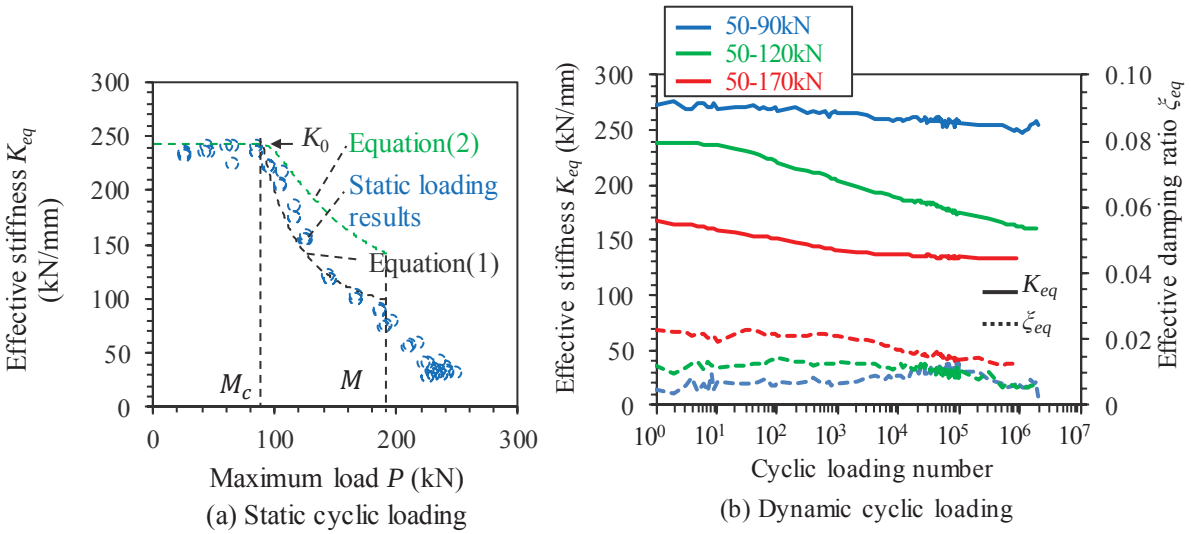

Figure 5: Effective stiffness and equivalent damping of PPC members

3 ANALYSIS

Previously mentioned experimental results were implemented into dynamic analysis expecting a number of train passage.

In the analyses, girders were modeled by elastic beam elements of which initial natural frequency was set to be $f = 50\sim80L_b^{-0.8}$. As shown in figure 6, the coefficient 50 implies that the girder frequency is approximately minimum stiffness defined in Eurocode. The initial damping ratio ξ was set to be 0.02. As shown in figure 7, the stiffness and modal damping ratio decrease with the number of the repeated loading cycle. Considering the test results, the stiffness was supposed to decreases 20% for RC members and 35% for PPC members at 1 million times cyclic loading. The damping ratio decreases from 2% to 1% at 1 million times cyclic loading for both members. The unit weight per length was set to be 200kN/m. Train load was modeled by moving concentrated load which suppose 12 cars and 300pph of running speed and 120kN of axial loads.

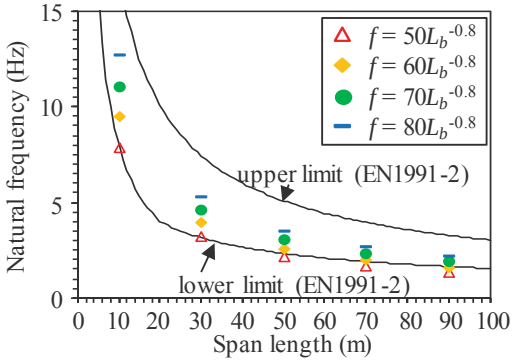

Figure 6: Initial natural frequency

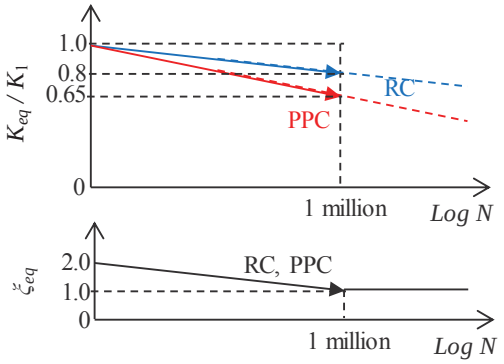

Figure 7: Dynamic characteristics deterioration

Figure 8 shows the displacement increase obtained by dynamic analyses. In the case of RC girder of which span is 10m, the displacement response grows with the cyclic number and exceeds the serviceability limit after 1 million cyclic loadings only when initial frequency is $50L_b^{-0.8}$. In the case of RC girder of which span is 30m, it doesn't exceed the serviceability limit even after 1 million cyclic loadings. In the case of PPC girders, the displacement increases more in the case of RC girders, and it tends to exceed the serviceability limit after 1 million cyclic loadings when initial frequency is $50L_b^{-0.8}$ and $60L_b^{-0.8}$. These results imply that excessive response can occur after millions of cyclic loading, especially in the case of PPC members, even if it were not observed in the initial stage of operations.

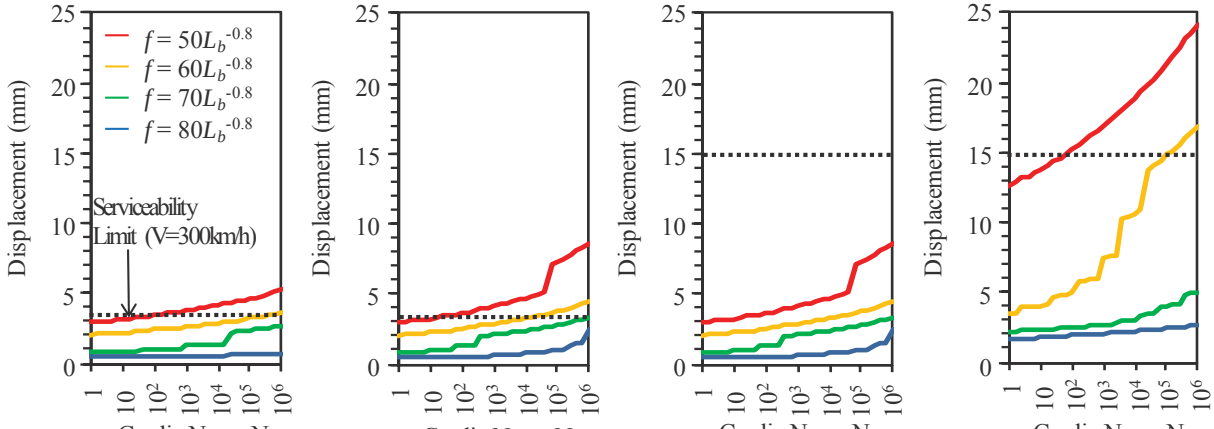

Figure 8. Displacement increase obtained by dynamic analyses

4 CONCLUSIONS

This study has evaluated the vibration characteristics of RC and PPC beam members under operational condition, based on fatigue tests. From these results, the following conclusions may be drawn:

- From static loading tests, it is found that the effective stiffness of RC members decreas-es with respect to increasing load, which is consistent with a previous evaluation formula. Nevertheless, the effective stiffness of the PPC members is overestimated relative to the same previous evaluation formula, which is consistent with Branson's cubic law.

- As a result of repeated dynamic loading, the effective stiffness decreases by approximately 6% to 16% for the RC members and 10% to 33% for the PPC members. Equivalent damping for the RC members is from 4.0% (relative to load size) and decreases to

around 0.5%, whereas for the PPC members it decreases from 1.5% to 0.5%. This means that repeated loading accompanying the train passing contributes to the shift to-wards increasing dynamic response, especially directing a large degree of influence on the PPC members.

- Dynamic analyses implementing the experimental results implied that excessive response can occur after millions of train passage, especially in the case of PPC members, even if it were not observed in the initial stage of operations.

Keywords: *Centrifuge experiment, Dynamic response, Dry Sand, Bending fracture, Maximum inertial force*

Abstract. *It is reported the pile foundations of many buildings were damaged by the 2016 Kumamoto Earthquake. The main shock of the massive earthquake measured magnitude 7.3. The city hall, built using an RC pile foundation was damaged, and inclined. Little is known about the fracture behavior of the soil-pile-superstructure interaction under a strong earthquake. This study investigated the fracture mode of RC pile foundations and the relationship between the pile fracture and the dynamic response of a superstructure and attempted to evaluate the ultimate lateral strength of a RC pile foundation.*

A shaking table test under a 50G centrifuge field was conducted to investigate the bending fracture behavior of RC pile members. A miniature RC pile model was proposed for the centrifuge experiment. The diameter of the pile model was 25 mm (prototype scale: 1.25 m) and consisted of mortar (17.1 MPa in compressive strength), 4 main reinforcements (1.2 mm in diameter), and a spiral hoop reinforcement (0.8 mm in diameter at intervals of 5 mm). The pile model demonstrated elasto-plastic behavior according to the element test without surrounding soil. It showed sufficient bending deformation capacity and the maximum strength exceeded the full plastic moment. The specimen for the centrifuge experiment was composed of dry soil, RC pile models, footing, and a superstructure. The footing was supported by four vertical pile models. The relative density of the dry soil (Toyoura dry sand) was 60%. The mass of the superstructure was 7.45kg (931ton in prototype scale), and the mass of the footing was 1.77kg (221ton in prototype scale). The natural period of the superstructure was 0.63 sec. This value corresponds to a 10-floor RC building. During the shaking table test, a total of 11 Rinkai waves, with different amplitudes, were input. A Rinkai wave is an artificial wave expected to form off the coast of Japan. The maximum acceleration of each shaking ranged between 0.41 m/s^2 to 7.06 m/s^2.

In the test result, bending fracture occurred at the pile head when the maximum input acceleration was 2.97 m/s^2. When the input acceleration was further increased, the inertial force acting on the superstructure also increased and exceeded the evaluated strength. Finally, at maximum inertial force of superstructure, the displacement of the footing further increased.

1 INTRODUCTION

In the 2016 Kumamoto Earthquake (the main shock of the earthquake was measured at magnitude 7.3), it was reported that several pile foundations of buildings were damaged [1]. Mashiki city hall, which had an RC pile foundation structure was damaged and inclined after the earthquake. Through damage investigation after the earthquake, it was found that some piles were severe damaged, and the city hall had to be rebuilt. The relationship between damage to the piles and the dynamic response of a superstructure under dry soil-RC pile-superstructure interaction is, the most part, unclear.

Few studies have investigated the facture behavior of RC pile foundations under soil-RC pile-superstructure interaction. Previous studies were conducted using a large shaking table test [2, 3], and a centrifuge model [4, 5]. Tamura et al., conducted shaking table tests using a large scale laminar shear box [2]. They revealed the dynamic behavior and failure mechanisms of small diameter RC pile models (diameter: 150mm) during soil liquefaction. Shibata et al., conducted a shaking table test of small diameter RC pile using E-Defense, which is largest shaking table in the world. The diameter of the RC pile model was 150mm, which was 1/10 of the full scale RC pile. It investigated the bending-induced damage mechanism and revealed the influence of axial load variation on the pile damage [3]. Even with the shaking table test under 1G field it is hard to reproduce the ultimate behavior of a large diameter RC pile. On the other hand, the centrifuge model test is available to reproduce the ultimate behavior of a large diameter RC pile. Kimura et al., conducted pushover loading and cyclic loading tests using small diameter RC pile models on dry sand under a centrifuge field [4]. According to the test result of the load-deformation relationship and observation of test specimen, the bending fractures had occurred at the RC pile models. Nevertheless, an evaluation method for ultimate strength hasn't been discussed. Higuchi et al., examined soil-large diameter RC pile interaction behavior until the main bar of the pile models yielded, using a dynamic centrifuge test [5]. However, there has not been any research on the strongly nonlinear behavior of soil-large diameter RC pile-superstructure interaction. Further, an evaluation of the ultimate lateral strength of RC pile foundation has not been undertake.

This study investigated the fracture mode of RC pile foundations and the relationship between the pile fracture and the dynamic response of a superstructure and attempted to evaluate the ultimate lateral strength of a RC pile foundation.

2 PILE MODEL FOR CENTRIFUGE TEST

2.1 RC pile model

The experiment was conducted under a 50G field using the centrifuge test system of the Disaster Prevention Research Institute at Kyoto University. An RC pile model (hereinafter called 'the pile model') that could reproduce elasto-plastic behavior was used to conduct the experiment. Figure 1 shows the details of the pile model. The pile model was designed to reproduce the elasto-plastic behaviour of concrete piles. It consisted of mortar, 4-main reinforcement bars (diameter: 1.2mm, yield strength: 374N/mm^2), and a spiral hoop reinforcement bar at intervals of 5mm (diameter: 0.8mm, yield strength: 432N/mm^2). The diameter of the pile model was 25mm (full scale: 1.25m). Table 1 shows a comparison of pile cross sections: the main reinforcement ratio and the hoop reinforcement ratio of the pile model almost correspond to the example cross section suggested by examples from foundation structures in Japan [6]

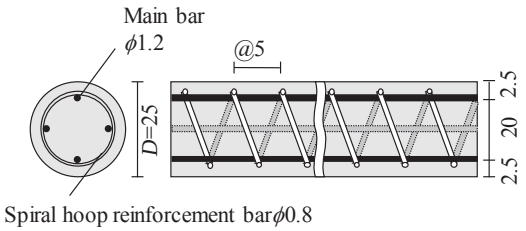

Figure. 1: Cross section of RC pile model (mm)

Table 1: Comparison of pile cross section

		Pile Model (Model scale)	Example cross-section (Real scale)
Diameter		25mm	1800mm
Main reinforcement bar	Rebar	4-ϕ1.2	45-D29
	Ratio	0.92%	1.13%
Hoop reinforcement bar	Rebar	ϕ0.8@5	D13@150
	Ratio	0.27%	0.26%

2.2 Static loading test

The static loading test was conducted to evaluate the performance of the pile model. Figure 2 shows the loading system of the test. The bottom of the pile model was rigidly jointed to a reaction force jig, and the top connected to a horizontal loading device by a pin jig and a vertical roller jig. The horizontal deformation was measured by a laser displacement transducer. The horizontal cyclic loading was input to 37.5mm (shear span ratio=1.5*D*, full scale: 1.875m) above the critical section, and the loading device was controlled according to rotation angles of 0.005, 0.01, 0.02, 0.04, 0.06, 0.08, 0.1, and 0.15 rad. The rotation angle of the pile model was calculated using the distance between the laser displacement transducer and the critical section (37.5mm). The compressive strength of the mortar of the pile model was 17.1 Mpa. The axial force for the pile model was 1,126N (full scale: 2.8MN). It was same value as the axial force for each pile model of the shaking table test, which is described later. The ultimate strength (loading capacity) of the pile model in this test is calculated as equation (1)

$$Q_u = \frac{M_u}{L} \tag{1}$$

where M_u is the full plastic moment of the pile model, and L is the shear span (37.5mm).

Figure 3 shows the relationship between load and rotation angle in full scale. The red line indicates the calculated ultimate strength (loading capacity, full scale: Q_u= 1.56MN). The RC pile model used in this study performed degradation behavior after reached ultimate strength. This behavior reproduced to a real RC member.

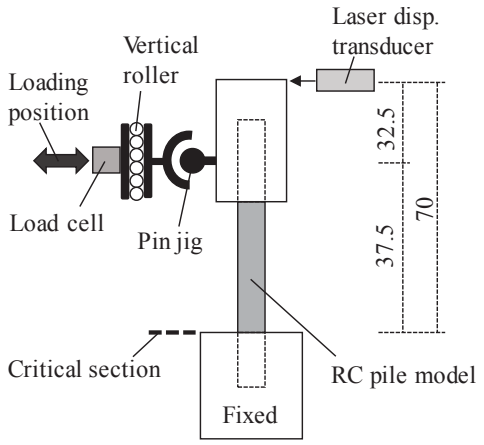

Figure 2: System of the test (mm)

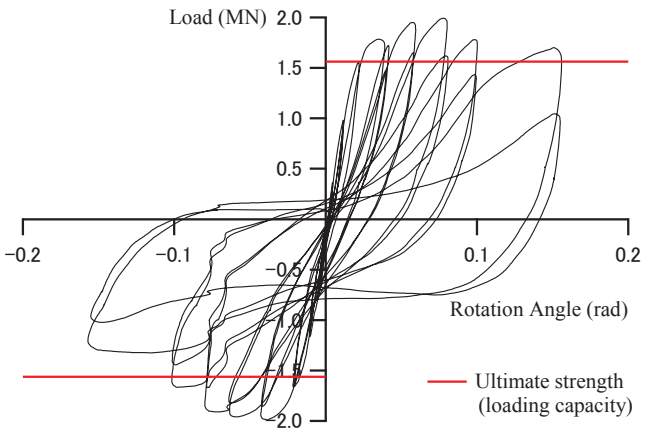

Figure 3: Test result

3 DYNAMIC CENTRIFUGAL MODEL TEST

3.1 Specimen

The shaking table test was conducted under a 50G field, the same as the static loading test in the previous section, using a centrifugal loading device at the Disaster Prevention Research Institute, Kyoto University. Figure 4 shows the specimen of the test and Table 2 shows its properties. The specimen was composed of dry soil, RC pile models, footing, and superstructure. The footing was supported by four 200 mm long piles with rigid connections at the pile head and bottom. The distance of the pile models was 150mm (full scale: 6*D*, 7.5m) in *X* direction, and 62.5mm (full scale: 2.5*D*, 3.13m) in *Y* direction. The mass of the footing was 1.77 kg while the mass of the superstructure was 7.42 kg. Therefore, the total mass was 4,503N (full scale: 11.3MN) and the axial force for each pile model was 1,126N (full scale: 2.8MN). This was roughly equivalent to the static loading test in the previous section. The primary natural period of the superstructure was 0.013 seconds (0.63 seconds in full scale). The primary natural period of the superstructure and the acting axial force of the pile were equivalent to a 10 story RC building (roughly a 35 m high building, with 5 to 6 m column spans). The soil consisted of Toyoura dry sand with a relative density of 60%

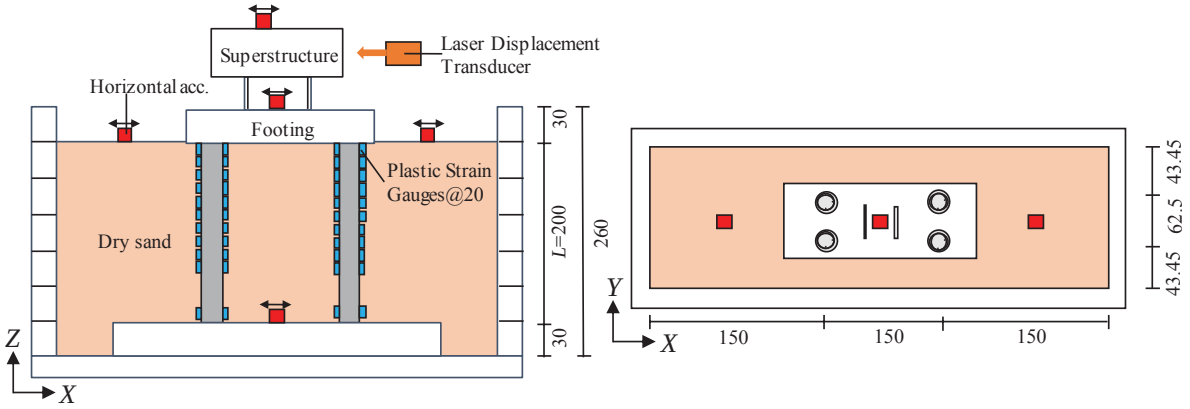

Figure 4 : Specimen of the shaking table test

Table 2: Properties of the spacimen

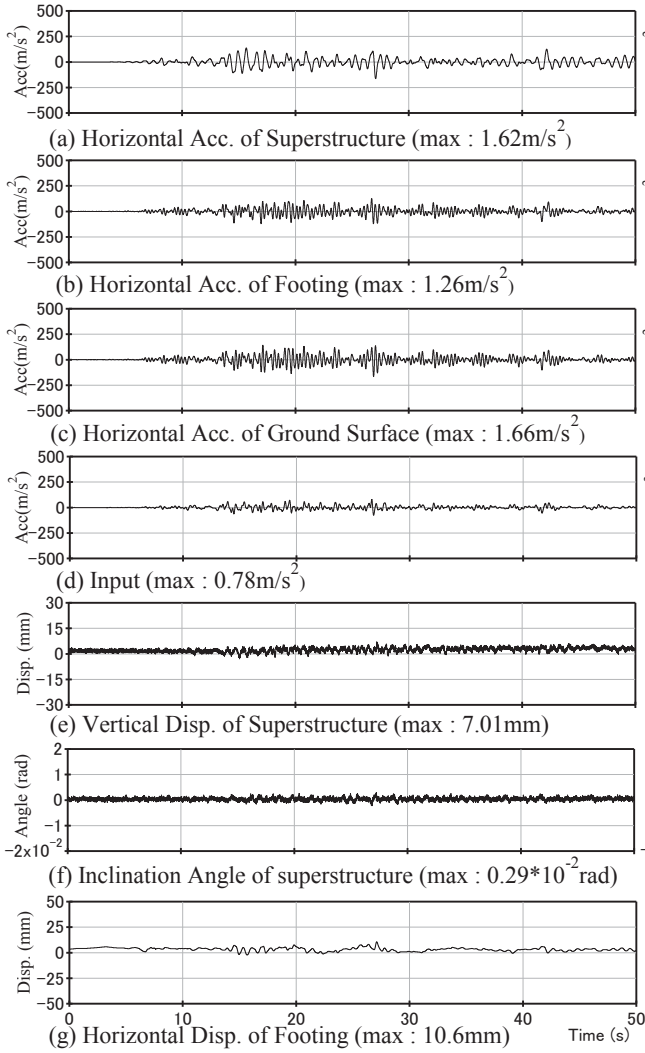
			Scaling Law	Unit	Full Scale	Model Scale
Piles	Length		1/λ	m	10	0.2
	Diameter		1/λ	mm	1250	25
	moment of inertia of area		$1/\lambda^4$	cm^4	1.29×10^7	2.08
	Yield stress of mortar		1	N/mm^2	17.1	17.1
	Main bar	Diameter	1/λ	mm	60	1.2
		Yield stress	1	N/mm^2	374	374
	Shear reinforcement bar	Diameter	1/λ	mm	40	0.8
		Pitch	1/λ	mm	250	5
		Yield stress	1	N/mm^2	432	432
Footing	Mass		$1/\lambda^3$	kg	221250	1.77
Superstructure	Mass		$1/\lambda^3$	kg	927500	7.42
Soil	Density		1	%	60	60

3.2 Shaking and measurement plan

The shaking was programmed to impose gradually progressive damage to the pile model using gradually increasing amplitudes of horizontal unidirectional input waves. A total of 11 Rinkai waves (JBDPA 1992) of different amplitudes were input. A Rinkai wave is an artificial wave expected to form off the coast of Japan. The maximum acceleration of each shaking ranged between 0.41 m/s^2 to 7.06 m/s^2 (from shaking 1 to 11). As showed in Figure 4, the accelerometers to measure the horizontal acceleration of the superstructure, footing, ground surface and bottom of the soil tank (input) were installed. Also, the horizontal displacement of the footing section was measured by laser displacement transducers. Plastic strain gauges were attached to the surface of the pile models to measure axial strain.

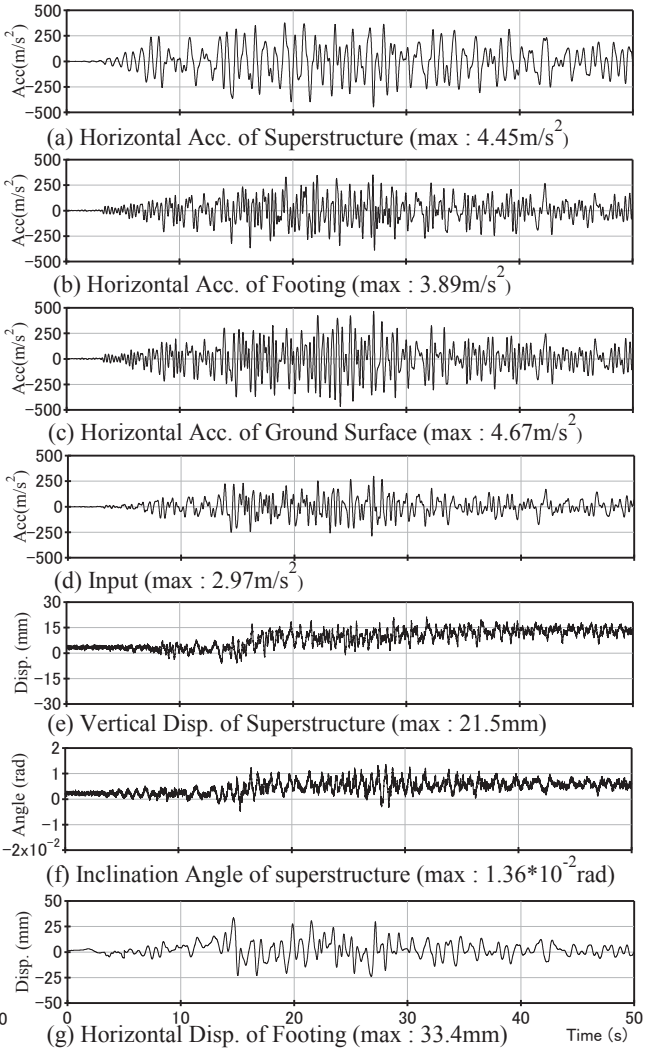
3.3 Test result

Figure 5-7 shows the main time history (0 to 50s) of the horizontal acceleration of the superstructure, footing, ground surface and input (bottom of the soil tank), vertical displacement and inclination angle of the superstructure, and horizontal displacement of the footing for shaking 2(elastic state), 4(plastic hinge occurred) and 11(final shaking) respectively. They are shown at full scale below. Figure 8 shows the damage to the pile model after the test.



(a) Horizontal Acc. of Superstructure (max : 1.62m/s^2)
(b) Horizontal Acc. of Footing (max : 1.26m/s^2)
(c) Horizontal Acc. of Ground Surface (max : 1.66m/s^2)
(d) Input (max : 0.78m/s^2)
(e) Vertical Disp. of Superstructure (max : 7.01mm)
(f) Inclination Angle of superstructure (max : 0.29*10^{-2}rad)
(g) Horizontal Disp. of Footing (max : 10.6mm)

Figure 5: The main time history of shaking 2



(a) Horizontal Acc. of Superstructure (max : 4.45m/s^2)
(b) Horizontal Acc. of Footing (max : 3.89m/s^2)
(c) Horizontal Acc. of Ground Surface (max : 4.67m/s^2)
(d) Input (max : 2.97m/s^2)
(e) Vertical Disp. of Superstructure (max : 21.5mm)
(f) Inclination Angle of superstructure (max : 1.36*10^{-2}rad)
(g) Horizontal Disp. of Footing (max : 33.4mm)

Figure 6: The main time history of shaking 4

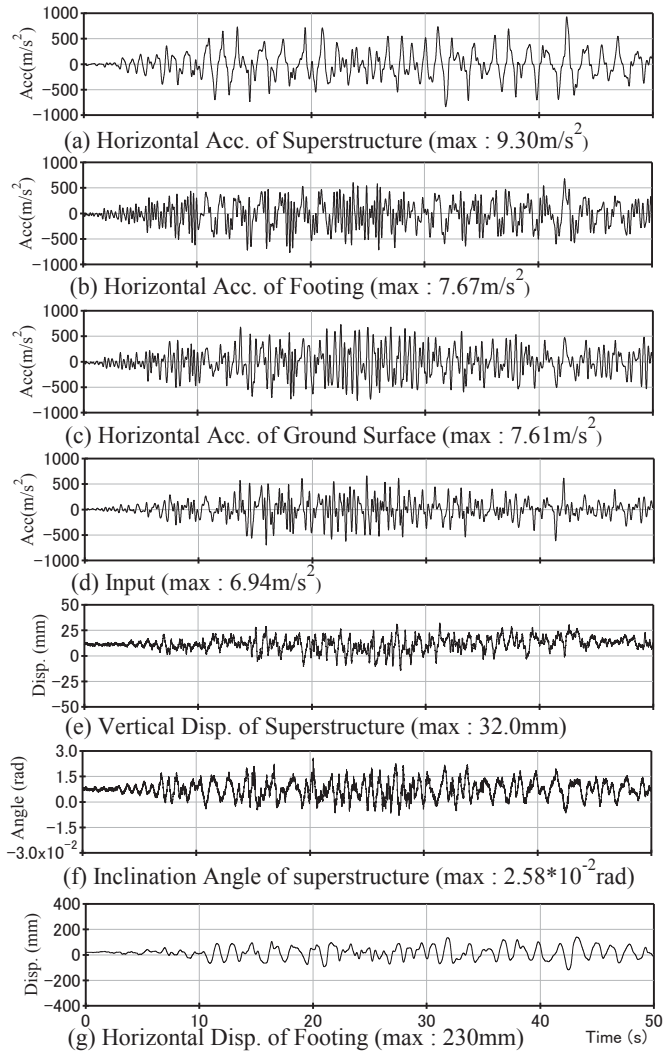


Figure 7: The main time history of shaking 11

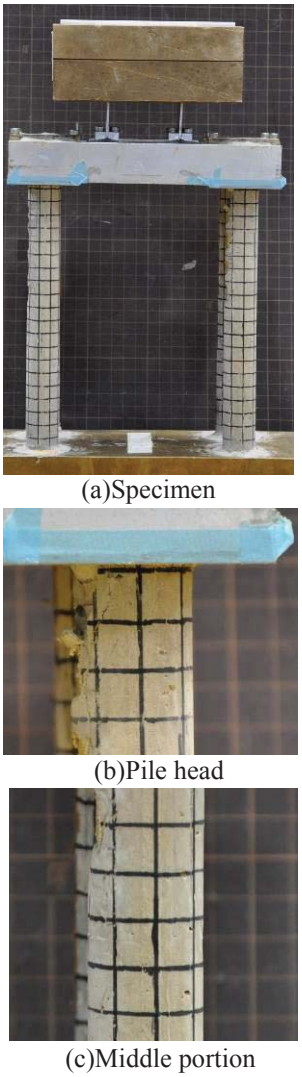

Figure 8: The damage of the pile model

In the test results, bending fracture occurred at the pile head. During shaking 2, the maximum response acceleration of the superstructure was 2.08 times larger than the input, and the maximum response acceleration of the footing was 1.62 times larger than the input. In contrast, during shaking 4, the maximum response acceleration of the superstructure was 1.50 times larger than the input, and the maximum response acceleration of the footing was 1.31 times larger than the input. This reduction of the response acceleration indicates that the bending fracture occurred at the pile head and formed a plastic hinge. During the final shaking (shaking 11), the damage of the pile model further progressed and the inclined angle of the superstructure also increased.

3.4 Relationship between relative displacement of the footing and inertial force

Figure 9 shows the relationship between the relative displacement of the footing to the bottom of the soil tank and the inertial force of superstructure and footing during shaking 2, 4, and 11. During shaking 2, the pile model kept a still elastic state according to the strain gauges. The blue dotted line indicates the initial stiffness based on the behavior during shaking 2. However, during shaking 4, the pile model performed elasto-plastic behavior because the plastic hinge occurred at the pile head and reached plastic state according. During shaking 11, maximum inertial force was 9.41MN. The relationship showed obvious nonlinear behavior. It indicates the pile model had reached ultimate condition.

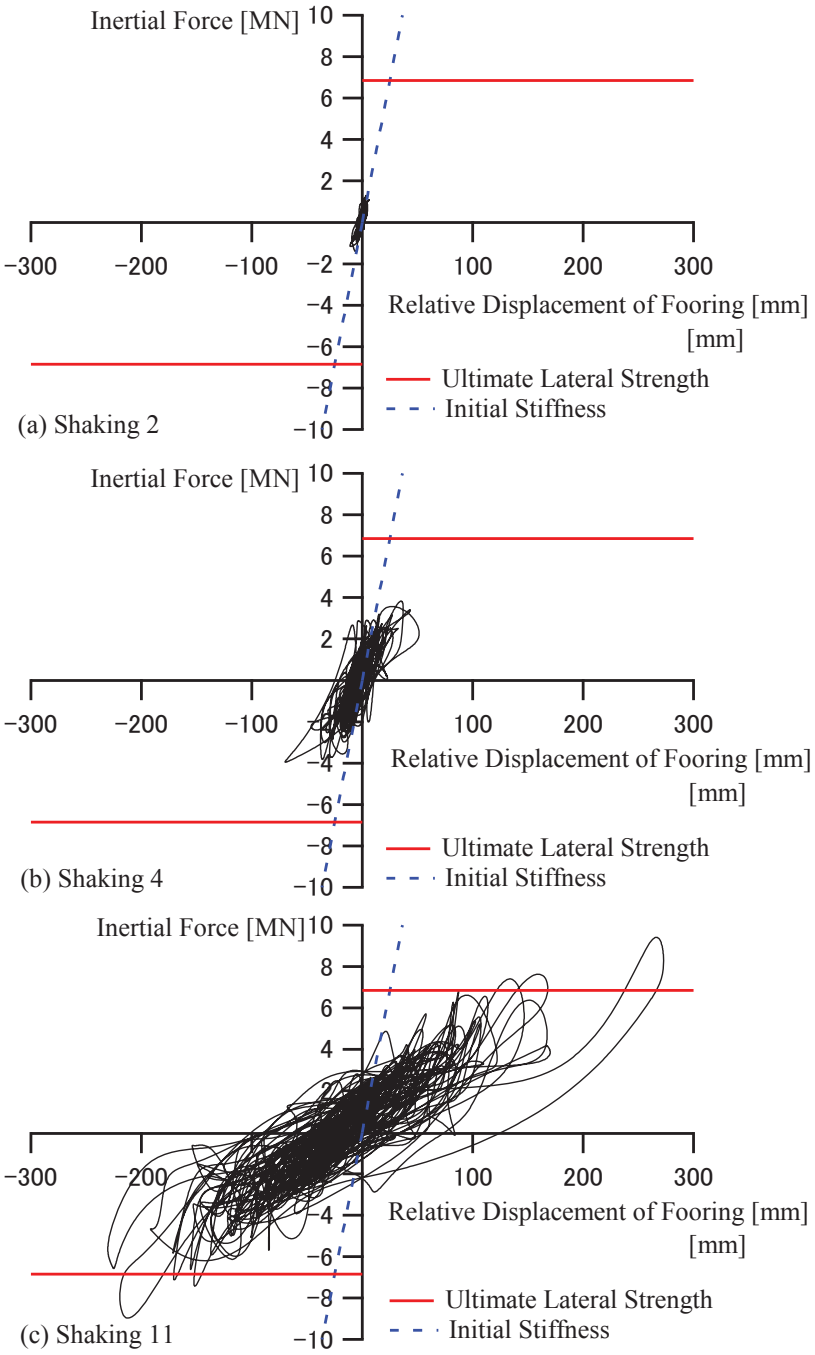

Figure 9: Relationship between the relative displacement of the footing and inertial force

4 ULTIMATE LATERAL STRENGTH OF AN RC PILE FOUNDATION IN THE CASE OF BENDING FRACTURE MODE

4.1 Evaluation method of an RC pile foundation

Broms proposed an equation to evaluate the ultimate lateral strength of a single pile [7]. The equation assumes that lateral reactions of soil are distributed in a triangle shape. The evaluation value of ultimate lateral strength Q is calculated as equation (2)

$$Q = 2.38\left(\frac{M_u}{K_p\gamma B^4}\right)^{\frac{2}{3}} K_p\gamma B^3 \tag{2}$$

where M_u is the full plastic moment of the pile, K_p is the coefficient of passive earth pressure, γ is the unit weight of soil, and B is the diameter of the pile.

4.2 Pile group effect

It is known that the strength of piles at the rear of a building is smaller than piles at the front if the pile foundation is affected by the pile group effect. In case of dry soil ground, the horizontal plastic ground reaction coefficient (pile group effect) κ is defined as less than 3. For a single pile, κ is determined as 3. Pile group effect κ is determined from equation (3) [8]

$$\kappa = \left\{ a\left(\frac{R}{B} - 1.0\right) + 0.4 \right\} \leq 3 \tag{3}$$

$$a = 0.55 - 0.007\phi$$

where R is the distance between front and rear piles.

Internal friction angle ϕ is calculated by equation (4) [9]

$$\phi = 32.5 - 20.6\frac{D_r - 40}{100} \tag{4}$$

where D_r is the relative density of the soil.

4.3 Comparison between the test result and evaluation value

In figure 9, the red line indicates the evaluated ultimate lateral strength. The strength of the front pile was calculated by equation (2). The strength of back side pile was determined by equation (2) and multiplied by pile group effect κ. The strength of the back pile was calculated by equation (5). The evaluated value was 6.85MN and maximum inertial force in the test result was 9.41MN. Therefore, the value was 72.8% of the test result. The value was estimated on the safe side.

$$Q_{back} = 2.38\left(\frac{M_u}{K_p\gamma B^4}\right)^{\frac{2}{3}} K_p\gamma B^3 \times \frac{\kappa}{3} \tag{5}$$

5 CONCLUSIONS

This paper conducted a dynamic centrifuge model test of the dry soil-RC pile-superstructure interaction. In addition, the author tried to evaluate the ultimate lateral strength of an RC pile foundation with surrounding ground. The following results were obtained.

1) An RC pile model was proposed for this study. According to the result of the static loading test, the pile model strength reached full plastic moment and then performed degradation behavior. This behavior reproduced to a real RC pile member.
2) A dynamic centrifuge model test of dry soil- RC pile-superstructure interaction was conducted. Bending failure (plastic hinge) occurred at the head of the pile models. This plastic hinge caused the reduction of response acceleration.
3) The ultimate lateral strength of an RC pile foundation was evaluated. The estimated value was smaller than the test result, and evaluated on the safe side.

6 ACKNOWLEDGEMENTS

This work is partially supported by a Kurata Grant awarded by the Hitachi Global Foundation. The authors are grateful to Associate Professor Shuji Tamura of Tokyo Institute of Technology for their valuable assistance throughout the centrifugal tests.

Abstract. *In this work, a series of seismic analyses of one-storey, one-span reinforced concrete (R/C) asymmetrical building frames under 2-D and 3-D conditions is performed and the effect of deformable soil on the seismic response of the structure is determined and discussed. A comparison is performed between the elastic behavior of R/C sections according to the building codes' provisions to possible inelastic behavior resulting in the analyses. The time history analyses aim at clarifying the role of SSI in the seismic behavior of simple R/C structures while investigating the possible elastic or elastoplastic behavior of critical sections with the aid of a realistic damage index. The conclusions drawn from these linear and nonlinear time history analyses provide helpful guidelines for the safer seismic design of structures.*

1 INTRODUCTION

According to current design codes [1], consideration of dynamic Soil-Structure Interaction (SSI) is usually required only for the design of special structures, structures supported on very soft soils, and structures on special foundations. Seismic codes usually neglect SSI for the design of common building structures since it is assumed that SSI results in decreased internal forces of the structural elements. However, recent research has shown that the deformability of the supporting soil may have a strong impact on the seismic response of common, low-rise reinforced concrete (R/C) buildings [2-3] as well as of special structures [4]. The present paper aims at presenting preliminary results of an ongoing investigation on the role of SSI on the seismic response of ordinary, low-rise symmetric and asymmetric one-storey R/C building frames. Both two dimensional (2-D) and three dimensional (3-D) buildings are considered.

2 DESCRIPTION OF CASE STUDIES AND ANALYSIS

In this work, simple 2-D and 3-D, one-span and one-storey R/C building frames are examined, as shown in Fig.1. The 2-D R/C one-storey frames have one span of 6.0 m and height 3.0 m, consisting of two vertical elements connected with a horizontal beam (Fig. 1.a). The cross-section of one column is constant at $0.40*0.40m^2$, while the cross-section of the other column increases in successive steps from $0.40x0.40m^2$ to $0.30x2.00m^2$, where the greater dimension of the later lies in the plane of the frame and is referred herein as "wall". In this way, a simple geometrical asymmetry of the frame is introduced. The horizontal R/C beam has a constant cross-section of $0.25x0.50m^2$.

Similarly, the 3-D one-storey R/C building frames consist of one slab 5.0m x 4.0m, supported by perimetric beams and 4 columns at the corners (Fig. 1.b). The height of the frame is 4.0m. The cross-section of the three columns, i.e. C1, C3 and C4 (Fig. 1.b) remains constant at $0.40x0.40m^2$, while the cross-section of one column, i.e. C2, increases in successive steps from $0.40x0.40m^2$ to $0.30x2.00m^2$ and is referred herein as wall. The cross-section of the horizontal beams remains constant at $0.25x0.60m^2$. The slab is 0.15m thick and considered to act as a rigid diaphragm.

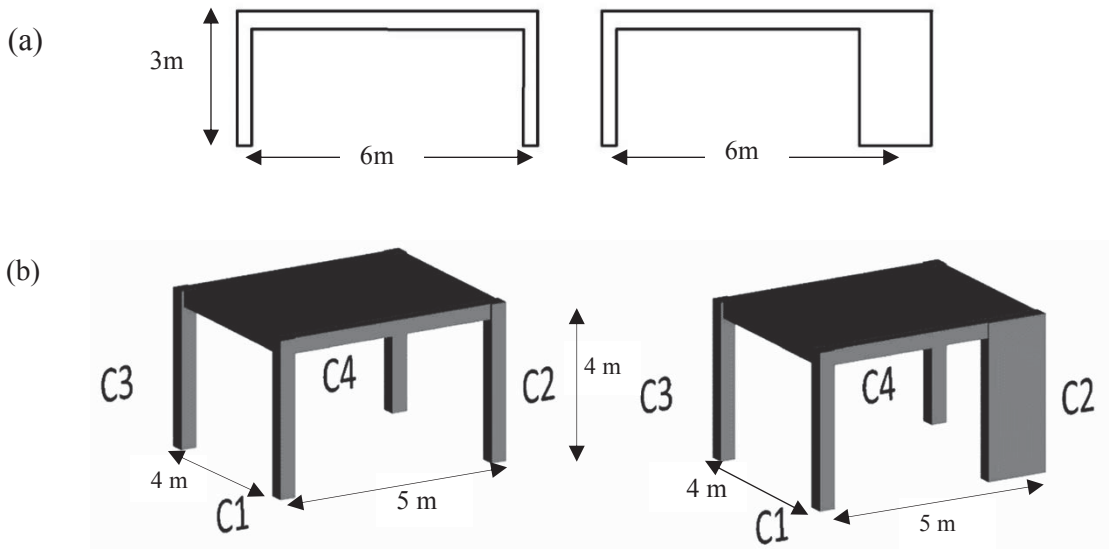

Figure 1: 2-D and 3-D symmetrical and asymmetrical frames under study.

In all 2-D and 3-D frames, the material is concrete C20/25 with steel reinforcement B500c. On the 2-D building frames, a uniformly distributed load of 34 kN/m is applied on the horizontal beam, approximately incorporating the entire dead and live load for typical structures with domestic/residential and office use [5]. For the 3-D building frames, a dead load of 12.24 kN/m acts directly on the beams, simulating the weight of a perimeter wall, while the load on the floor consists of 2.0 kN/m^2 dead load and 0.6 kN/m^2 live load [5].

The 2-D and 3-D building frames are dimensioned according to the current codes [1, 6] for medium ductility class using the typical fixed base assumption (Fig. 2.a,c). The dimensioning assumptions are zone ground acceleration a_g=0.36g, spectrum type I, importance factor γ_I=1.00, viscous damping ratio ξ=5%, and soil type C [1]. For all 2-D frames, the behavior factor is considered as q=3.30, while for the 3-D frames the behavior factor is considered according to the current codes [1]. Capacity design of R/C 2-D and 3-D frames is performed.

The foundation of the 2-D and 3-D frames consists of footings connected to each other with R/C beams (Fig. 2.a-d), all dimensioned according to the current codes [1, 6]. In addition to the above, for the 3-D frames only, a mat foundation is considered (Fig. 2.e), dimensioned according to the current codes [1, 6].

The effect of SSI is considered through discrete elements of a simple spring-dashpot-mass system, as shown in Fig. 2.b,d. The values of the parameters of the spring-dashpot-mass system are calculated according to Gazetas [7]. For the purposes of this study, the soil properties are Poisson ratio ν_s=0.4, soil density ρ_s=1750 kgr/m^3, modulus of elasticity E_s=150MPa, and shear velocity V_s= 175 m/sec, corresponding to a medium clay.

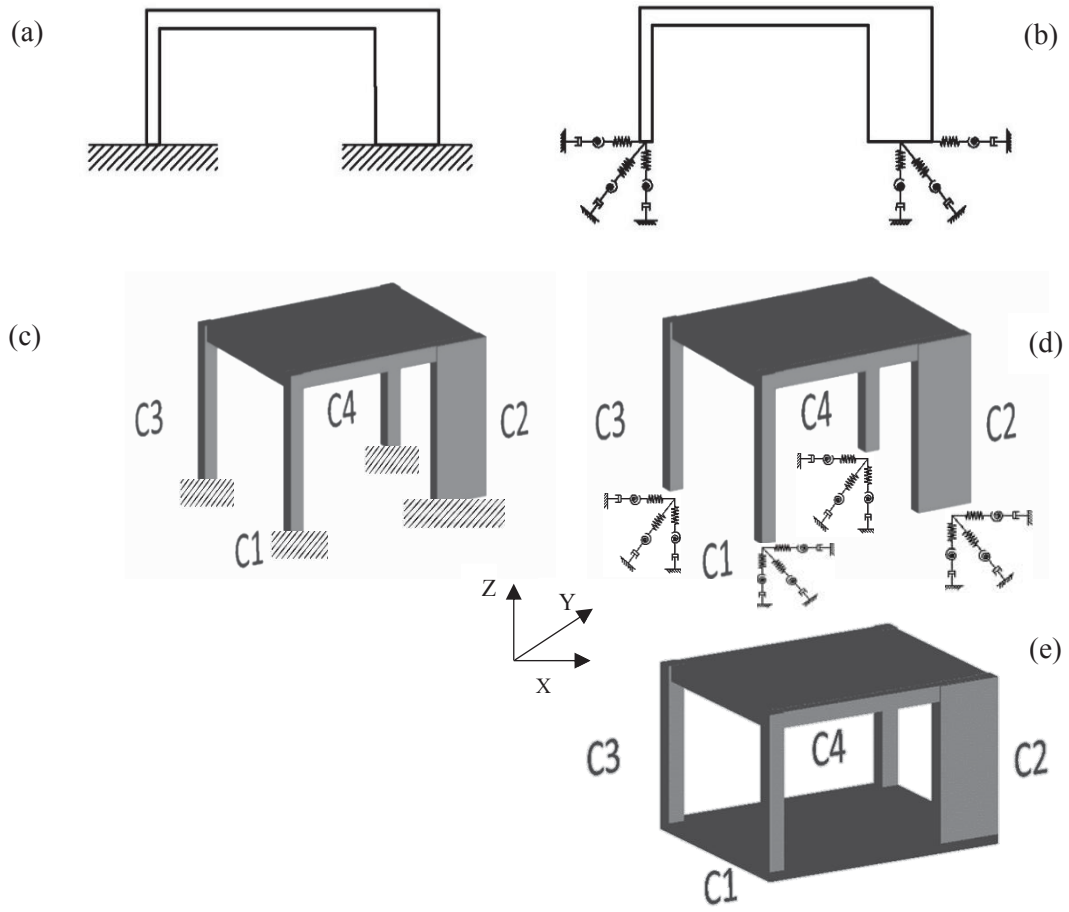

Figure 2: 2-D (a, b) and 3-D (c, d, e) frames on rigid soil (a, c) and deformable soil (b, d, e).

The 2-D building frames are analyzed by the ETABS software [8] using an artificial accelerogram compatible to the design spectrum of Eurocode 8 [1] based on the earthquake of Argostoli (Kefalonia, Greece) of 2014 [9] and constructed by ETABS [8]. A stiffness reduction of R/C elements is performed according to the current codes [1,6] while they are considered to maintain elastic behavior. Elastoplastic analyses are performed in the time domain using the fiber model of Sfakianakis and Fardis [10] and Sfakianakis [11]. According to this elastoplastic model of R/C sections, point hinges at both ends of all R/C elements are applied including all material and section properties of interest, i.e. dimensions, reinforcement, reduced stiffness, elastoplastic mechanical properties, deformation, curvature limits, etc. Possible shear failure of R/C elements is checked according to the Greek Interventions Regulation "KANEPE" [12]. The elastic and elastoplastic time-history analyses are performed by ETABS [8], first assuming a rigid base and then SSI.

Similarly, the 3-D building frames are studied using elastic and elastoplastic analyses and the earthquake of Vasiliki (Lefkada, Greece) of 2015 [9]. The numerical investigation of the structural response is affected by the incidence angle of the horizontal seismic input [2,13]. The effect of the incidence angle of the seismic motion is investigated here by analyzing the 3-D buildings for incidence angles $\varphi=0°$ and $\varphi=90°$, which are along the two primary geometrical axes, and $\varphi=45°$, which is close to the direction of the diagonal axis.

For the elastoplastic behavior of R/C elements the following response parameters/procedures are used:

1. The maximum interstorey drift ratio (IDR) is calculated for each dynamic analysis and compared with the limits of the performance levels for R/C framed structures according to FEMA 356 [14]. At the performance level IO - Immediate Occupancy, corresponding to the performance level DL - Damage Limitation of EC8 [1], the limit of IDR is 1%. At the performance level LS - Life Safety, corresponding to the performance level SD – Severe Damage [1], the limit of IDR is 2%. At the performance level CP - Collapse Prevention, corresponding to the performance level NC-Near Collapse [1], the limit of IDR is 4%.
2. A simple damage index is employed to evaluate the elastoplastic behavior of R/C elements and frames. For each elastoplastic analysis, the final deformations/curvatures and the maximum internal forces/moments of each point hinge are checked, and each vertical member is classified according to the limits of performance levels [1]. In the Greek Interventions Regulation "KANEPE" [12] values of damage indices r_R for damaged R/C elements without repair or retrofit are provided. A correspondence between the performance levels of [1] and r_R of [12] is noticed as shown in Table 1. The values of the index r_R vary in the range of 0~1, where 0 indicates collapse and 1 refers to elastic behavior [12]. If different states of performance levels are indicated at the ends of an R/C element, the element is ranked using the lower of the two indices.

Performance level [1]	Description of Performance Level	Damage index, r_R [12]
A≤DL	Elastic behavior – Operational	1.00
A≤DL	Damage Limitation - light damages	0.90
DL≤SD	Severe Damage - significant structural damages, retaining full vertical load-bearing capacity	0.80
SD≤NC	Near Collapse – heavy damages at the verge of collapse	0.50
>NC	Collapse- total element loss	0

Table 1: Correlation of Damage Index [12] and Performance Levels [1].

The damage index estimation is extended for the whole one-storey frame, as quantified by the overall structural damage index r_g, expressed as [15]

$$r_g = \frac{\sum_{i=1}^{n}(V_{Rd,c,i} \cdot r_{R,i})}{\sum_{i=1}^{n} V_{Rd,c,i}} \quad (1)$$

where n is the number of vertical structural elements, r_R is the element damage index (Table 1), and $V_{Rd,c}$ is the design shear resistance of the R/C member without shear reinforcement [6].

The estimation of the loading capacity of the frame, considering structural asymmetry, can be expressed by the general modified damage index r_f as [15]

$$r_f = \frac{r_g \cdot K_R}{\gamma_I} \quad (2)$$

where K_R is a factor expressing the geometric symmetry/normality of the structure with values ranging from 1.0, for normal/symmetric structures to 0.8 for asymmetric ones, and γ_I is the importance factor [1, 15]. The range of values of r_f is 0~1, where 0 indicates "collapse" and 1 elastic behavior. This damage index procedure presents the advantages of simplicity, calculation speed, and the ability to roughly characterize a whole R/C frame.

3 RESULTS OF SEISMIC RESPONSE

3.1. 2-D building frames

In this section, the numerical results of the 2-D frame analyses are shown and discussed. The following parameters are examined and presented in the plots.

- *I(wall)/I(col)* is the ratio of the moment of inertia of the wall to the column. The ratio *A(wall)/A(col),* which involves the cross-sections, is defined similarly.
- *M(s)/M* is the ratio of the maximum absolute value of the internal bending moment of a vertical element when SSI is considered to the corresponding value, at the same location, considering rigid soil. This ratio is considered at the lower end ("bot") and the upper end ("up") of the vertical element. The ratio of the internal shear forces *V(s)/V* is defined similarly.
- Interstorey drift ratio (IDR) with the notation "r.s." for rigid soil, or "ssi" for SSI consideration.
- r_R is the damage index of each vertical element and r_f is the frame damage index.

The internal axial forces of R/C elements are not examined here because of their high compressive strength. The internal force diagrams refer only to internal forces of vertical elements, which are considered as the main structural elements undertaking the seismic action.

As shown in Figs. 3-4, the elastic M(s)/M, at the top and base section of C1, as well as the elastic V(s)/V of C1, increases along with the increase of the wall section. The elastic M(s)/M at the top and base and the elastic V(s)/V of the wall, C2, decrease along with the increase of its cross-section (Figs. 3-4). The column is burdened due to SSI, while the wall benefits from SSI.

As shown in Fig. 5, the elastoplastic M(s)/M of C1 increases at its base up to 1.18 for I(wall)/I(col)=22.89 and decreases for greater wall sections to 0.99, while at its top section increases up to 1.95 for I(wall)/I(col)≈52 and decreases for greater wall sections to 1.05. The elastoplastic M(s)/M of the wall base increases up to 1.14 for I(wall)/I(col)=22.89 and decreases almost linearly to 0.29 for I(wall)/I(col)=93.75 (Fig. 5). The elastoplastic M(s)/M of the wall top section increases rapidly up to 2.24 for I(wall)/I(col)=11.72 and for greater wall sections decreases to 0.53 for I(wall)/I(col)=93.75 (Fig. 5).

As shown in Fig. 6, the elastoplastic V(s)/V of C1 increases up to 1.39 for A(wall)/A(col)=2.81 and decreases to 1.02 for A(wall)/A(col)=3.75. The elastoplastic V(s)/V of C2 is almost stable around the value 1.07~1.09 for A(wall)/A(col)≤2.81 and decreases for larger wall sections to 0.33 for A(wall)/A(col)=3.75 (Fig. 6).

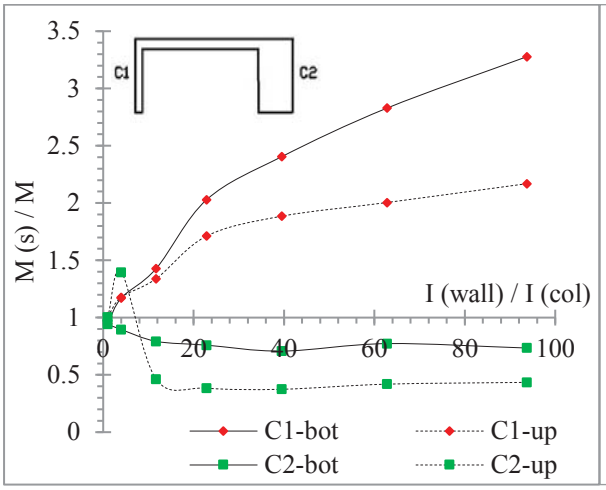

Figure 3: Elastic M(s)/M versus I(wall)/I(col).

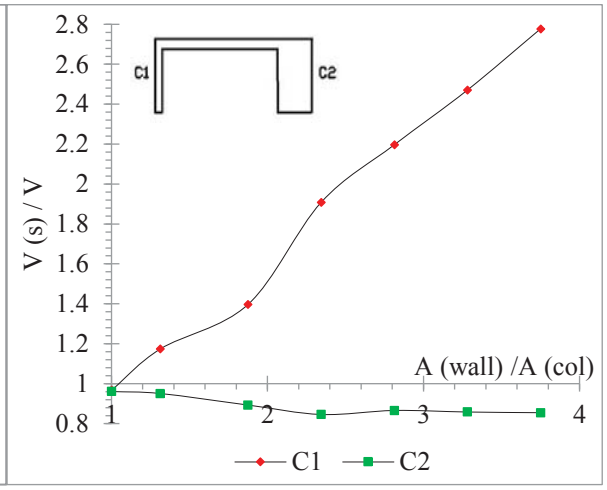

Figure 4: Elastic V(s)/V versus A(wall)/A(col).

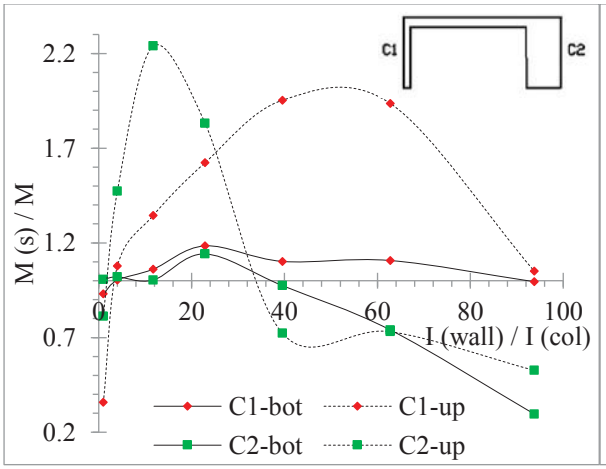

Figure 5: Elastoplastic M(s)/M versus I(wall)/I(col).

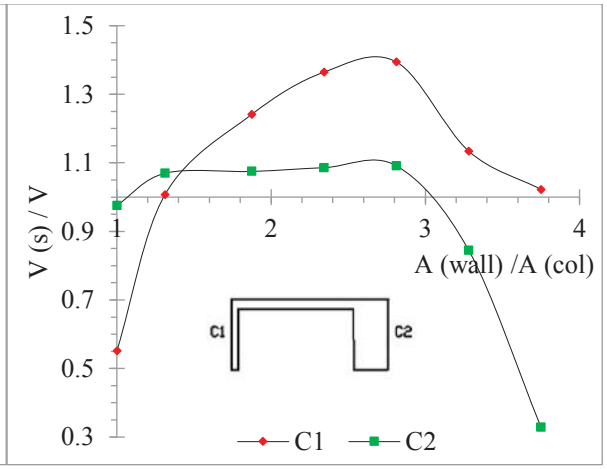

Figure 6: Elastoplastic V(s)/V versus A(wall)/A(col).

As shown in Fig. 7, the elastic IDR for both rigid soil and SSI decreases along with the increase of the wall section. Both remain below the limit of 1% [14], while the elastic IDR with SSI is greater than the respective for rigid soil. As shown in Fig. 8, the elastoplastic IDR for SSI is greater than the IDR for rigid soil for almost all wall sections. The elastoplastic IDR for rigid soil remains within the limit of 2% [14] (Fig. 8). The elastoplastic IDR for SSI remains almost below the limit of 2% [14] for all sections except for A(wall)/A(col)=2.81, where it exceeds slightly 2% while staying constantly within 4% [14] (Fig. 8).

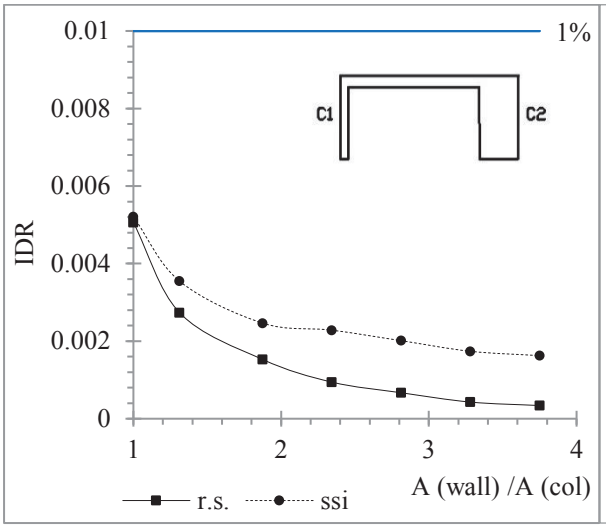

Figure 7: Elastic IDR versus A(wall)/A(col).

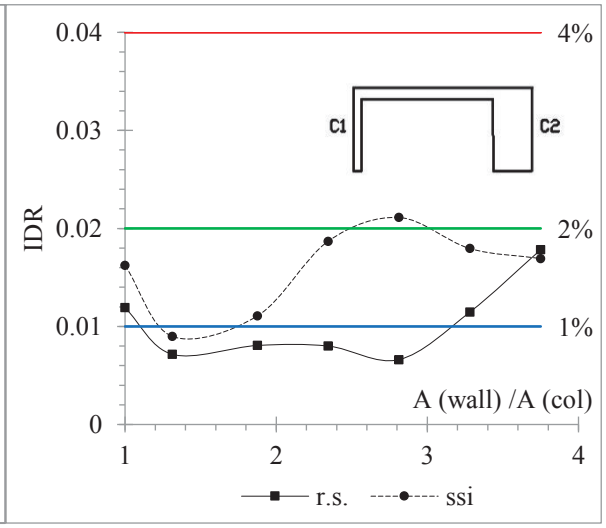

Figure 8: Elastoplastic IDR versus A(wall)/A(col).

As shown in Fig. 9, the r_R of C1 and C2 fluctuates for SSI and for rigid soil in the range of overlapping values 0~1 for both boundary conditions. As shown in Fig. 10, the frame damage index has smaller values for SSI than for rigid soil for A(wall)/A(col):1.31~2.81, indicating more damage is expected for SSI at this range of wall sections.

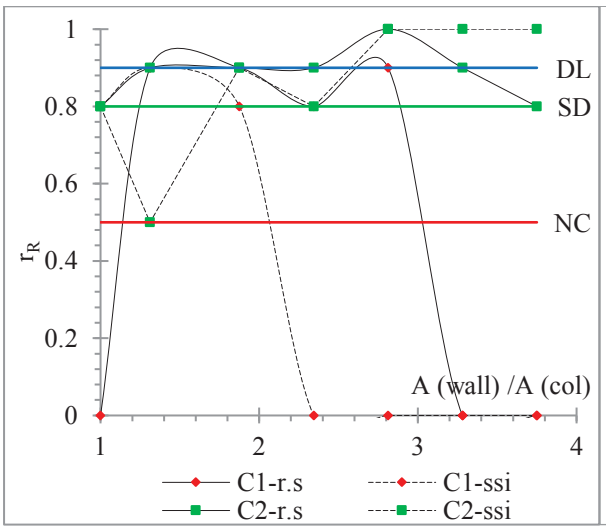

Figure 9: r_R versus A(wall)/A(col).

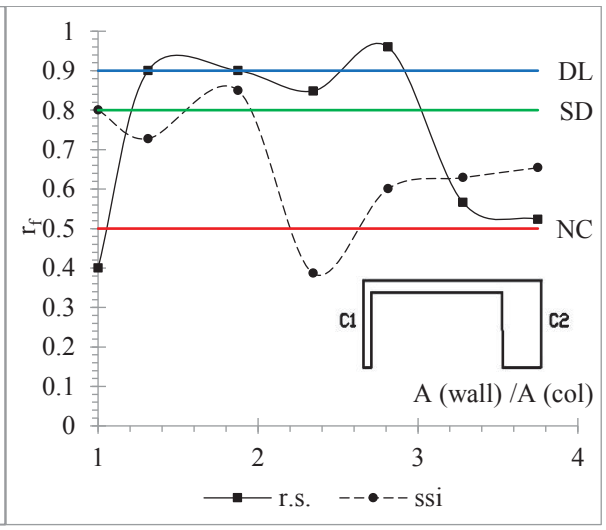

Figure 10: r_f versus A(wall)/A(col).

3.2. 3-D building frames – numerical results and discussion

Similarly to the analysis of plane frames, the following parameters are examined and presented in the plots regarding 3-D, 1-storey R/C building frames.

- *M(s)/M* is the ratio of the maximum absolute value of the internal bending moment of when SSI via footings with connecting beams is considered, at the lower end ("bot") and the upper end ("up") of the vertical element. *M(m)/M* is a similar ratio when SSI via foundation mat is considered. These ratios are examined at both internal transverse axes of R/C vertical elements. Here, due to lack of space, only the plots regarding the major internal moment ratio (*M3*) defined for the transverse axis of R/C vertical elements, coinciding here to the Y-axis, are shown.

- *V(s)/V* is the ratio of the shear forces defined similarly when SSI via footings with connecting beams is considered. *V(m)/V* is the respective ratio when SSI via foundation mat is considered. There are presented here only the plots of major shear force ratio (*V2*) defined for the transverse axis of R/C vertical elements, coinciding here to the X-axis.
- *IDR* with the notations "r.s." for rigid soil, or "s" for SSI via footings with beams, or "m" for SSI via foundation mat, on both horizontal global axes, X and Y.
- r_R is the damage index of each vertical R/C element and r_f is the frame/storey damage index.

As shown in Fig. 11, considering footings for the incidence angle φ=90°, the elastic M3(s)/M3 of the top and base section of C1 increases along with the increase of the wall section, up to 2.73~3.01 for I(wall)/I(col)=93.75, while remains close to 1 for the top and base sections of C3 and C4 and decreases to 0.86 for the base section of the wall and 0.39 for the top section of the wall for I(wall)/I(col)=93.75. Considering foundation mat for φ=0° (Fig. 12), a similar form of the plot is obvious with greater values on average, such as that the elastic M3(m)/M increases close to 2.09 for C3 and C4, at their top and base sections, close to 1 for the base section of the wall, up to 12.51 for the top section of the wall and up to 8.53 for the top section of C1 and 15.36 for the base section of C1 for I(wall)/I(col)=93.75.

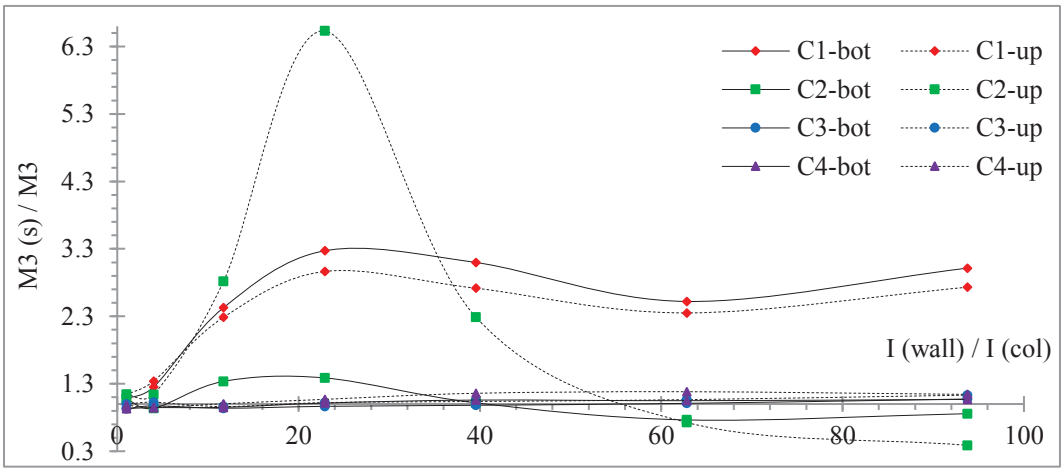

Figure 11: Elastic M3(s)/M3 versus I(wall)/I(col) for footings and φ=90°.

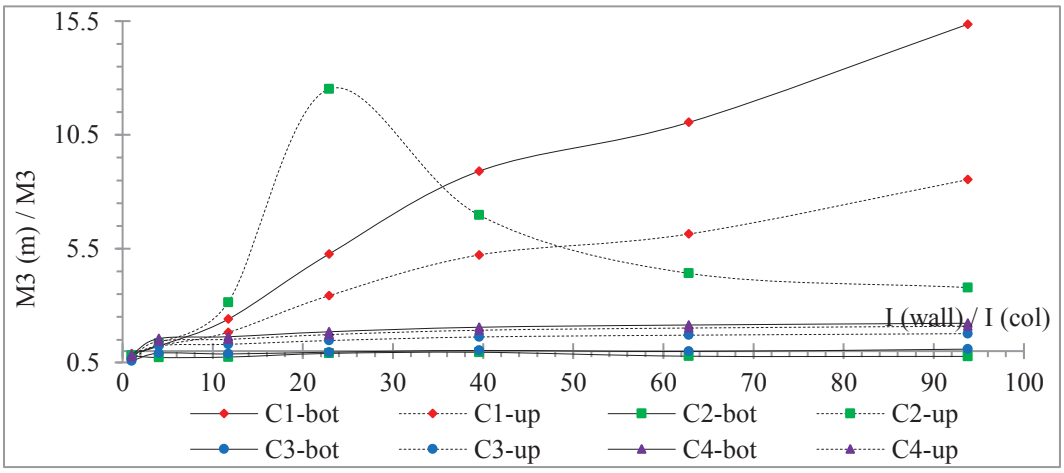

Figure 12: Elastic M3(m)/M3 versus I(wall)/I(col) for foundation mat and φ=0°.

As shown in Fig. 13, comparing foundation mat to rigid soil for φ=45º, the elastoplastic M3(m)/M of C3 and C4, at their top and bottom sections, increases slightly along with the increase of the wall section up to 1.13~1.27 for I(wall)/I(col)=93.75, while for the top and bottom sections of C1 increases intensely up to 2.12~2.20. The elastoplastic M3(m)/M3 of the top section of C2 increases intensely along with the increase of the wall section up to 3.44 for I(wall)/I(col)=93.75, while for the relevant bottom section has almost steady decreased values around 0.63~0.71 (Fig. 13).

As shown in Fig. 14, comparing footings to rigid soil for φ=90°, a similar form of the plot of elastoplastic M3(s)/M3 is observed to the previous paragraph (Fig. 13) with smaller general values. The elastoplastic M3(s)/M3 of C1, C3, and C4, at their top and base sections, varies with overlapping values tending to decrease along with the increase of the wall section in the range of 0.9~1.29 (Fig. 14). The elastoplastic M3(s)/M3 of the top section of the wall varies tending to increase up to 1.33 for I(wall)/I(col)=39.55 and decreases for greater wall sections close to 1 for I(wall)/I(col)=93.75 (Fig. 14). Respectively, the elastoplastic M3(s)/M3 of the base sections of C2 and C3 varies tending to decrease to 0.77 for I(wall)/I(col)=62.81 and increases to 1 for I(wall)/I(col)=93.75 (Fig. 14). The top sections of all vertical elements tend to show greater values of the elastoplastic M3(s)/M3 than the respective bottom sections (Figs. 13-14).

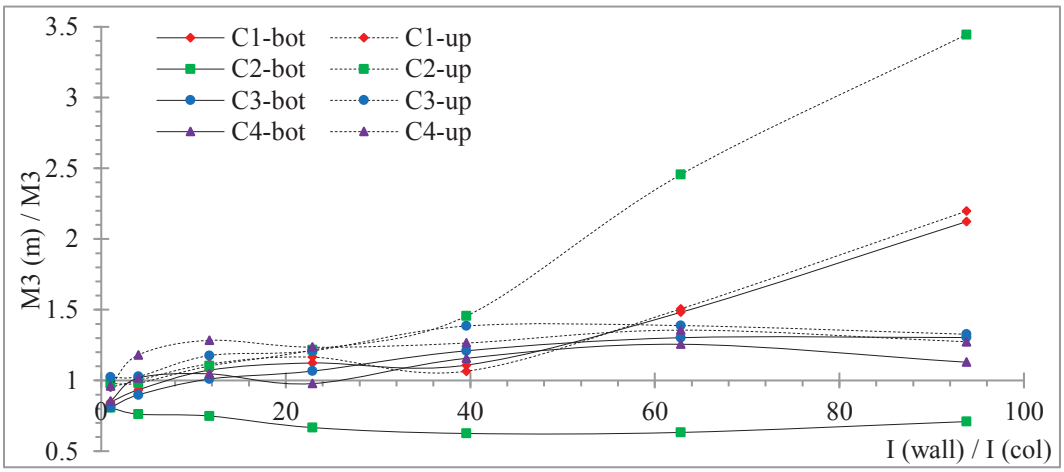

Figure 13: Elastoplastic M3(m)/M3 versus I(wall)/I(col) for foundation mat and φ=45°.

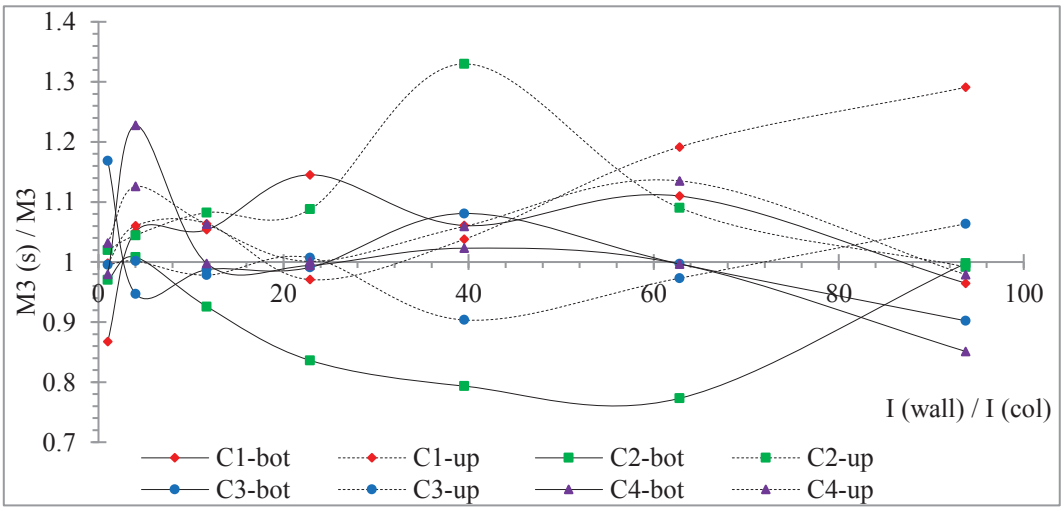

Figure 14: Elastoplastic M3(s)/M3 versus I(wall)/I(col) for footings and φ=90°.

As shown in Fig. 15, comparing foundation mat to rigid soil for φ=0°, the elastic V2(m)/V2 of C1 increases along with the increase of the wall section up to 12.33 for A(wall)/A(col)=3.75. The elastic V2(m)/V2 of C4 increases up to 2.17 for A(wall)/A(col)=3.75, while the elastic V2(m)/V2 for C2 and C3 remains close to 1 for all wall sections (Fig. 15).

For footings and φ=90°, as in Fig. 16, the elastic V2(s)/V2 of C1 increases up to 3.14 for A(wall)/A(col)=2.34 and varies to 2.89 for A(wall)/A(col)=3.75. The elastic V2(s)/V2 of C3 and C4 increases along with the increase of A(wall)/A(col) up to 1.10 for A(wall)/A(col)=3.75 (Fig. 16). The elastic V2(s)/V2 of the wall increases up to 1.66 for A(wall)/A(col)=2.34 and decreases variably for greater wall sections, e.g. to 1 for A(wall)/A(col)=3.75 (Fig. 16).

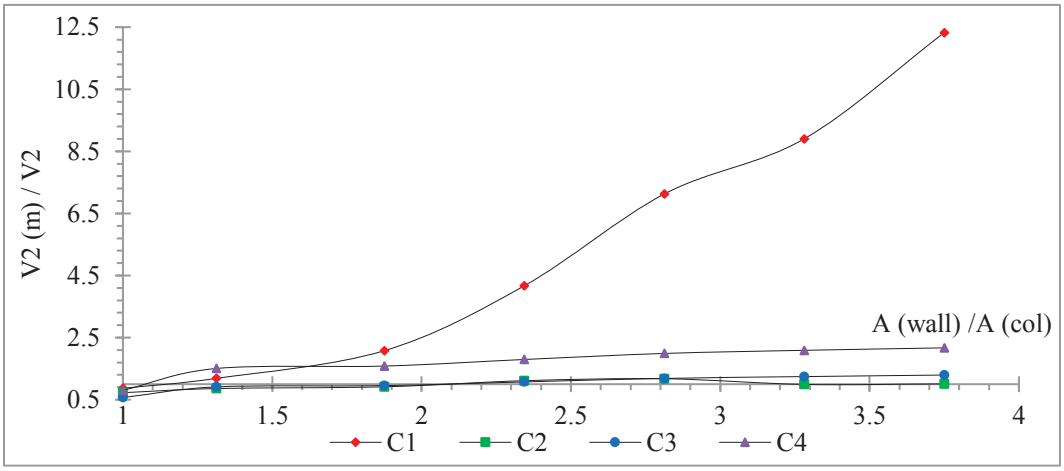

Figure 15: Elastic V2(s)/V2 versus A(wall)/A(col) for foundation mat and φ=0°.

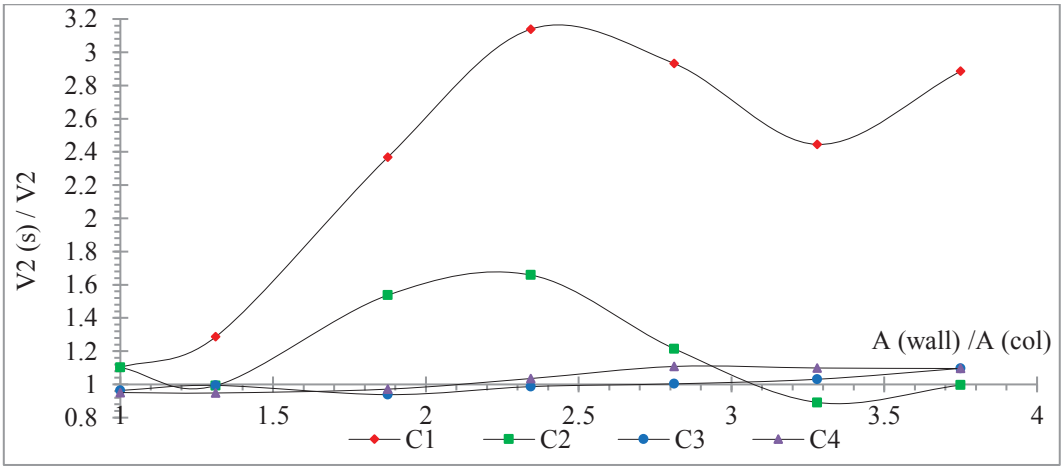

Figure 16: Elastic V2(s)/V2 versus A(wall)/A(col) for footings and φ=90°.

Considering the foundation mat to rigid soil for φ=45°, as in Fig. 17, the elastoplastic V2(m)/V2 increases for the columns along with the increase of the wall section up to 2.24 for C1, to 1.34 for C3, and 1.16 for C4, all values for A(wall)/A(col)=3.75. Respectively, the elastoplastic V2(m)/V2 of the wall decreases to 0.79 for A(wall)/A(col)=3.75 (Fig. 17).

Similarly, as shown in Fig. 18, for foundation mat and φ=0°, the elastoplastic V2(m)/V2 increases for the columns along with the increase of the wall section up to 1.67 for C1, to 1.38 for C3 and 1.56 for C4, all for A(wall)/A(col)=3.75. Respectively, the elastoplastic V2(m)/V2 of the wall decreases to 0.50 for A(wall)/A(col)=3.75 (Fig. 18).

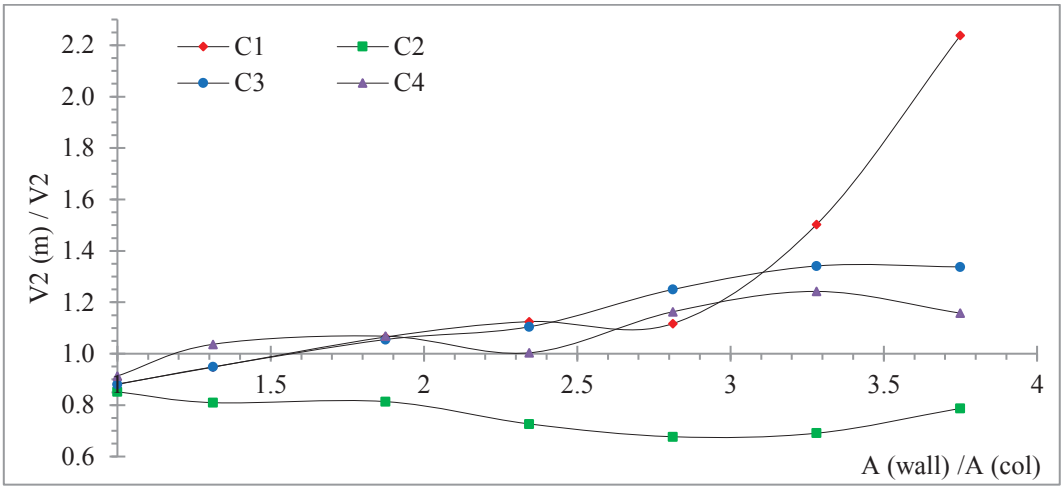

Figure 17: Elastoplastic V2(m)/V2 versus A(wall)/A(col) for foundation mat and φ=45°.

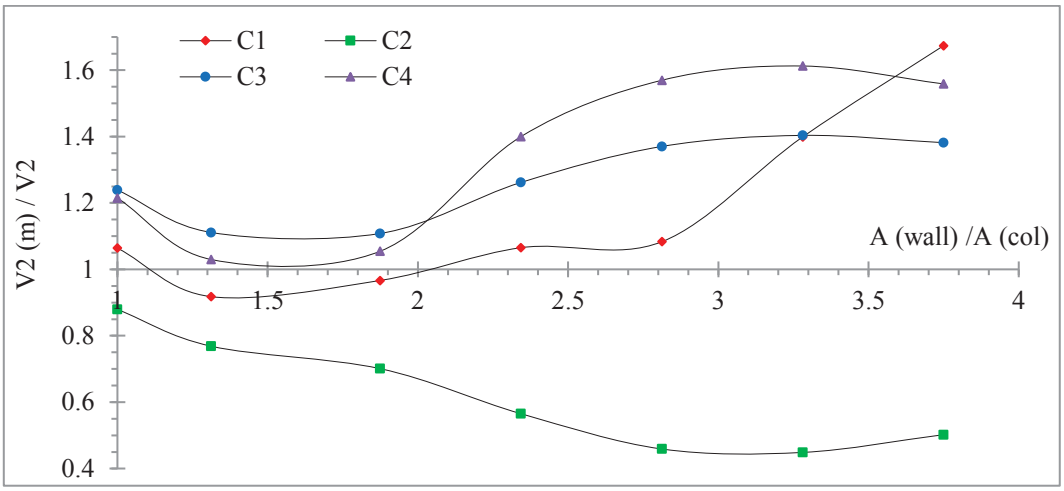

Figure 18: Elastoplastic V2(m)/V2 versus A(wall)/A(col) for foundation mat and φ=0°.

As shown in Fig. 19, for φ=0°, the elastic IDR on the X-axis for rigid soil decreases along with the increase of the wall section to 0.0044 for A(wall)/A(col)=3.75, for footings to 0.0058, while for foundation mat increases to 0.01, all values for A(wall)/A(col)=3.75. For φ=0°, as in Fig. 20, the elastic IDR on Y-axis for rigid soil decreases to 0.004 for A(wall)/A(col)=3.75, for footings to 0.0055, while for foundation mat remains in the range of 0.0145~0.0135, e.g. over the limit of 1% [14]. For all incidence angles on both axes, the elastic IDR is greater for the foundation mat, less for the rigid soil, while for footings has intermediate values closer to the rigid soil.

As shown in Fig. 21, for φ=45º, the elastoplastic IDR for all boundary conditions on X-axis decreases along with the increase of the wall section in the range of 1-2% [14], where the IDR for foundation mat has greater values close to 2%, the IDR for rigid soil has fewer values and the IDR for footings has intermediate values closer to ones for the rigid soil. For φ=90º, the elastoplastic IDR on Y-axis for all boundary conditions increases along with A(wall)/A(col) in the range of 1-2% [14], where the IDR for foundation mat has greater values, while the IDRs for rigid soil and footings have fewer overlapping values to each other (Fig. 22).

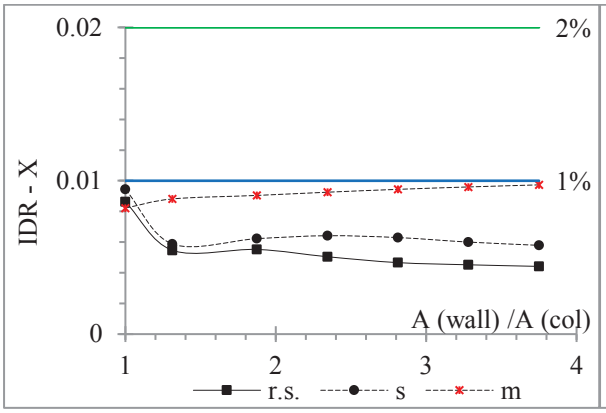

Figure 19: Elastic IDR on X-axis versus A(wall)/A(col) for φ=0°.

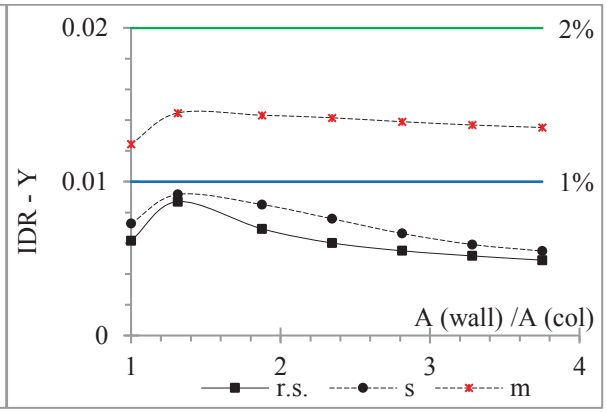

Figure 20: Elastic IDR on Y-axis versus A(wall)/A(col) for φ=0°.

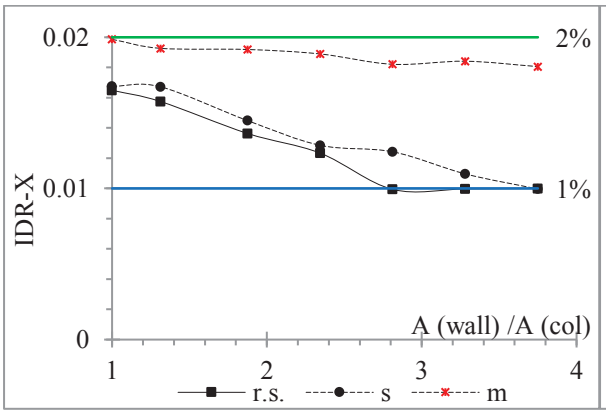

Figure 21: Elastoplastic IDR on X-axis versus A(wall)/A(col) for φ=45°.

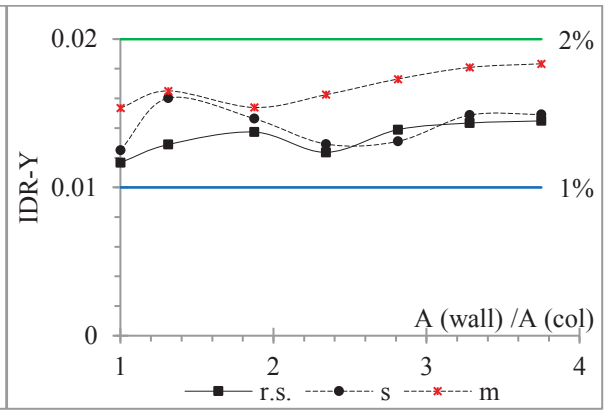

Figure 22: Elastoplastic IDR on Y-axis versus A(wall)/A(col) for φ=90°.

As shown in Fig. 23, for φ=0º, the damage index for all elements varies in the range of 0~0.9, e.g. approaching to collapse while less than DL performance level. For φ=0º, as in Fig. 24, the r_f for rigid soil decreases variably along with the increase of A(wall)/A(col) with greater values than for the other boundary conditions for A(wall)/A(col)=1.31~1.88 and smaller for A(wall)/A(col)≥2.81. Respectively, the r_f for foundation mat increases with smaller values for A(wall)/A(col)=1.31~1.88 and greater for A(wall)/A(col)≥2.34 and the r_f for footings tend to variably decrease with intermediate values to the other ones (Fig. 24).

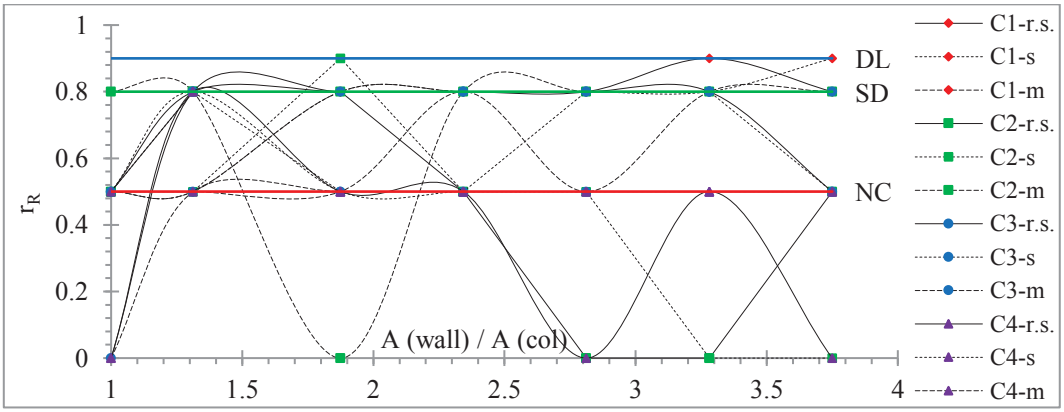

Figure 23: r_R versus A(wall)/A(col) for φ=0°.

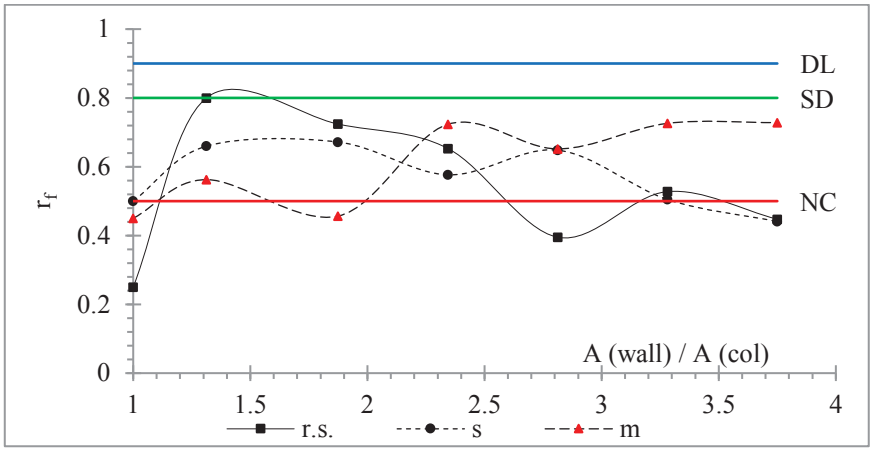

Figure 24: r_f versus A(wall)/A(col) for φ=0°.

Comparing the effect of the incidence angle of the earthquake on the analyses, the plot of the elastic M3(s)/M3 has a greater range of values for φ=90°, while the plot of the elastoplastic M3(m)/M2 has a greater range of values for φ=45° (Figs. 11-14). The plot of the elastic V2(m)/V2 has a greater range of values for φ=0°, while the plot of the elastoplastic V2(m)/V2 has a greater range of values for φ=45° (Figs. 15-18). The plots of the elastic IDR on X and Y axes have a greater range of values for φ=0°, while the plot of the elastoplastic IDR on X-axis has a greater range of values for φ=45° and the plot of the elastoplastic IDR on Y-axis has a greater range of values for φ=90° (Figs. 19-22). The plot of the damage index r_f tends to a smaller range of values, indicating more damages, for φ=0° (Fig. 24).

4 CONCLUSIONS

SSI affects strongly the structural seismic response and proves to be necessary for the design of low-rise usual R/C buildings. From the current analyses of the selected 2-D and 3-D building frames, the following conclusions can be stated.

1. The elastic M(s)/M and V(s)/V of the columns increase along with the increase of the wall section, while the respective ratios of the wall decrease. Indicatively, for example, the elastic M(s)/M of the column is greater by 349% at its base and 389.6% at its top for the greatest wall section, while the elastic V(s)/V of the column is greater by 227%, compared to the respective ones of the wall. Respectively, for comparison purposes, the elastoplastic M(s)/M of the column tends to be greater by 233% at its base and 9% at its top for the greatest wall section, while the elastoplastic V(s)/V of the column is greater by 209%, compared to the respective ones of the wall.

   The elastoplastic M(s)/M and V(s)/V of all vertical elements have a fluctuating behavior because their elastoplastic hinges act as "movable" limits of the internal moment depending on deformation and loading conditions at the end of each element for every time step. If in an elastoplastic hinge a limit is reached, then this acts as a barrier and influences rapidly all other elements by rapidly transmitting an extra load to them. In general, the columns carry more load considering SSI compared to the rigid soil, where their top sections tend to be burdened more than their respective base sections, in terms of the elastoplastic M(s)/M ratio, e.g. greater than 75% for I(wall)/I(col)=39.55~62.81. The wall tends to generally benefit from SSI compared to the rigid soil. Thus, its top section occasionally tends to larger values of the elastoplastic M(s)/M ratio, e.g. up to 124% greater than its respective base, for I(wall)/I(col)=11.72.

Also, in 3-D building frames, the column C1, connected to the wall through a beam along the X-axis, tends to be burdened more than the other columns from SSI, e.g. having greater elastic M(s)/M ratio at its base by 668% and at its top by 382% and elastoplastic M(s)/M at its base by 93% and at its top by 73%, as well as greater elastic V(s)/V by 613% and elastoplastic V(s)/V by 163%, all values calculated for the greatest wall section.

2. The elastic IDRs for SSI and rigid soil decrease along with the increase of the wall section under the limit of 1%, which refers to the Immediate Occupancy performance level, while the elastic IDR for SSI is greater than the one for rigid soil. The latter is observed in 2-D frames, for SSI via footings as compared to rigid soil, and in 3-D, 1-storey buildings, for SSI via footings with tie beams, as well as via foundation mat, compared to rigid soil. However, in both 2-D and 3-D frames, the elastoplastic IDRs vary in a greater range of values, e.g. 1~2%, than the elastic IDRs, e.g. less than 1.5%.
   In general, smaller values of r_f, such as less than 0.73, are observed along with greater values of elastoplastic IDR, such as closer to 2%, indicating heavier damages, corresponding to the Severe Damage performance level.
3. The incidence angle of the seismic motion affects each response parameter differently. This means that for each response parameter the greater range of values of the respective plots is observed for different incidence angles, which are not always the same for all response parameters. Therefore, a general conclusion, defining the "most detrimental angle of incidence", is not obvious.
4. The foundation mat tends to increase the average range of values of the internal moment and shear ratio compared to separate footings connected with beams. The plots of the elastoplastic internal moment and shear ratio have a more fluctuating form for footings than for foundation mat. In general, at the examined 3-D R/C building frames, the foundation mat tends to affect their seismic response more negatively, though more stably, than the footings.

THE RESPONSE OF DIFFERENT BUILDINGS TO FREE-FIELD EXCITATION – A STUDY USING DETAILED FINITE ELEMENT MODELS

Lutz Auersch[1], **Susanne Ziemens**[1]

Berlin 12200 Germany
e-mail: lutz.auersch-saworski@bam.de

Keywords: building vibration, office building, residential building, soil-building resonance, floor resonance, column/wall resonance.

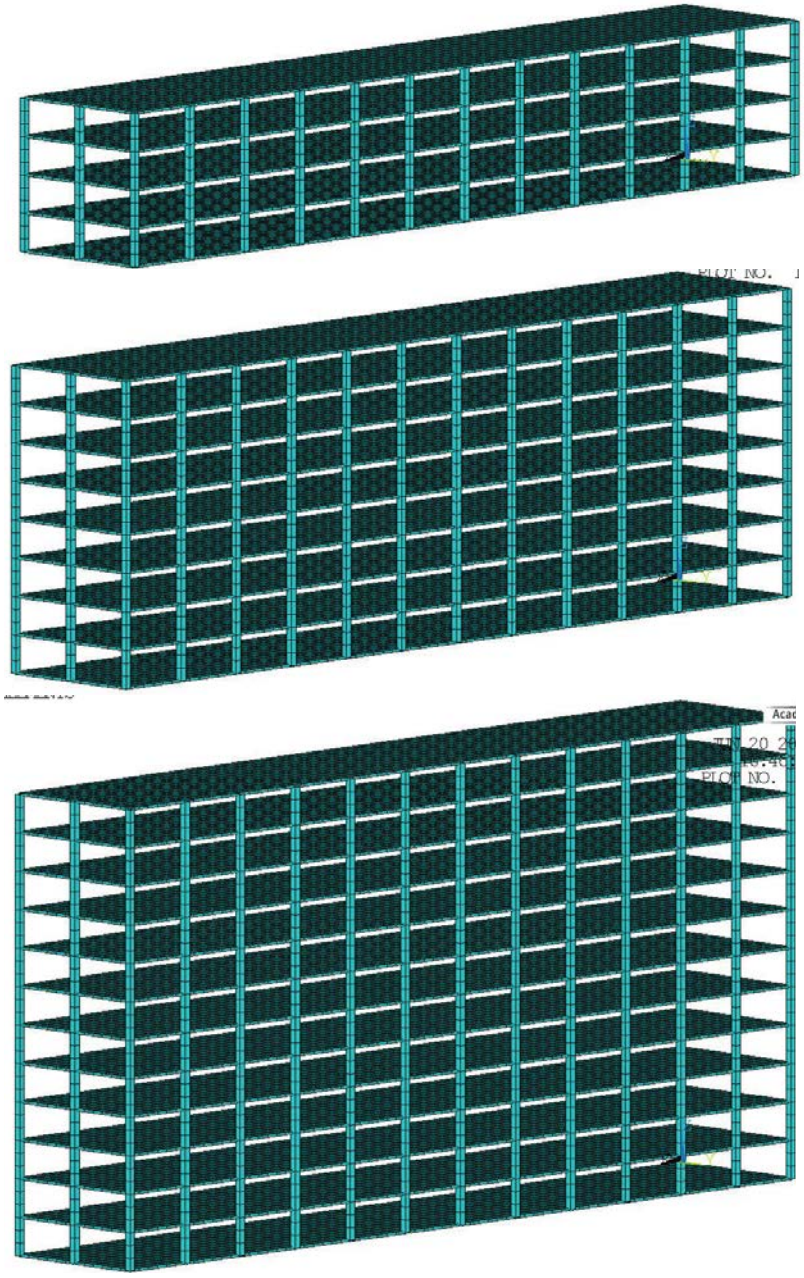
Abstract. *A study on building vibrations has been performed by finite element calculations. Family houses, multi-storey residential buildings, office buildings and office towers have been modelled in detail. The frequency-dependent response due to a free-field excitation has been evaluated for walls, columns and floors. The ratio of building amplitudes to free-field amplitudes starts with $u_B/u_0 = 1$ at zero frequency and is usually lower than 1 at 50 Hz, the end of the frequency range considered here. In between, amplifications occur due to several reasons. There are „soil resonances“ where the whole building is vibrating on the compliant soil, “column resonances” where the upper storeys are vibrating on the compliant columns, and the “floor resonances” where the floors are vibrating excited by their supports. Results are presented for all building types, but a special focus is set on office buildings. A parameter study shows the influence of the stiffness of the soil, the number of storeys, and the width of the building. It has been found that the “soil resonance” is strongly modified by the low-frequency floor resonances for the normal office building. The main resonance of a twenty-storey office tower is determined equally by the “soil mode” and the “column mode”. It is an important observation for these office buildings that the resonances can differ for different parts of the building such as the centre, the edge, the corner, and the core of the building. This leads to non-uniform vibration modes across the building, which look like another type of “floor resonance” and which have been observed in several real building projects. Experimental results will be shown which can confirm the calculated phenomena.*

1 INTRODUCTION

The response of buildings to ground vibration had been studied by experiments and some rules have been derived. The transfer from free-field to foundation amplitudes and to floor amplitudes had been established for small residential buildings [1,2]. These rules, however, cannot be applied to larger and more complex buildings, namely to office buildings with their column-type rather than wall-type structure. Therefore, a finite-element analysis of different building types has been performed where the parametric study of office buildings was of high interest [3].

2 DIFFERENT BUILDINGS

The basic office building consists of four storeys, three lines of thirteen columns, and 5 x 2 x 12 floors (Fig. 1). The columns and floors are of concrete with the material parameters



a)

b)

c)

Figure 1: Office buildings with 2 x 12 floor bays and a) 4, b) 8, and c) 12 storeys.

$E_C = 3\ 10^{10}$ N/m^2 the elasticity modulus, $\rho_C = 2.5\ 10^3$ kg/m^3 the mass density, and the geometrical parameters 3 m x 0.6 m x 0.6 m for the columns and 6 m x 6 m x 0.2 m for the floors. There is a 2 m x 2 m shallow foundation under each column of which the stiffness is calculated as $k = 4\ G/(1-\nu)\ \sqrt{A/\pi}$ and the damping as $c = 3.4\ A/\pi(1-\nu)\ \sqrt{G\rho}$. The soil parameters $G = 8\ 10^7$ N/m^2 the shear modulus, $\nu = 0.33$ the Poisson ratio, $\rho = 2\ 10^3$ kg/m^3 the mass density are used together with the foundation area $A = 2$ m x 2 m.

The number of storeys has been varied between 4, 8, and 12, see Figure 1. The number of rows of floors has been varied between two (the standard) and three. The stiffness of the soil has been varied between $G = 4.5$, 8 and 18 10^7 N/m^2.

High-rise office buildings of 20 storeys have been analysed with a different ground plan (Fig. 2). There are 4 x 3 floor bays of 6 m x 6 m which are completely supported by columns as before (Fig. 2a) or supported by an additional inner core of walls with $d_W = 0.2$ m (Fig. 2b).

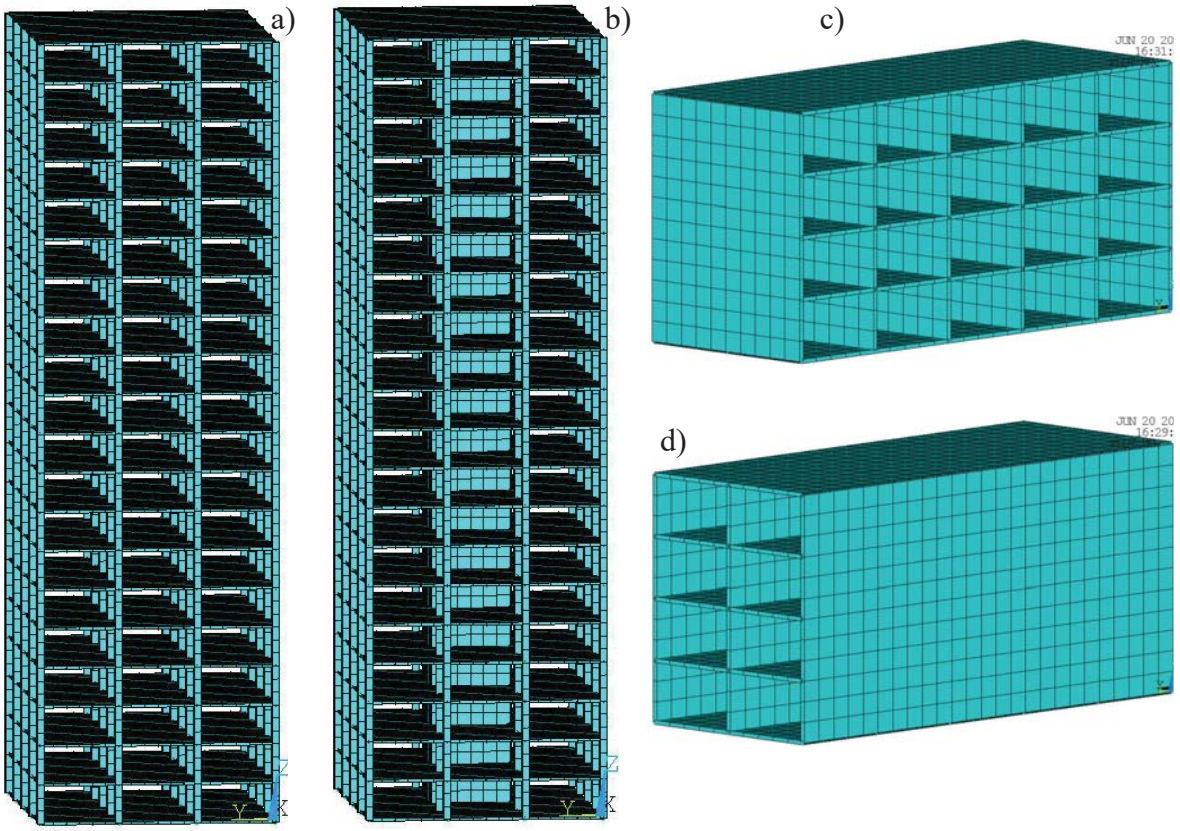


Figure 2: Office towers of 3 x 4 floor bays and 20 storeys, a) without core walls, and b) with core walls, 4-storey residential buildings with 2 x 5 floor bays and c) walls across and d) walls along the building.

Two 4-storey wall-type residential buildings have been analysed (Fig. 2c,d). Both buildings have 2 x 5 floor bays of 5 m x 5 m width, and one building has its walls across the building and the other has its walls along the building. Whereas the floors are of concrete, the walls are made of masonry with the material parameters $E_M = 5\ 10^9$ N/m^2 the elasticity modulus, $\rho_M = 2.5\ 10^3$ kg/m^3 the mass density, and a thickness of $d_W = 0.25$ m.

A small 2-storey residential building with varying floor dimensions (Fig. 3) is analysed once with equal floors in the storeys and once with a different floor of 7 m x 6 m in the ground floor.

All buildings are excited by a constant harmonic free-field of frequencies between 1 and 50 Hz. The response of the building is plotted as the ratio to the free-field amplitude giving the frequency-dependent transfer functions of the different building points.

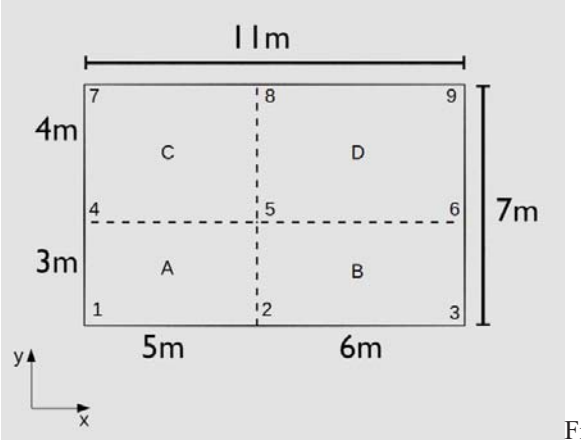

Figure 3: 2-storey residential building, floor plan.

3 A PARAMETER STUDY FOR OFFICE BUILDINGS

3.1 Transfer functions and vibration modes

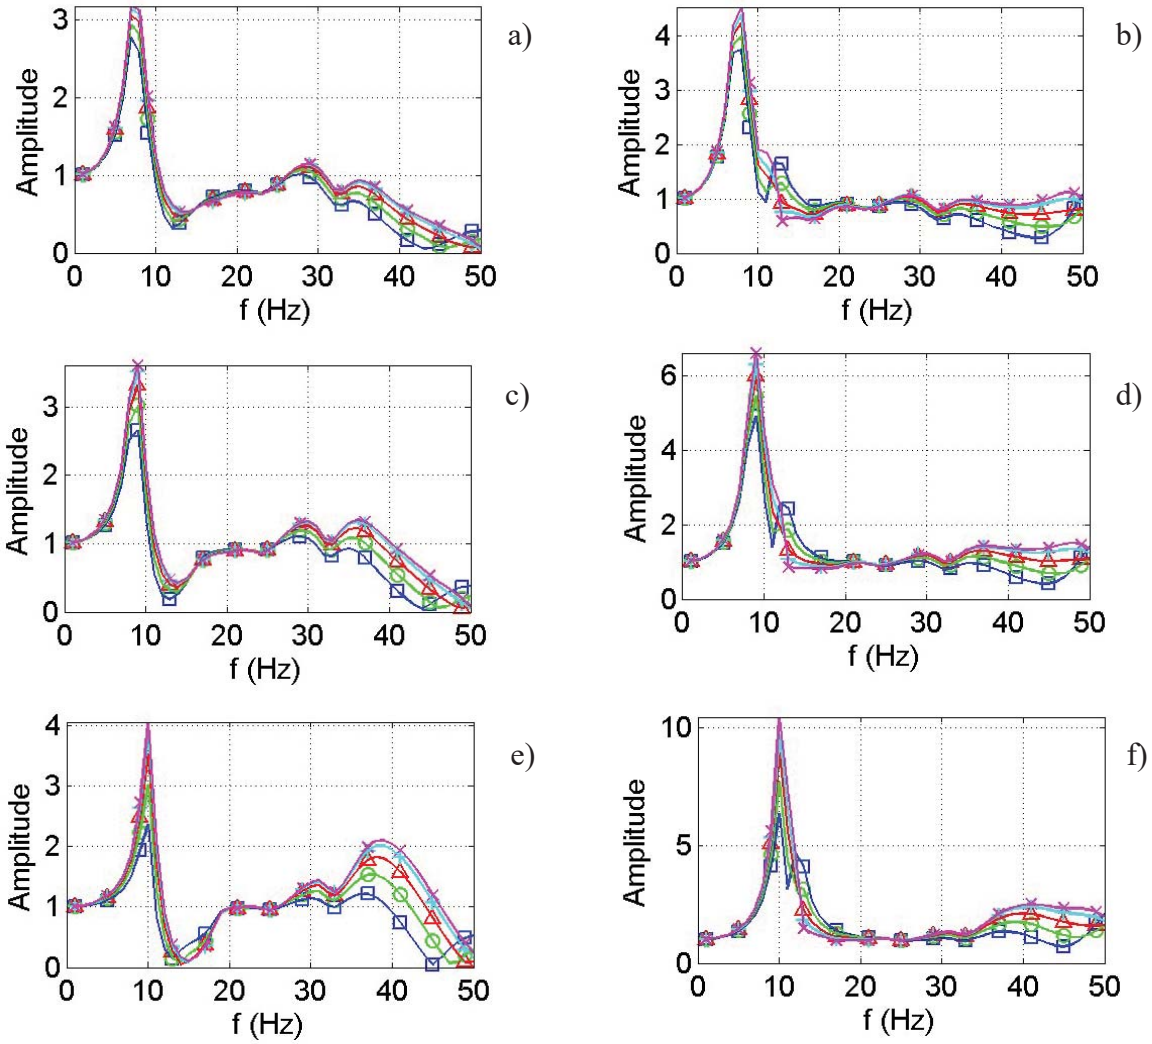

Figure 4: Transfer functions of the 4-storey office buildings, a,c,e,g) mid columns, b,d,f,h) floors, ☐ ground, ○ 1st, △ 2nd, + 3rd storey, × roof, a,b) soft soil, c,d) medium soil, e,f) stiff soil, g,h) average of all storeys, ☐ soft, ○ medium, and △ stiff soil.

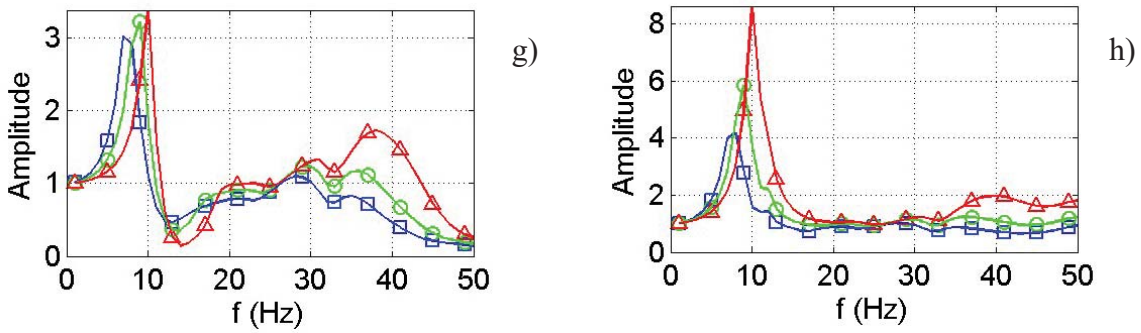

Figure 4: continued.

The freefield-building transfer functions are shown in Figure 4c,d for the five storeys of the standard office building. Figure 4c shows the transfer functions for a central column, and Figure 4d for the midpoint of a central floor. These transfer functions show some general characteristics. All freefield-building transfer functions start with $V = 1$ at zero frequency and usually end below $V < 1$ at 50 Hz. That means that the free field is not modified by the building at low frequencies whereas the free field is reduced by the building at high frequencies. In between, amplifications of the free field can occur due to several reasons. The standard office building shows an amplification at 9 Hz for the column as well as for the floor points where the floor amplitudes are higher at $V \approx 6$ compared to the column points at $V \approx 3$. The points higher in the building (the upper storeys) have a little higher amplitudes. This is also true for a weak amplification at 29 and 37 Hz. Another weak amplification can be found at 13 Hz for the floor points. To be complete, there is also a relative maximum of almost $V \approx 1$ at 15 Hz for the outer columns.

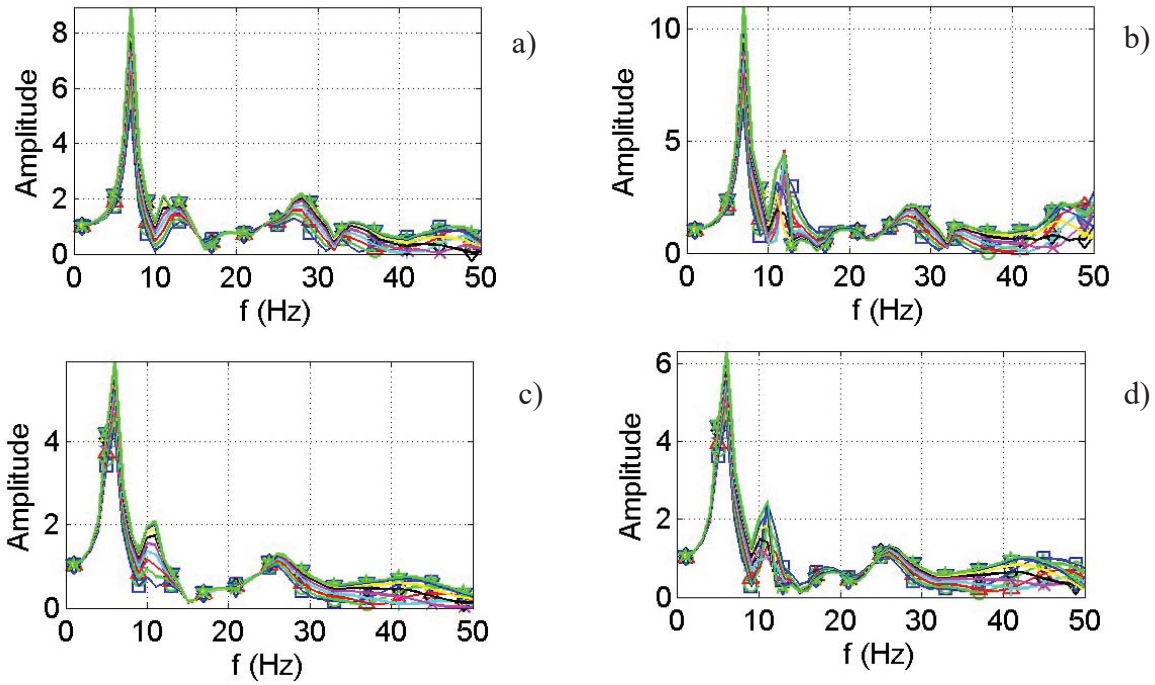

Figure 5: Transfer functions of the 8- (a,b) and 12-storey buildings (c,d), a,c,e,g) mid columns, b,d,f,h) floors, □ ground, ○ 1st, △ 2nd, + 3rd storey, × 4th, ◇ 5th, 6th, 7th, roof, e,f) average of all storeys, □ 4-storey, ○ 8-storey, and △ 12-storey building.

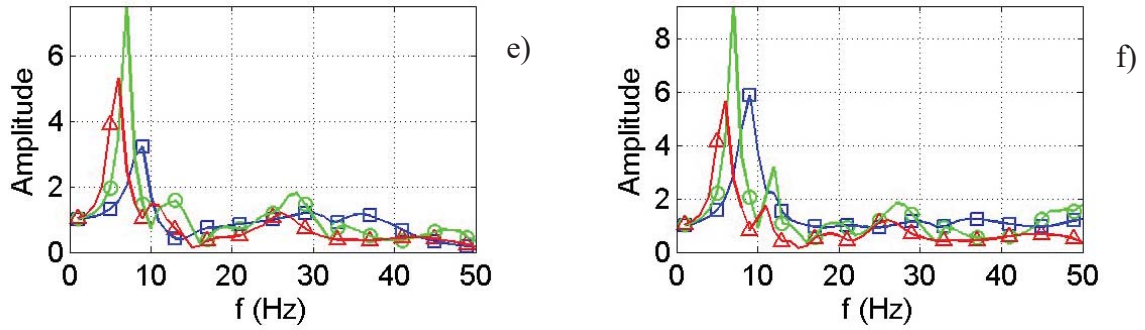

Figure 5: continued.

The results for the variation of the soil can be found in Figures 4a,b,e,f. If the stiffness of the soil is modified once to the soft (Fig. 4a,b) and once to the stiff side (Fig. 4e,f), the fundamental resonance frequency is shifted to 7 Hz and to 10 Hz. At the same time, the amplitudes are increased from 3 to 4 for the columns and from 4 to 10 for the floors from the soft to the stiff soil. The stiff soil yields also a more pronounced second maximum at 13 Hz. Corresponding to that, a common minimum can be observed at 13 Hz for the columns which is also strongest for the stiffest soil.

The variation of the number n of storeys of the office building is shown in Figure 5. The transfer functions of higher office buildings show a lower resonance frequency, 7 Hz for the 8-storey building and 6 Hz for the 12-storey building. The second maximum is now a little stronger ($V \approx 4$) at 11 or 12 Hz.

Finally in Figure 6, it is demonstrated that the fundamental resonance does not change if the total width of the storey floor is increased from 2 x 6 m to 3 x 6 m.

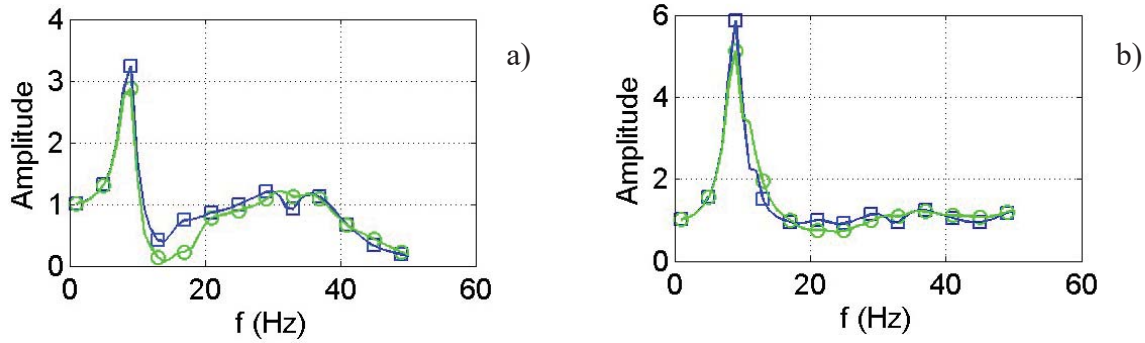

Figure 6: Transfer functions of the office buildings with □ 2 x 12, and, ○ 3 x 12 floor bays, a) mid columns, b) floors, average of all storeys.

Some mode shapes of the different buildings are shown in Figure 7. The 4-storey office building shows clear equal deformations of each storey for the first resonance frequency at 9 Hz (Fig. 7a). The maximum displacement occurs in the middle of the building along the central columns. It looks like a resonance of the entire floor of the storey, but it is the resonance of the central building on the soil, see more examples in [4,5]. Figure 7b shows the local floor resonances at 12 Hz which are in anti-phase for the top and the bottom floors. The 12-storey building (Fig. 7c) has clearly increasing amplitudes from bottom to top at the first resonance frequency of 6 Hz, that means a vertical deformation of the whole building which is called the "column mode".

The resonance amplitudes vary with the stiffness of the soil and the height of the building. The highest amplitudes are for the 8-storey building with $V = 8$ for the columns and $V = 10$

for the floors. This can be explained by the coupling of different modes, see the next section. For the 8-storey building, the “soil mode”, the “floor mode”, and the “column mode” coincide. The 12-storey building with the lowest resonance frequency has a combination of the “soil mode” and the “column mode”. The 4-storey building has a coincidence of the soil and the floor mode. Therefore, the 4-storey building and the 12-storey building have only medium strong resonances of $V = 6$ at the floors. The amplitudes increase with the stiffer soils as the theoretical soil-building resonance frequency comes closer to the floor resonance frequency and reaches $V = 10$ for the stiff soil of $G = 18\ 10^7$ N/m^2.

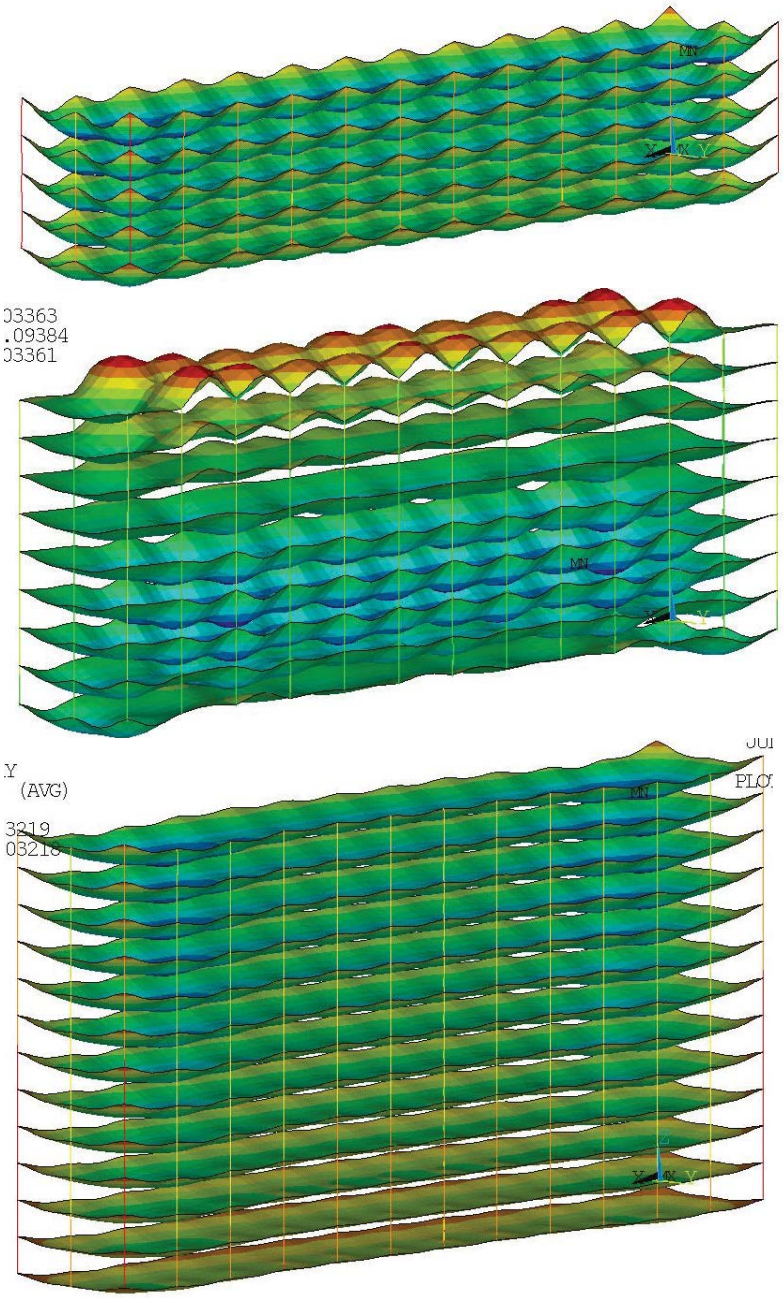

Figure 7: Vibration modes of the column-type office buildings with a) 4, b) 8, c)12 storeys, at 9 Hz (a), 12 Hz (b), and 6 Hz (c).

3.2 Analysis of resonance frequencies and the coupling of modes

All these resonance frequencies are analysed in more detail by Figure 8. The fundamental

resonance frequencies from the finite element calculations are compared with the theoretical soil-building resonance frequencies. The theoretical soil-building frequency $f_S = \sqrt{k/m}$ compares the stiffness k of the foundation and the mass m of the building. Therefore, the theoretical soil-building resonance frequency varies with $f_S \sim v_S = \sqrt{G/\rho}$ and with $f_S \sim n^{-0.5}$. There are differences between the soil-building resonance frequency for the whole building, for the outer building (with a lower mass and a higher resonance frequency), and for the central building (with a higher mass and a lower resonance frequency). The fundamental resonance frequencies from the finite-element calculation are even lower than the theoretical ones. The difference is 11.7 Hz to 9 Hz for the standard soil of $G = 8\ 10^7$ N/m^2 ($v_S = 200$ m/s), from 8.7 Hz to 7.5 Hz for the soft soil of $v_S = 150$ m/s, and greatest for the stiff soil $v_S = 300$ m/s from 17.5 Hz to 10 Hz. Moreover, the power laws from the finite-element calculations are clearly weaker than the theoretical laws. All these observations indicate another influence on the fundamental resonance.

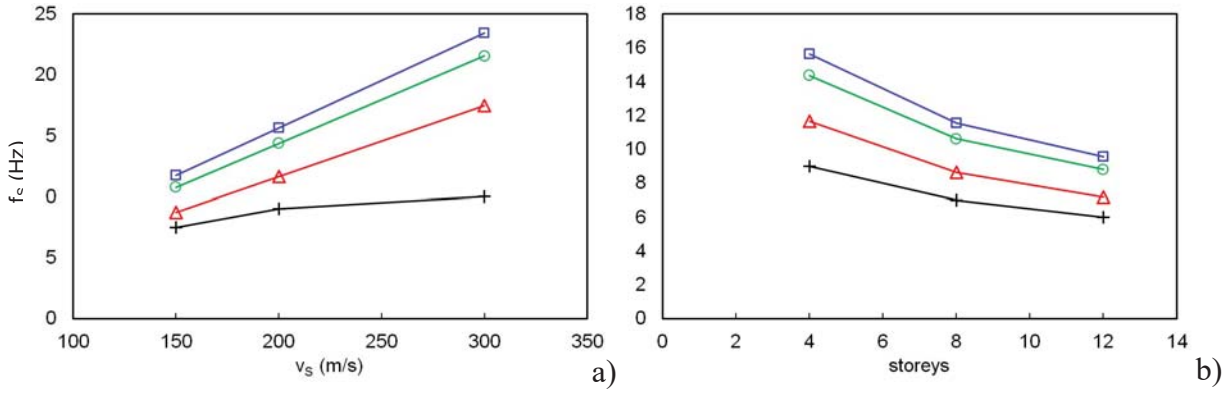

Figure 8: Theoretical soil building resonance frequencies for ○ the whole building, △ the inner building and □ the outer building, + the fundamental resonance frequency from the finite-element calculation, a) variation of the soil, b) variation of the number of the storeys.

This influence is identified as the influence of the floor resonance. Approximately, the floors are clamped at each column and the rotation along the sides is prevented due to the interaction with the neighbouring floors. The theoretical floor resonance frequency is therefore 13.7 Hz, see [4]. This floor resonance frequency is not far from the soil-building resonance frequency so that both resonances work together and yield a lower fundamental resonance frequency.

The higher office buildings have lower soil-building resonance frequencies which are further away from the floor resonance frequency. Therefore, the floors have a weaker influence on the soil-building resonance frequency. There is another influence in case of higher buildings. The upper storeys are amplified compared to the lower storeys. This "column mode" means a stronger mass effect than for a rigid building, and this yields also a reduction of the soil-building resonance frequency.

4 OFFICE TOWERS

The two 20-storey office towers considered here can be seen in Figure 9 with their typical vibration modes. Figures 9a,b,d show the column mode of the tower without and with core walls where the amplitudes are increasing from the bottom to the top of the building. Figure 9c shows a second "column mode" at 9 Hz where top and bottom of the building are in anti-phase.

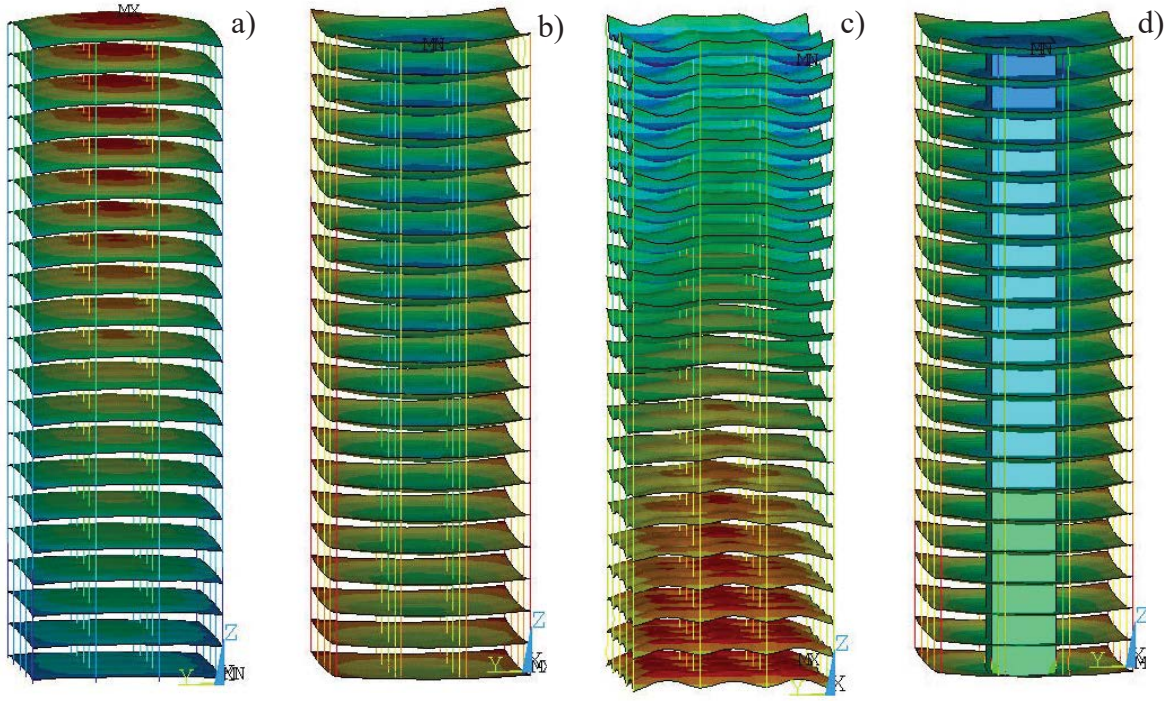

Figure 9: Vibration modes of the 20-storey office towers without (a,b,c) and with (d) core walls, a) 4 Hz, b) 4 Hz (imaginary part), c) 9 Hz, d) 4 Hz.

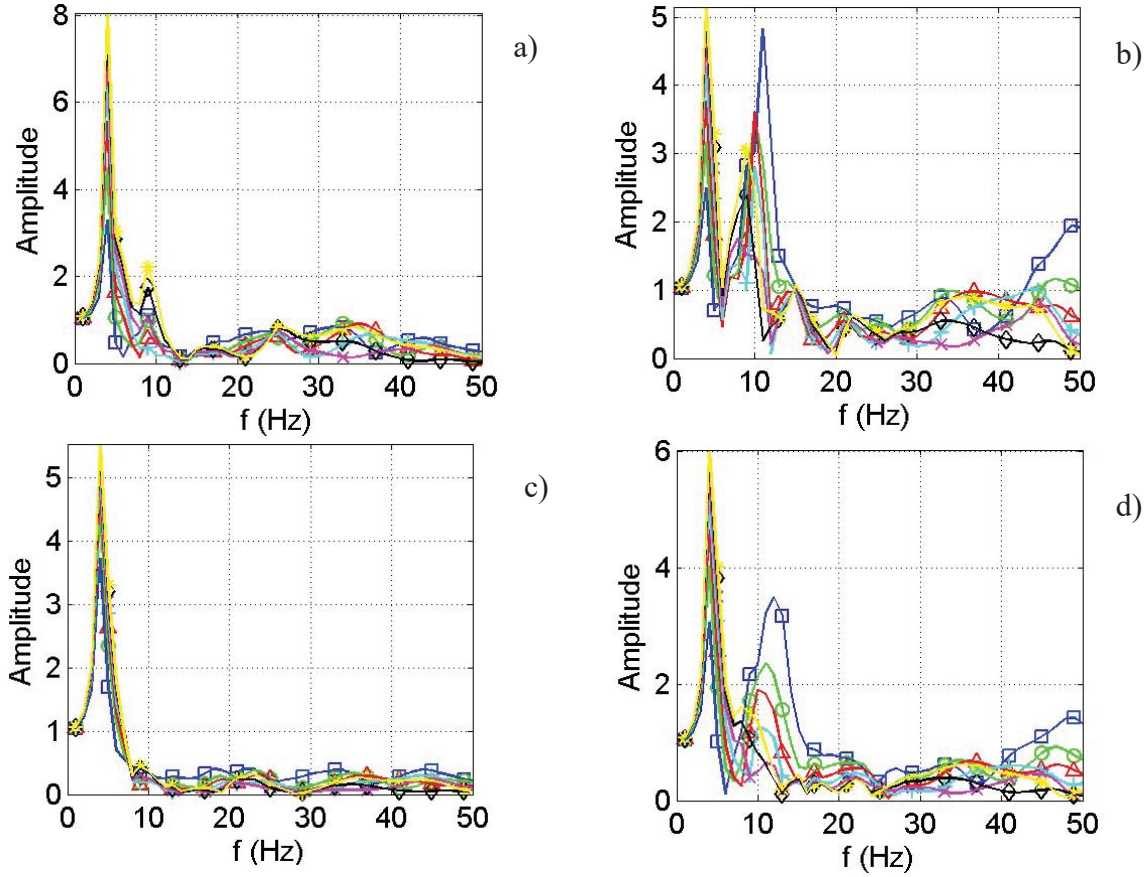

Figure 10: Transfer functions of the 20-storey buildings (a,b) without and (c,d) with core walls, a,c) mid columns, b,d) floors, □ ground, ○ 4th, △ 7th, + 10th, × 13th, ◇ 16th, ∗ 19th storey.

The transfer functions of the two tower buildings have some similarities (Fig. 10a,c). The main resonance is at 4 Hz and a considerable amplification from bottom to top can be observed. The tower without core reaches amplitudes of $V = 8$ and some influence of the floors at 9 Hz can be found. The tower with core has lower amplitudes with a maximum of $V = 5$. Some floor resonances can be seen at 11 to 13 Hz for the floor points (Fig. 10b,d).

The main resonance of the twenty-storey office towers is determined similarly by the "soil mode" and the "column mode". The theoretical soil-building resonance frequency is 6 Hz and the theoretical column resonance is also $f_C = v_L/4H \approx 6$ Hz, see [6] for details. Both together yield a fundamental resonance frequency of 4 Hz.

The floor resonance frequencies depend on the position of the floor. It is lowest with $f_0 = 11$ Hz at the corner, with $f_0 = 12$ Hz at the edge of the storey, it is higher with $f_0 = 15$ Hz near the core, and highest with $f_0 = 24$ Hz inside the core.

5 RESIDENTIAL BUILDINGS

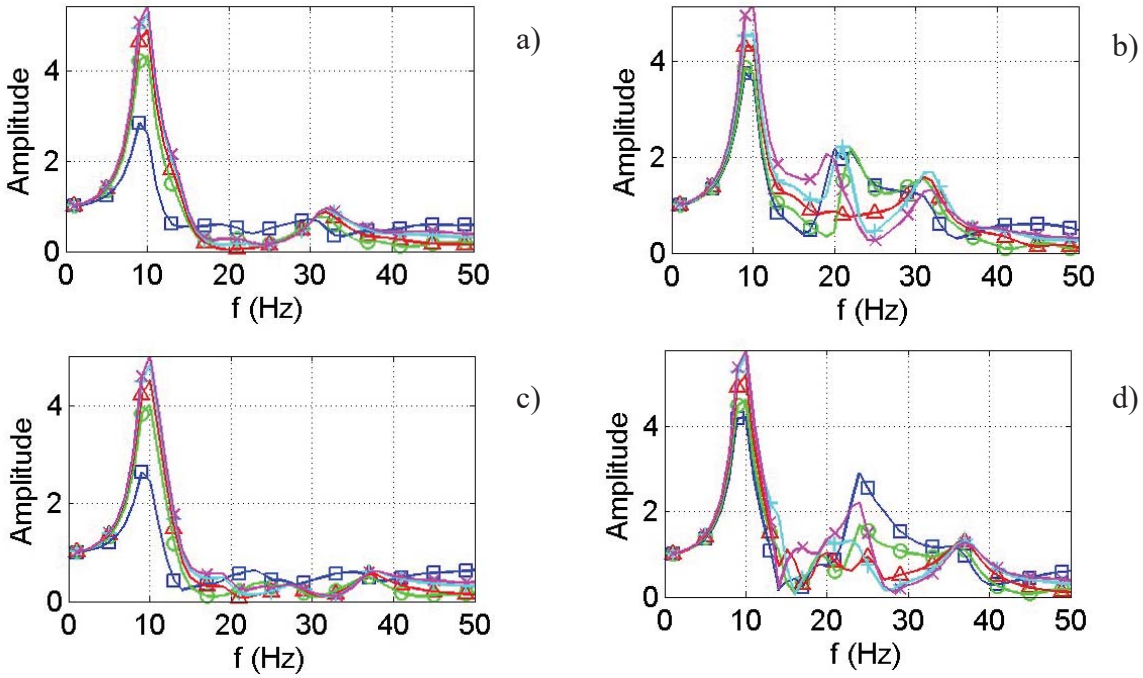

Figure 11: Transfer functions of the 4-storey residential buildings (a,b) with walls across and (c,d) walls along the building, a,c) mid wall, b,d) floors, □ ground, ○ 1st, △ 2nd, + 3rd storey, × roof.

The two types of 4-storey residential buildings have a different orientation of the walls and there is only a small difference of the building mass. Therefore, they have almost the same theoretical soil-building resonance frequency at 12 Hz. The resonance frequency of a rigid building is reduced to 10 Hz for the flexible building (Fig. 11) which is due to a small effect of the floor mode and the wall mode. The floor resonances are at 20 Hz in case of the longitudinal walls and at 24 Hz in case of the transverse walls. The resonance frequency in case of the longitudinal walls is defined by a clamped boundary at the central wall and a hinged boundary at the outer wall. This yields the eigen frequency $f_0 = 20$ Hz for the floor span of 5 m. In case of the transverse walls, the boundary condition is clamped-clamped which yields the higher floor resonance frequency. The 20 Hz floor resonance can be found in Figure 11b, but the amplitudes are not higher than $V = 2$. The floor resonance amplitudes are

reduced by the compliance of the soil. Around 20 Hz, the foundation and wall amplitudes are very low so that the floor resonance amplitudes are limited (absorber effect).

Figure 12 shows two floor resonances of the residential building, the first at 23 Hz, the second at 37 Hz. Both floor modes comprise anti-phase motions. At 24 Hz, the top and bottom floors are in anti-phase (Fig. 12a), at 37 Hz, all floors are in anti-phase to the walls (Fig. 12b).

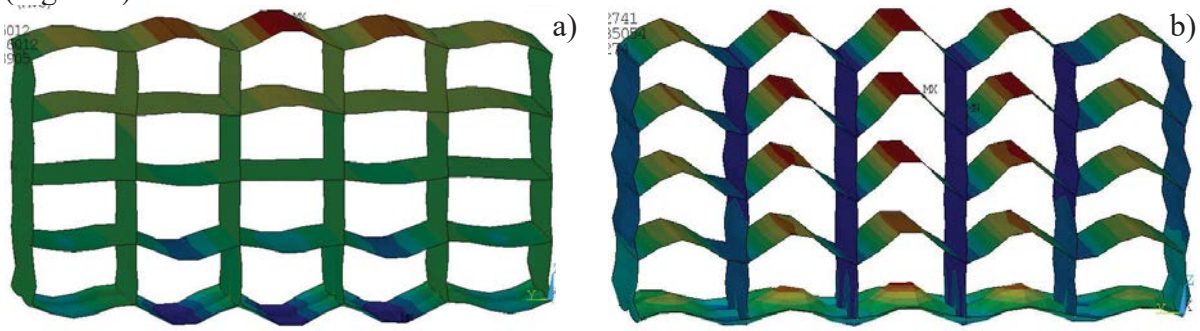

Figure 12: Vibration modes of the residential building with walls across the building, at a) 24 Hz, and b) 37 Hz.

Finally, the small 2-storey residential building is analysed in Figure 13. The highest soil-building resonance of 15 Hz can be found. All four rooms have different dimensions, but no floor resonance can be seen in Figure 13b, not even for the largest room. Only if the ground and the first storey have different walls, the floor resonance at 17 Hz can be found with a high amplitude of $V = 8$ (Fig. 13d). The resonance frequency agrees with the resonance frequency of a 6 m x 7 m large plate which is hinged at all boundaries.

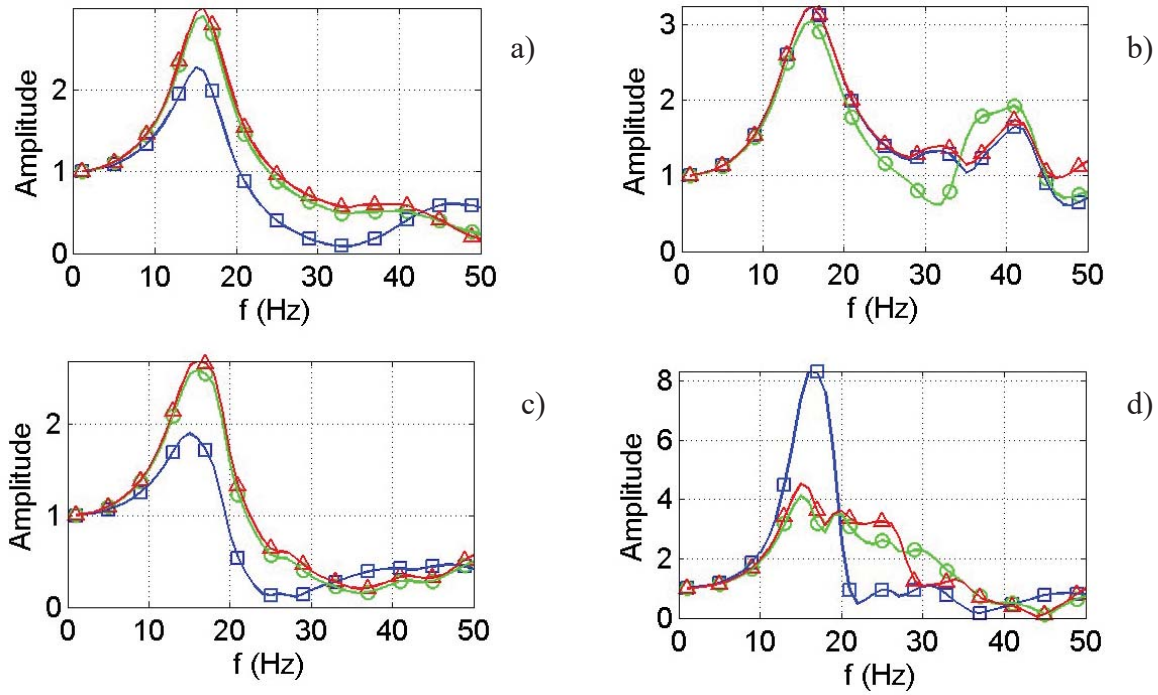

Figure 13: Transfer functions of the 2-storey residential buildings, a,b) with regular floors and c,d) with a separated large floor a,c) mid wall, b,d) floors, □ ground, ○ 1st floor, △ roof.

6 COMPARISON OF THE DIFFERENT BUILDING TYPES

All buildings have a clear fundamental resonance which is mainly a soil-building resonance in most cases. The floor resonance can be observed for all buildings, but not so

clearly. The column resonances as an effect of the flexibility of the columns can be found for the high office buildings. Moreover, many anti-phase modes have been found in many buildings, floor against columns/walls, inner against outer building, and top against bottom. A column-type office building is obviously not a rigid structure.

The highest resonance amplitudes have been found for the stiffest soil, the highest building, and for the separated floor in the small residential building with amplitudes of $V = 8$ to 10. The amplitudes are reduced with increasing frequencies, strongest for the office towers which have amplitudes below $V < 1$ above 7 Hz, even lower for the tower with core walls. The residential buildings start with amplitudes below $V < 1$ at 15 Hz, the small residential building starts at 20 Hz. The office buildings have the highest amplitudes at higher frequencies, usually at $V \approx 1$, even higher for the stiff soil, whereas the soft soil yields amplitudes below $V < 1$ starting from 30 Hz. In general, the column-type office buildings have been identified as the most sensible buildings.

7 EXPERIMENTAL RESULTS

The soil-building resonance which is dominant in the theoretical results has also been found in measurements of small residential buildings (Fig. 14 from [2]). The soil-building resonance frequencies have been measured in the range of 5 to 10 Hz. These lower frequencies have been attributed to an inhomogeneous soil with a soft material on top of the soil.

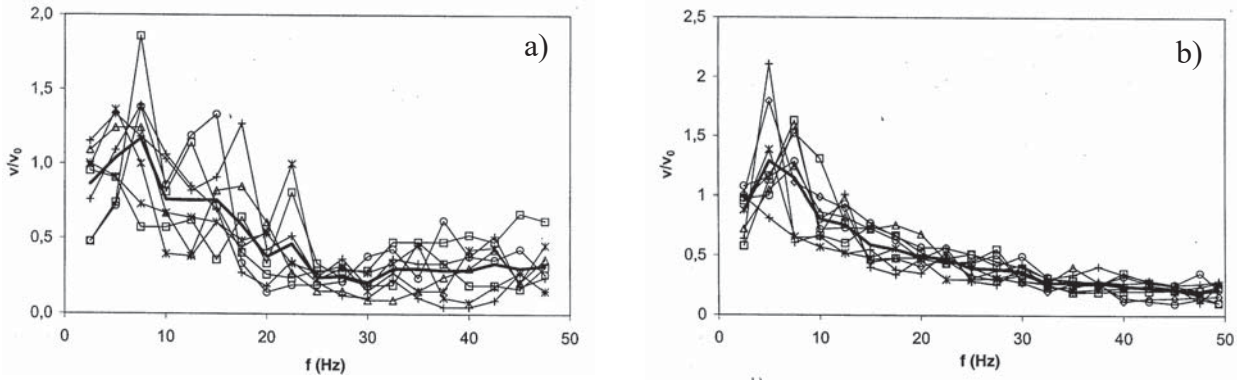

Figure 14: Transfer functions of several small residential buildings measured during pile driving (a) and train passages (b), eight buildings and the average (thick line).

Many measured floor resonances have been evaluated in [6,7]. The resonance amplitudes (compared to the free field) are in the range of $V = 1$ to 10. The low floor resonance amplitudes of the present numerical study are probably due to the very regular modelling of the building. All reducing effects are stronger if all the same floors act together, for example reducing the foundation amplitudes [6]. Also, the regular interaction of the inner and outer columns leads to an anti-phase floor excitation and smaller resonance amplifications.

The wall or column resonance has been observed in some measurements of 6- to 8-storey buildings [1]. The strongest wall and column effect can be found in the office towers. Such a tower building has been measured and also modelled in detail. The resulting soil-building transfer functions have been compared (Fig. 15). The wall/column mode resonance with increasing amplitudes at higher storeys can be clearly seen below 10 Hz in theory and measurements. The floor resonances follow between 10 and 17 Hz.

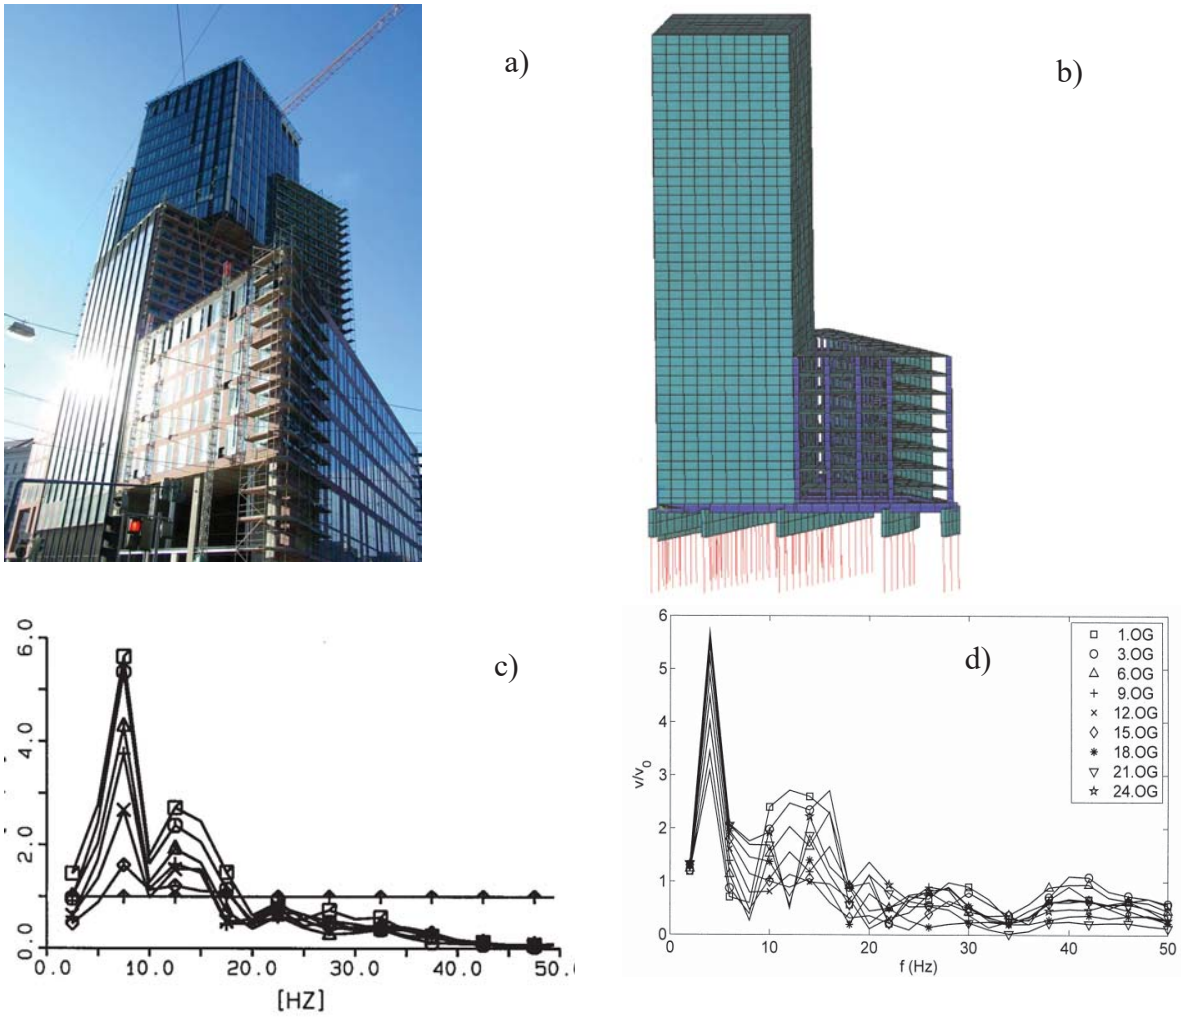

Figure 15: Office tower (a), finite element model (b), measured transfer functions (c, □ 24th, ○ 21st, △ 18th, + 15th, × 12th, ◇ 6th, ♦ ground storey), and calculated transfer functions (d).

8 REAL BUILDING PROJECTS

Finally, some real building projects are presented. The real building projects are not as regular as the buildings of the preceding parameter study. The foundation consists of end-bearing piles which are necessary for the soft sandy soil under building 1 (Fig. 16a). Buildings 2 and 3 (Fig. 16b, e) are above from traffic lines (motorway or metro) so that pile foundations are used close to the traffic lines while plate foundations are used for the rest of the building. The building plan is also irregular, for example triangular for building 1 (Fig. 16c). The building structure is usually mixed with core walls and columns.

Some building-soil transfer functions are given in Figure 17a-d for building 1. The transfer functions of the core wall display the soil-building resonance at 10 Hz and a quit regular behaviour at higher frequencies. The column near the core wall (Fig. 17b) shows some more column deformations but still the basic resonance at 10 Hz. The column in the column section has a lower resonance at 7.5 Hz with a strong amplification from bottom to top (Fig. 17c). The floor resonances are between 15 and 20 Hz (Fig. 17d).

Building 2 has a 10-storey and a 20-storey part where the 10-storey part is situated above the metro line. The side parts include the walls whereas the middle parts are built with columns. The soil-building transfer functions of the wall part (Fig. 17 e, f) show only the floor

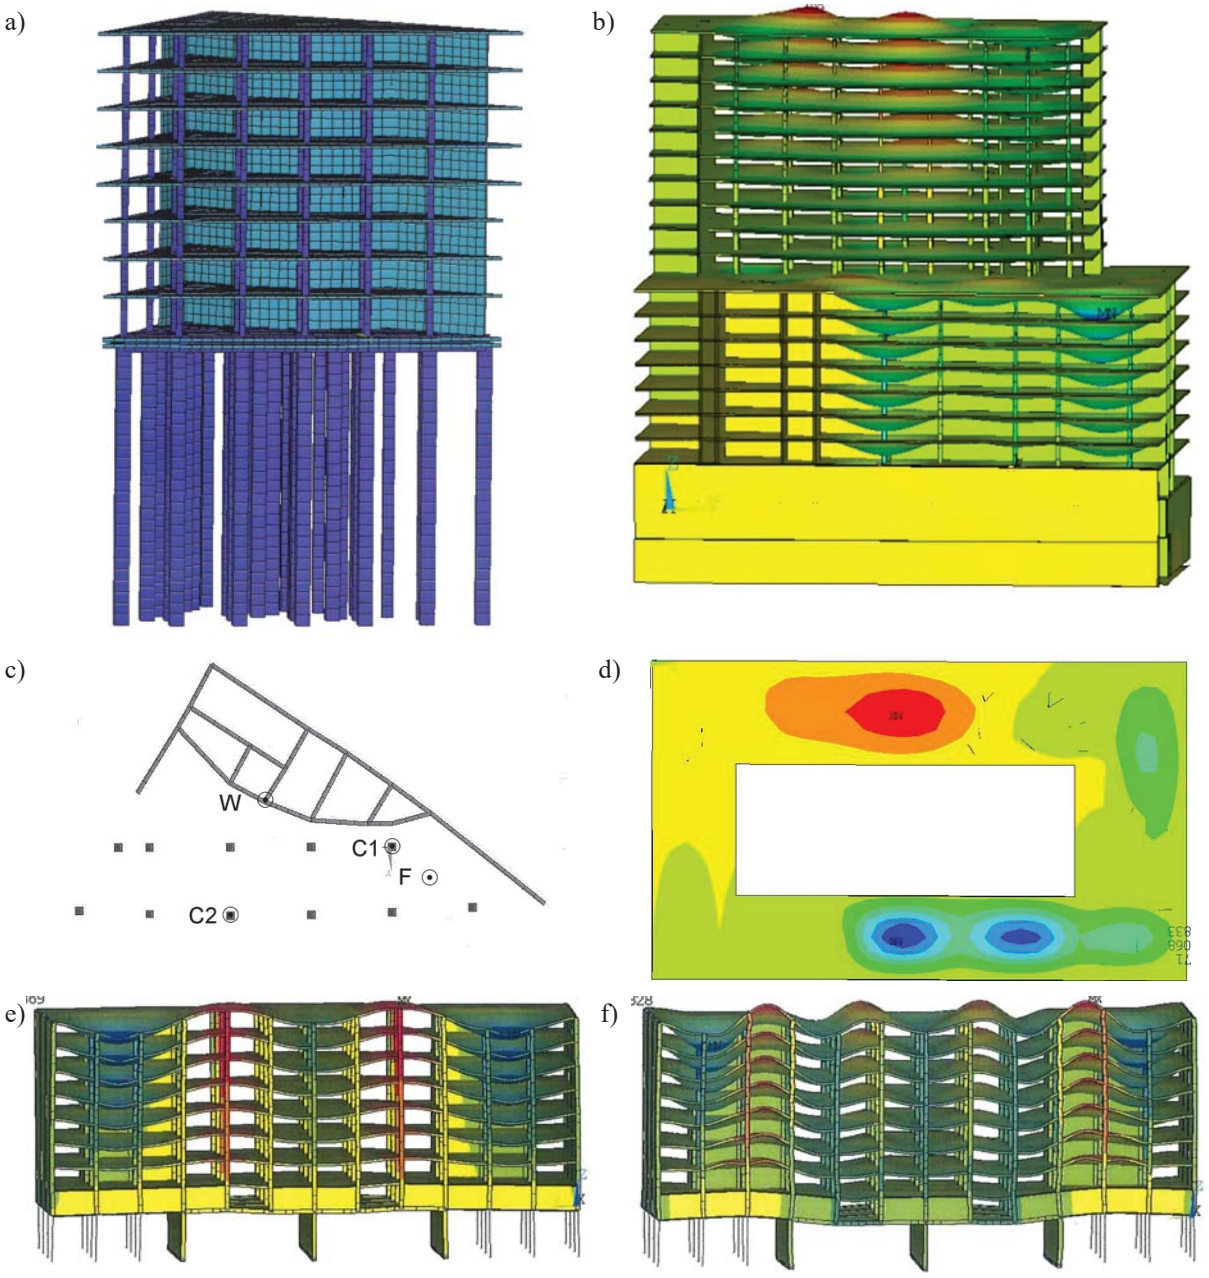

Figure 16: (a, c) Building 1 on piles with core walls and columns, (b, d) building 2 above metro line vibration modes at 12 and 8 Hz, (e, f) Building 3 above motorway, modes at 9 and 14 Hz.

resonances at 20 Hz. The column part (Fig. 17 g, h) show a strong column resonance at 10 Hz and some floor resonances around 25 Hz.

Building 3 has eight storeys and lies above a motorway. The floors are built on rather small columns (0.35 m x 0.35 m). Walls at the two ends and at two staircases at the back side provide the stiffness. The building-soil transfer of a column near the staircase (Fig. 17i) has a higher column resonance at 8 Hz than a column in the column section with 5 Hz (Fig. 17j).

The vibration modes in Figure 16 show the basic building resonance always at the softest part of the building, in the front (the column section) of building 3 (Fig. 16e), and at the central columns of building 2 (Fig. 16d). This result from irregular realistic buildings underlines the observation of the preceding parameter study with regular buildings.

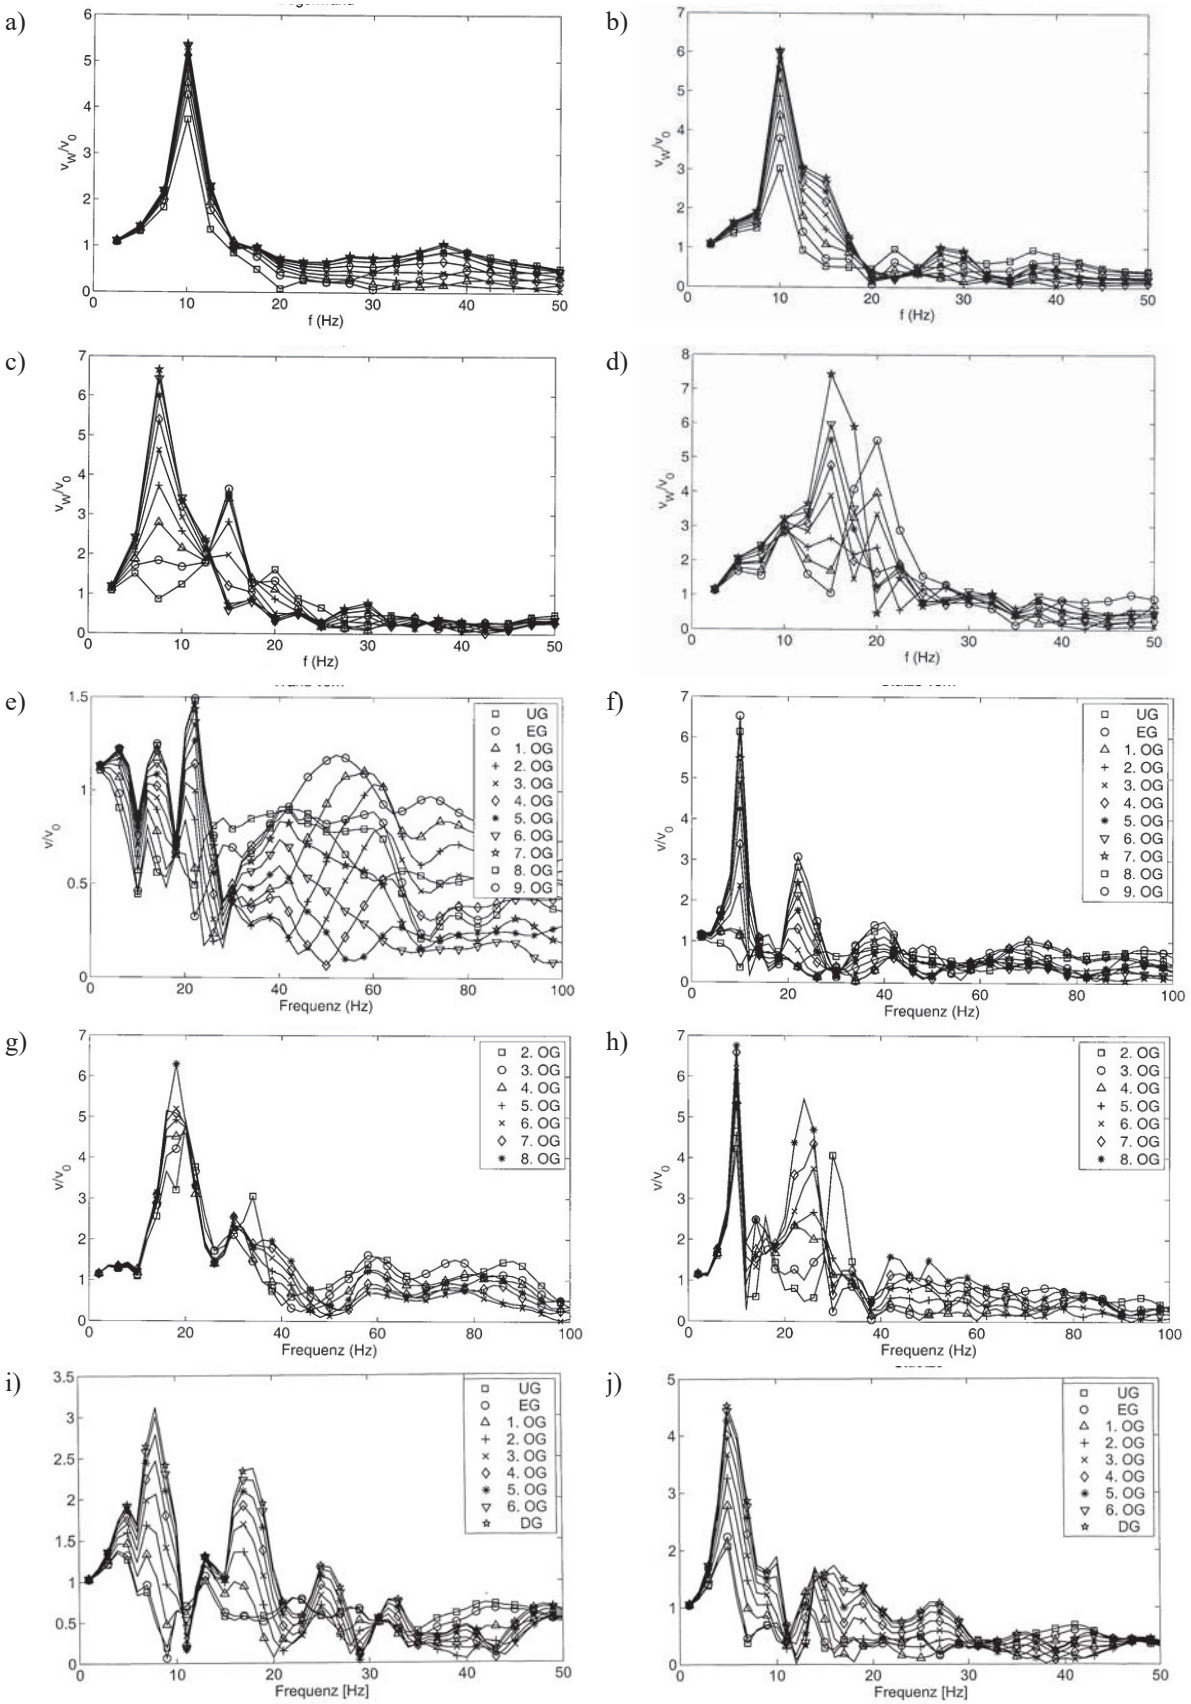

Figure 15: Transfer functions of building 1 (a-d), 2 (e-h), and 3 (i, j), walls (a, e), near-wall columns (b, e, i), columns (c, f, j), near-wall floors (g) near-column floors (d, h).

9 CONCLUSIONS

Different types of buildings have been modelled by the finite element method and calculated in frequency domain to obtain the transfer functions of the floor, wall and column points compared to the free-field excitation. Soil-building, floor and wall/column resonances have been observed. Strong coupling effects between these modes have been found for the office buildings. The fundamental resonance is a combination of the soil and floor mode in case of the lower office buildings or a combination of the soil and column mode in case of high office buildings. The combined resonance frequencies are usually smaller than the theoretical soil-building resonance frequencies. The characteristics of the office buildings compared to the residential buildings are the higher flexibility of the columns compared to the walls and the lower floor resonance frequencies because of the less constrained support conditions. The low floor resonance frequencies are close to the soil-building resonance frequency and induce strong coupling effects. The compliance of the soil under the foundations leads to a reduction of the resonance amplitude of the floors. A clear floor resonance has only been found for the irregular 2-storey residential building. Measurements show higher resonance amplitudes of the floors as real buildings have more irregular variations than the building models here. Measured examples of the soil-building and the column resonance show a good agreement between theory and experiment. The results of this study should help to find simplified models for a fast prediction of ground-induced building vibrations [8-10].

Abstract. *In recent years, the use of robotic systems to enhance the productivity of machining operations has received significant attention from the research and manufacturing communities. Robots have the potential to further improve productivity, for example by providing automated workpiece fixturing, or by providing a flexible and reconfigurable platform from which a variety of subtractive or additive manufacturing operations could be performed. One possible approach is the use of a robotic arm to provide additional fixturing or support of the workpiece during the machining operation. This can increase the stiffness of the workpiece system during machining, which can improve productivity by limiting the onset of undesirable vibrations such as chatter. Chatter is a form of self-excited vibration which leads to low surface quality of the workpiece, shortens the cutting tool life and increases the cutting forces. In this paper, an actively controlled robot arm is simulated in order to suppress the chatter, in an effort to further improve the chatter stability. During the milling operation, preload can be applied through the robot to support the flexible structure, however, the robot cannot suppress high-frequency forces. Since the stiffness and damping ratio of the large flexible structure vary during the operation due to material removal, active vibration control is performed. A proof-mass actuator is proposed that can provide 45 N force up to 2000 Hz with 2 mm stroke. The dynamic properties of the device are identified experimentally as part of a model of a robot fixture prototype. The robotic arm is modelled as a three degree of freedom system; this is combined with a simplified representation of the workpiece dynamics, and the proof-mass actuator, within a Matlab environment. The effect of active control on the chatter stability is evaluated, focussing initially on the use of direct velocity feedback as a control strategy. Estimated chatter stability predictions, along with time, frequency domain simulation results, show that the application of active control method in robotic-assisted machining can suppress the chatter vibrations during machining and hence increase productivity.*

1 INTRODUCTION

Thin-walled structures such as jet engine parts and aerospace fuselage components are common in the aeronautical industry. However, large flexibility of these components leads to excessive vibrations which are called chatter vibration during machining. Chatter is a form of self-excited vibration which leads to low surface quality of the workpiece, shortens the cutting tool life and increases the cutting forces. Milling stability theory [1] can be used to improve the chatter stability by selection of the process parameters which are cutting speed, feed rate and depth of cut. Also, in order to increase the productivity of the process, dynamic stiffness and damping ratio of the workpiece can be improved. There are many techniques with fixed supports [2] and mobile supports [3] to avoid chatter but an interesting current approach is to use robotic systems as part of the machining system. Robots can be used to directly machine components, yet they tend to exhibit very low stiffness which exacerbates excessive vibration. Recently, considerable literature has grown up around the theme of robotic assisted machining. Robots can be used to improve the fixturing or support of the workpiece during machining. The method is called robotic assisted milling when a robot supports a workpiece from the opposite surface to the milling process.

For instance, Ozturk et. al. [4] presented a new concept called robotic assisted milling of thin-walled structures. The authors used two types of end effectors to support the workpiece from the back surface. Experimental results showed that the surface roughness decreased considerably by using moving support. During the milling, robot and the cutting tool moved synchronously. As it is mentioned in the paper, the process was monitored not controlled. The authors did not take account of stiffness change during machining. As the workpiece's stiffness changes due to the material removal, the supporting force needs to be adjusted to achieve better dynamic response improvement.

Fei et al. [5] presented a moving damper to increase the stability of the process. Stability of the process increased substantially. Nonetheless, since the moving damper is fixed to the machine itself, it can be used for only a particular workpiece unless the moving damper design is changed. The authors also investigated the deformation model for moving fixture [6]. Surface quality and machining errors are improved. Esfandi and Tsao [7] suggested using an industrial robotic manipulator to avoid machining vibrations for turning process of the thin walled cylindrical structures. The results encouraged the use of manipulator which provides higher cutting stiffness. Nevertheless, the robot sometimes influences negatively the stability of the machining process given that the robotic arm itself is not rigid.

Some researchers have also studied the effect of the supporting preload force. Bo et al. [8] investigated the influence of supporting force of moving support on machining stability during mirror milling operation of the thin-walled structure. Supporting force influences not only machining stability but also the dynamic behaviour of the workpiece.

In this paper, an actively controlled robot arm which is modelled as a three degree of freedom system, is simulated for milling process in time and frequency domain. The aims are to improve chatter stability, select the most effective actuator assembly point, and compare the effect of the contact type between robot and workpiece. In section 2, contact parameter identification using the receptance coupling formula is presented. In section 3, an inertial actuator which can provide active control for robotic assisted milling is introduced. The effect of the active control on the chatter stability improvement is simulated and evaluated, focussing on the direct velocity feedback (DVF) as a control strategy. In the last section, the stability lobe diagram is estimated for the process.

2 IDENTIFICATION OF CONTACT PARAMETERS

The proposed robot and machine tool configuration is shown schematically in Figure 2.1. Here, a flexible robot is pushed against a flexible workpiece via a soft contact interface whose dynamics must be identified. The machining stability can be improved by using an active vibration control device on the end effector. During the milling operation, preload will be applied through the STAUBLI TX90 robot to stiffen the flexible workpiece. It should be noted that for the purposes of this proof-of-concept experiment, a nominal 'thin walled workpiece', is replaced by a solid workpiece block that is mounted on a flexure. The contact parameters which are stiffness and damping ratio, between the end-effector that is hard rubber, and the flexure are identified by receptance coupling formula [9]. Parameters are identified when 240 N support force is applied to the flexure.

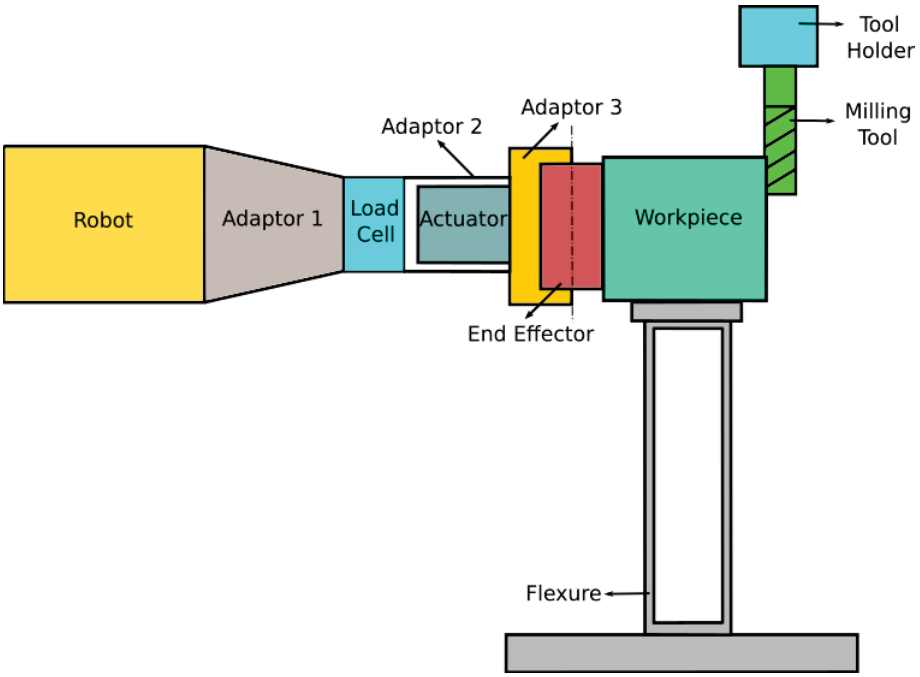

Figure 2.1: Actively Controlled Robot Arm for Milling

The workpiece and robot are modelled as single and three degree of freedom system, respectively. The combined system's frequency response function (FRF) is calculated as;

$$FRF_{combined} = FRF_{part} - FRF_{part}(FRF_{part} + FRF_{robot} + \frac{1}{K'})FRF_{part} \tag{1}$$

$$K' = k + iwc \tag{2}$$

where $FRF_{combined}$, FRF_{part}, FRF_{robot}, k, c and w are the combined FRF, workpiece FRF, robot FRF, contact stiffness, damping and the frequency, respectively.

As a first step, flexure and robot were tested using a modal hammer and accelerometer. The flexure FRF was measured at its midpoint. Since the robot's stiffness varies due to the configuration, the robot was tested on the end-effector while the robot was not touching the flexure but very close to the measurement point. Then, the experiments were repeated with

hard rubber supporting the workpiece at the middle point of the flexure. The flexure flexibility is improved 61% by utilizing preload through the robot as seen in Figure 2.2. Seeing that the experimental contact is flexible, the coupled system's natural frequency is changed from 380 Hz to 399 Hz. The contact stiffness and damping are identified for flexible contact as 4.5e5 N/m and 35.5 Ns/m, respectively.

Also, the combined FRF is estimated for rigid contact. If the contact was assumed as rigid contact, which can be provided with a metal castor end-effector presented by Barrios et. al. [10] by using a different robot, natural frequencies would have been shifted close to robot's natural frequencies which are 32, 76 and 136 Hz.

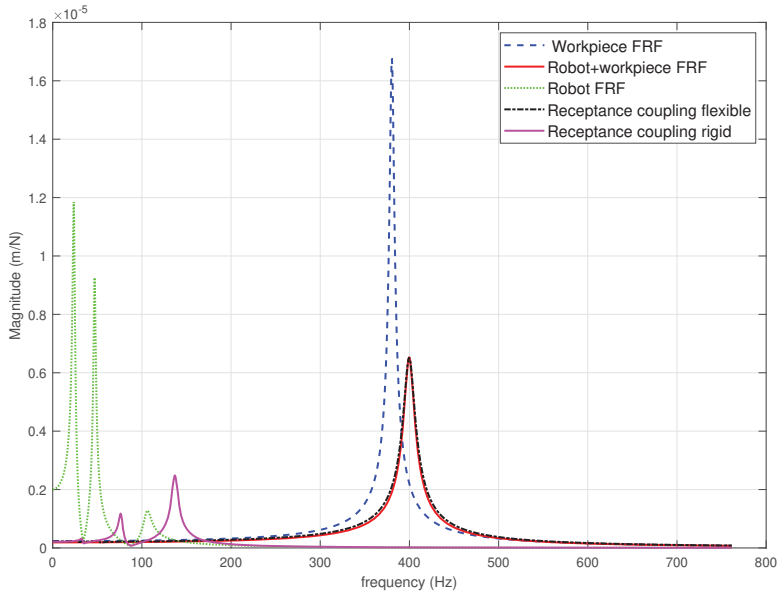

Figure 2.2: Frequency Response Functions and Receptance Coupling Model

3 ACTIVE CONTROL AND SIMULATION RESULTS

Active control is simulated for robotic assisted milling by using an actuator as shown in Figure 2.1. The direct velocity feedback (DVF) control system is selected as it is a model free control method and easy to apply. Once it is implemented, only the gain needs to be adjusted. An inertial actuator is chosen as this approach is easily deployed on the robot's end effector.

3.1 Inertial Actuator

The inertial actuator seen in Figure 3.1 can be represented by a vibrating mass m_p with a damper c_p and spring k_p. The mass is excited by a electromagnetic force f_a according to the voltage input V_{in}. The transfer function between the mass displacement x and the voltage input V_{in} can be written as,

$$\frac{x(s)}{V_{in}(s)} = \frac{G_1 G_2}{ms^2 + cs + k} \tag{3}$$

where G_1 is the electromagnetic gain and G_2 is the power amplifier gain [11].

The transfer function between the reaction force f_a and the voltage input V_{in} can be written as,

$$\frac{f_a(s)}{V_{in}(s)} = \frac{-G_1 G_2 m s^2}{ms^2 + cs + k} = g_a \frac{s^2}{s^2 + 2\zeta\omega_p s + \omega_p^2} \tag{4}$$

where ω_p is the natural frequency, ζ is the damping ratio of the actuator and g_a is the actuator gain [11].

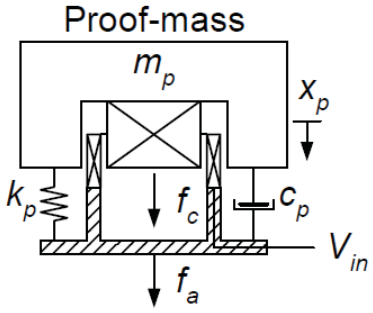

Figure 3.1: Proof-Mass Actuator [12]

An inertial actuator which is a model of Micromega Dynamics, is used to perform the simulations. This actuator has a mode at 8.4 Hz and is capable of applying up to 45 N supporting force up to 2000 Hz. Its transfer function [13] can be written as:

$$\frac{f_a(s)}{V_{in}(s)} = 5\frac{s^2}{s^2 + 15.834s + 2785.6} \tag{5}$$

3.2 Case Studies

In this section, 4 cases which show the effect of the actuator, actuator assembly point, and effect of the contact parameters, are presented. Time domain solutions are solved by ODE 45 function within a Matlab environment. This function implements a Runge-Kutta method with a variable time step for the time domain solution. Robot and workpiece are modelled as a three and single degree of freedom, respectively. Model parameters and cases can be seen in Table 3.1 and Table 3.2.

Table 3.1: Model Parameters

Parameters	Value (kg)	Parameters	Value (N/m)	Parameters	Value (Ns/m)
M_1	32.8	K_1	7.3e5	C_1	573
M_2	21.6	K_2	1.88e6	C_2	368
M_3	21.4	K_3	9.47e6	C_3	1210
M_4	0.748	K_4	4.5e5	C_4	35.5
M_a	1	K_5	4.27e6	C_5	25
		K_a	2785.6	C_a	15.83

Table 3.2: Cases

Case Number	Explanation
Case 1	Preloaded case, without actuator
Case 2	Actuator on the end-effector, flexible contact
Case 3	Actuator on the end-effector, rigid contact
Case 4	Actuator on the workpiece, flexible contact

The first case is uncontrolled and has a flexible contact. Three degree of freedom robot supports the workpiece. Vibration on the workpiece is suppressed by applying preload through the robot. Its spring-mass model can be seen in Figure 3.2.

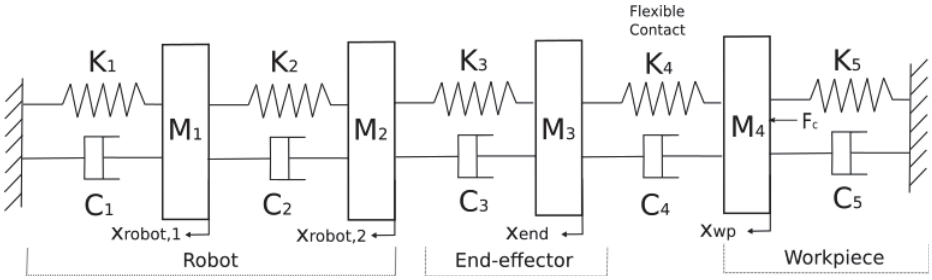

Figure 3.2: Flexible Contact Without Actuator

The natural frequency of the workpiece is shifted from 380 Hz to 399 Hz in this configuration. The model natural frequency is calculated by Cramer's rule [14]. The amplitude of the workpiece is reduced by around 61%. This scenario matches the results already presented in Figure 2.2.

Case 2 is with the actuator mounted on the end-effector seen in Figure 3.3. So as to carry out the direct velocity feedback (DVF) control method, vibration of the end-effector is differentiated to velocity and the velocity is multiplied with feedback gain to drive the actuator.

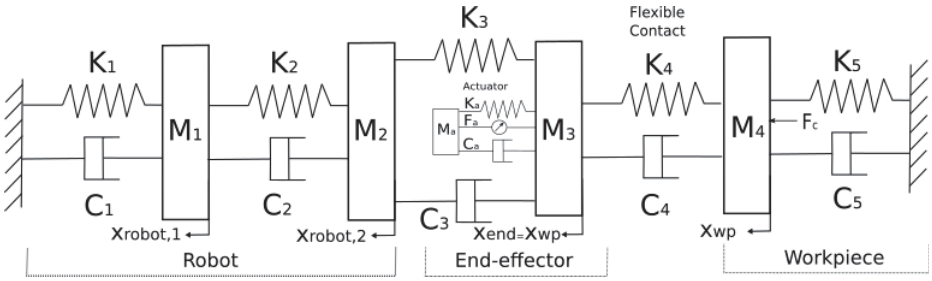

Figure 3.3: Actuator on the End-effector with Flexible Contact

The simulated FRF for this case is shown in Figure 3.4. The input force is implemented on the end-effector and workpiece while output is measured on workpiece for both simulations. Direct FRF (red dashed line) for the workpiece has only one mode at 399 Hz yet the cross FRF (blue solid line) has two modes at 19 Hz and 54 Hz. In practice when the optimum gain limit is exceeded, the system becomes unstable due to actuator nonlinearities such as force and stroke

saturation. So, the optimum actuator gains were determined via simulations and the best case scenario is presented in Figure 3.5. In the simulations, a sinusoidal excitation force of 100 N at 399 Hz, was applied to the workpiece to approximately represent the forces due to the milling operation. Figure 3.5 shows the simulated workpiece response under these conditions. It can be seen that the actuator cannot provide enough force to suppress the vibration on the workpiece since the vibration on the end-effector is too small due to the flexible contact. Consequently, the actuator is ineffective and the workpiece vibrations are not suppressed.

Nevertheless, if the system is excited with 100 N at 19 Hz, vibration on the workpiece is suppressed by 23% shown in Figure 3.5b. Vibration on the workpiece is decreased up to feedback gain g=800. Gain greater than 800 makes the system unstable due to the actuator nonlinearity.

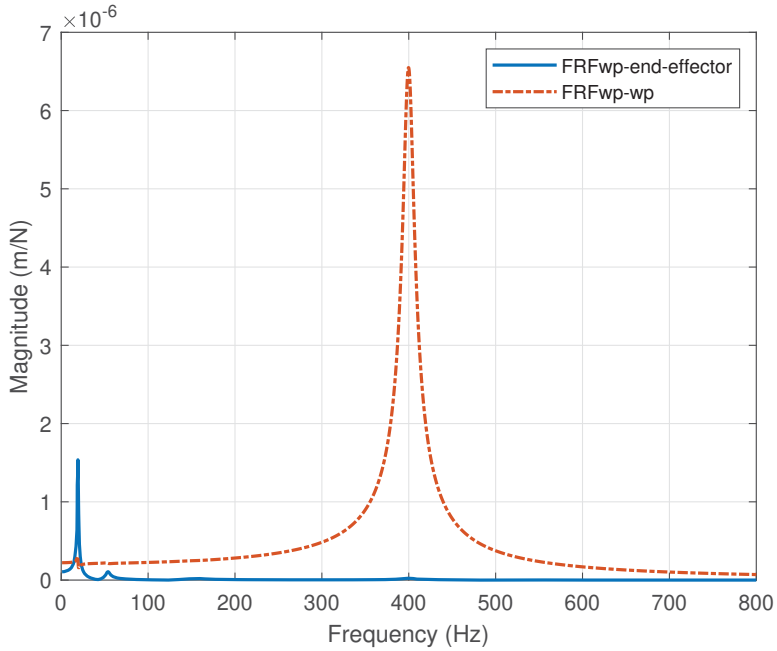

Figure 3.4: Frequency Domain Model for Case 2

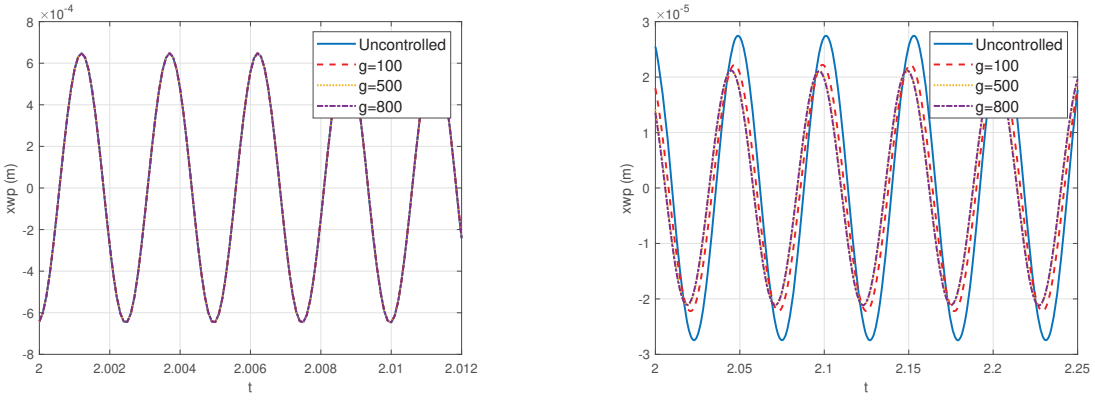

(a) Excitation Force at 399 Hz

(b) Excitation Force at 19 Hz

Figure 3.5: Workpiece Vibration for Case 2

Case 3 is with the actuator on the end-effector with rigid contact (metal castor) as shown in Figure 3.6. Since the vibration on the end-effector is equal to workpiece's vibration, the actuator can provide the vibration suppression on the workpiece. Rigid contact decreases the natural frequencies to 34, 65, 160 Hz. All three modes are damped by active control.

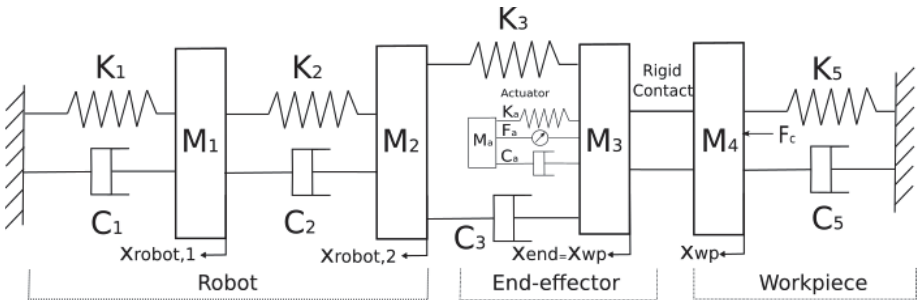

Figure 3.6: Actuator on the End-effector with Rigid Contact

To excite the system a sinusoidal force which is 50 N at 65 Hz is applied. 65 Hz is the most flexible frequency for the workpiece. Actuator force varies from 13 N to 45 N for the gains: 100 (dashed red line), 500 (dotted yellow line), 1000 (dash-dot purple line), 2500 (solid green line) and blue solid line is for the uncontrolled system shown in Figure 3.7. Workpiece vibration is suppressed around 90% for the case 3. Since the maximum produced force by the actuator is 45 N, gain can be increased up to 2500 for this excitation force value. If the gain is selected greater than 2500, the system will be unstable owing to the force saturation.

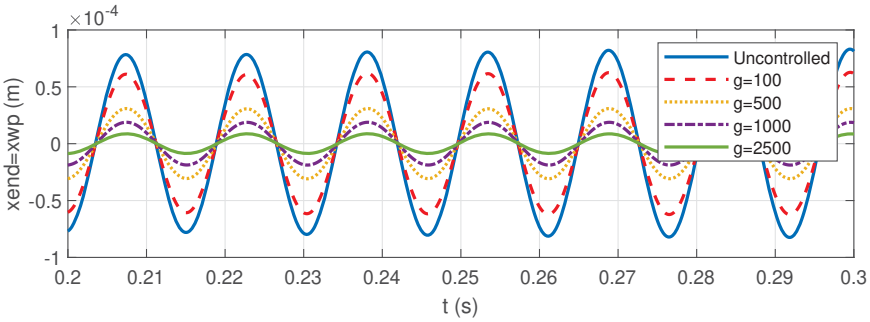

Figure 3.7: Time Domain Model with Rigid Contact

Case 4 with actuator on the workpiece can be seen in Figure 3.8. The contact between the end-effector and the workpiece is flexible. In this case, the support is fixed support since the actuator is assembled directly to the workpiece. 50 N at 399 Hz sinusoidal excitation force is implemented. Optimum gain is determined as 5000, yet the gain only can be increased to 150 owing to the actuator force limitation. Time domain result is shown in Figure 3.9. Actuator force varies from 20 N to 45 N for the gains 10 (dashed red line), 50 (dotted yellow line), 100 (dash-dot purple line), 150 (solid green line). Vibration on the workpiece is suppressed around 90%. If the gain was increased up to 5000 without actuator force limitation, vibration on the workpiece could have been suppressed around 99%.

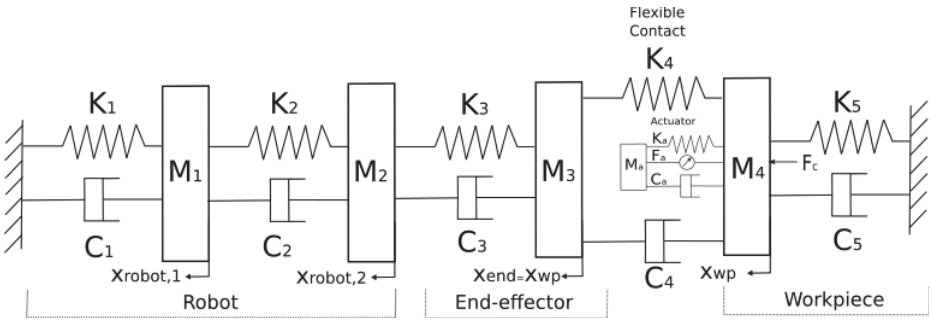

Figure 3.8: Actuator on the Workpiece

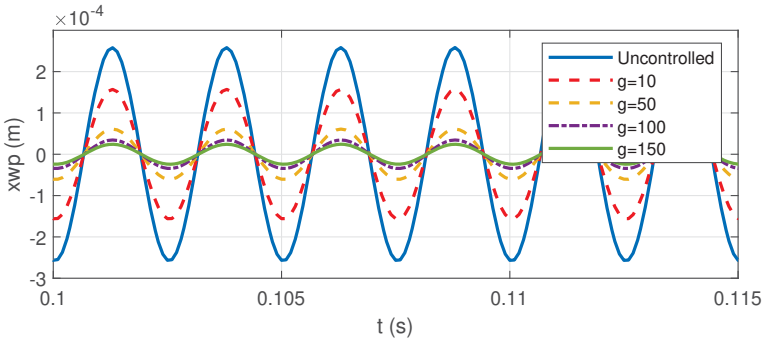

Figure 3.9: Time Domain With Actuator on the Workpiece

All the cases are compared in regards of workpiece vibration whilst the robot applies the preload to the midpoint of the flexure. The effect of preload point can affect the results slightly, which is given in the next section.

3.3 The Effect of Robot Position

The robot applied the preload to the midpoint of the flexure in the previous section. The flexibility of the flexure is improved 61%. However, if the robot applies the preload to the edge point of the flexure, the flexibility is improved 51%. Case 4 results are compared for both robot's preload position and it is presented in the Figure 3.10. The DVF control method is applied with the same gains (10, 50, 100, 150) to the case 4 for both robot's position. In terms of controlled vibration results, there is no significant difference.

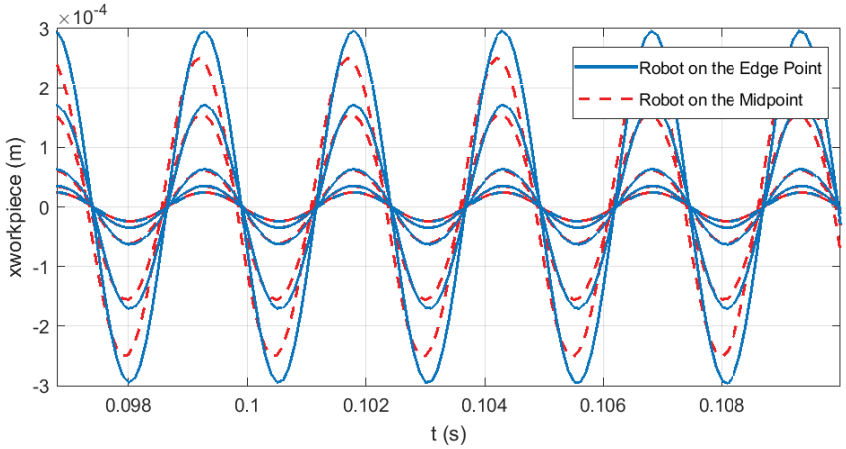

Figure 3.10: Comparison of Robot's Position Effect on Vibration Result

All cases are evaluated regarding vibration of the workpiece. By using active control through the robot, the dynamic response of the structure can be improved significantly. Contact parameters and the actuator assembly point are very critical in order to get a well damped and stable system. Selection of the end-effector and the actuator assembly point must be taken into consideration for further applications. From a machining context the implications of this vibration suppression can be considered from the perspective of the chatter stability. This is considered in the next section.

4 STABILITY LOBE DIAGRAM

Selection of proper axial depth of cut and spindle speed is important to avoid chatter vibrations [1]. Stability lobe diagram is often used to select optimal parameters so as to improve productivity. The stability lobe diagram is estimated for the robot configurations described in Section 3 in order to demonstrate the performance improvement that can be obtained from a manufacturing context.

The stability lobe diagrams were obtained using Budak and Altintas's method [15]. Details of this approach are outside the context of the current contribution, but the theory and method is widely reported elsewhere [1, 15]. Down milling was a assumed, with a 20 mm diameter 4 tooth tool and a radial immersion of 3 mm. The workpiece was assumed to have a cutting stiffness of Ks=796e6 N/m2, Kt=768e6 N/m2, corresponding to Al-7075-T6 material. With reference to Figure 4.1, five scenarios are shown:

- Flexible workpiece without active control and preload (blue solid line)
- Case 1: With preload which is implemented through the robot arm (red dashed line)
- Case 3: With the actively controlled robot arm by the inertial actuator on the end-effector, rigid contact (for g=150 dotted green line, for g=2500 purple dash-dot line)
- Case 4: With the actively controlled robot arm by the inertial actuator on the workpiece, flexible contact (for g=150 black solid line)

SLD is not developed for case 2 since the FRF was no improved in this scenario.

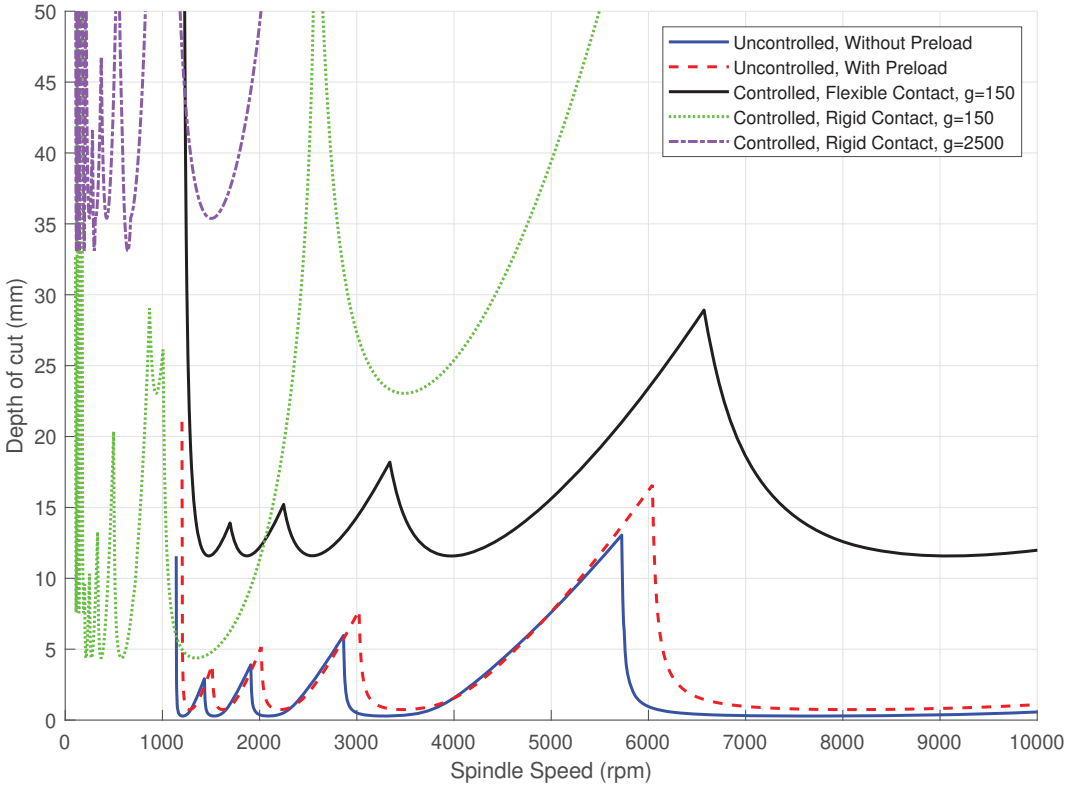

Figure 4.1: Stability Lobe Diagram

Comparison of the limiting (min) depth of cut for each cases can be seen in Table 4.1.

Table 4.1: Comparison of the Limiting Depth of Cut b_{lim}

Cases	blim (mm)
Uncontrolled, Without Preload	0.29
Case 1, Uncontrolled, With Preload (240 N)	0.74
Case 3, Controlled, Actuator on the End-Effector, Rigid Contact, g=150	4.38
Case 3, Controlled, Actuator on the End-Effector, Rigid Contact, g=2500	33.09
Case 4, Controlled, Actuator on the Workpiece, g=150	11.58

As seen in Figure 4.1 and Table 4.1, the depth of cut is increased around 2.5 times with preload through the robot arm. To achieve greater depth of cut, active vibration control is applied. The greatest depth of cut is achieved when the actuator is assembled on the end-effector with rigid contact, gain=2500. However, when the actuator is mounted directly onto the workpiece, the depth of cut is improved more than when the actuator is mounted on the end-effector.

5 CONCLUSIONS

The purpose of the current study is to determine the dynamic response improvement in milling operation by using an actively controlled robot arm. The concept is evaluated in terms

of the contact type between the robot, workpiece, and actuator. Direct velocity feedback (DVF) control method is performed in order to improve the dynamic response. It is concluded that the actively controlled robot arm can improve the productivity of the milling process by decreasing the vibration on the workpiece.

In the conducted simulations, workpiece vibration is damped around 61% by applying preload through the robot to the midpoint of the flexure. An inertial actuator is mounted on the end-effector and the workpiece for different cases to compare the effect of the actuator assembly point on the dynamic response. An actuator on the end-effector with flexible contact cannot improve the dynamic response of the workpiece except at low frequencies. However, when the actuator is assembled on the end-effector with rigid contact, the vibration on the workpiece is significantly decreased to around 90%. If the actuator is mounted directly onto the workpiece, rather than via the robot, then the workpiece vibration decreases by around 90%. Similar performance improvements can be observed in the so-called stability lobe diagram for a machining scenario. To summarise, the work has proved the concept of using a robotically assisted active vibration control system, for the machining of flexible workpieces. It has been shown via simulations that improved machining stability can be achieved even when accounting for the flexibility of the robot and the workpiece to robot contact.

As future work, all the simulations will be validated by experimental study. Direct velocity feedback control method will be compared with more sophisticated control methods such as PID, LQG, LQR and H_∞. Finally, different end-effectors can be designed to compare the contact parameter effect on the chatter stability.

Keywords: Accidental torsion, response spectrum analysis, response history analysis

Abstract. *Building codes for seismic resistant design of building structures generally include requirements for imposing an "accidental" torsion response. Methods for incorporating such effects into the analysis are ad-hoc at best and have not changed significantly over the past 50 years. This is despite the tremendous advanced in analytical and computational capabilities over the same period. The current building code methodology for including accidental torsion depends on the analytical method. For linear static approaches, lateral forces are applied at an eccentricity that depends on the sensitivity of the system to torsional effects. Where modal response spectrum analysis (MRSA) is used, the torsion may be included by imposing a mass offset or adding the accidental torsion as in linear static analysis. Where linear or nonlinear time history analysis is utilized, the mass offset approach has been used almost exclusively.*

In a recent report published by FEMA (FEMA P-2012), it was found that the dynamic mass offset procedure could produce grossly unsafe designs relative to the static load approach for torsionally sensitive systems. For this reason, it was recommended that the mass-offset approach not be used in MRSA or in linear time history analysis (LTHA) for systems with extreme torsional irregularities. A recent supplement to ASCE 7-16 included the restriction on MRSA but not on time history analysis. In this paper, the mass-offset approach for including accidental torsion in the dynamic analysis is evaluated in detail and compared with the static analysis for different building configurations. It was found that for the analyzed buildings, MRSA predicts well the demands obtained using LTHA, and hence, the prohibition of the mass offset approach for accommodation accidental torsion should be extended to response history analysis.

1 INTRODUCTION

Current codes and standards such as the ASCE 7-16 [1] provide three approaches that can be used to perform a seismic structural design considering accidental torsion in buildings using linear analyses. The first approach implemented uses the equivalent lateral force (ELF) procedure, the second one uses modal response spectrum analysis (MRSA), and the third uses linear time history analysis (LTHA).

The ELF procedure uses a linear static analysis to represent the seismic force distributed along the building´s height. This procedure concentrates the seismic loads at the center of mass of each floor. In addition, if the building is torsionally irregular, accidental torsion is included in two steps: 1) moving the applied load to an eccentricity of 0.05 times the building width perpendicular to the direction of loading, 2) amplifying the effect if the torsion is considerable. The amplification factor A_x is calculated using equation (1), The factor is computed using the maximum (δ_{max}) and average displacements (δ_{avg}). The amplification factor need not be taken as less than 1.0, and has an upper limit of 3.0.

$$A_x = (\delta_{max}/1.2\delta_{avg})^2 \qquad (1)$$

The modal response spectrum analysis uses the modal shapes of the structure to calculate its dynamic response. When this procedure is used, two methodologies are proposed to incorporate accidental torsion if the structure is torsionally irregular. The first one consists in adding accidental torsion to the modal response as a static load. For this purpose, the modal analysis is carried without a mass eccentricity. The second method, which is commonly used, is to explicitly incorporate the eccentricity in the dynamic properties of the model by applying a mass eccentricity to the building so the effect of accidental torsion is inherent.

The linear response history analysis approach uses ground motions scaled to the design spectrum to calculate the building's response. Accidental torsion is explicitly included by moving the center of mass. This approach demands more computational resources than the previous ones but has certain advantages, such a retaining the signs of the computer response quantities.

In a recent report, FEMA P-2012 [2], it was found that the dynamic mass offset procedure could result in unsafe building designs relative to the static load approach for torsionally sensitive systems. Similar findings were reported in De la Llera and Chopra (1994) [3]. FEMA P-2012 recommends that the mass-offset approach not to be used in linear dynamic analysis. However, a 2019 update to ASCE 7 included the prohibition for modal response spectrum analysis but not for linear response history analysis. Thus, the main focus of this paper is to establish differences in responses when the mass-offset approach is used in ELF, MRSA and LTHA. First, displacement and rotation demands are computed using the ELF and MRSA approaches in a series of one-story buildings with different configurations. Then, the paper studies the pertinence of MRSA to capture the same demands produced in the LTHA and, therefore, note a contradiction in that recommendation regarding the prohibition of MRSA for torsional sensitive buildings in ASCE 7.

2 METHODOLOGY

The FEMA P-2012 recommendations state that the difference between the ELF and the MRSA is critical under torsionally sensitive buildings. Therefore, to compare both design methodologies three-dimensional models with different plan ratios (PR) and lateral system distributions were used. The models are based on a previous torsional research building stud-

ied by Flores et al (2018) [4], which consists of a 9-story building with buckling restrained braces (BRBs) as a lateral resisting system. However, in this research, only the top floor was taken as a one-story building, varying the lateral system positions as seen in Figure 1a to investigate different torsional irregularities. The element sections are shown in Figure 1b. Also, the archetype present leaning columns uniform distributed on the building area to capture geometric second-order effects.

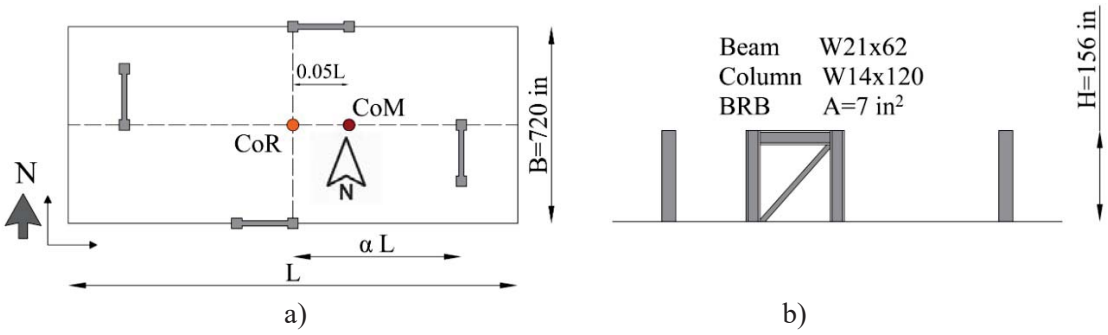

Figure 1 a) Plan View and b) elevation view

The mass of the building was assigned with lumped masses distributed according to Figure 2, and each node on the grid had a lateral mass only acting in each direction (i.e. North-South and East-West). The rotational mass moment of inertia was generated automatically by linking all nodes with a rigid diaphragm. In order to consider accidental torsion, a portion of the mass was shifted from the left to the right side, so each side sum (1-*x*)*M*/2 and (*x*)*M*/2, respectively. The value for *x* was chosen as 0.50 and 0.60, giving rise to eccentricities of 0% and 5% respectively. The total mass assigned to the structure was calculated to obtain a fundamental period of 1 second approximately on each lateral direction for merely academic purposes.

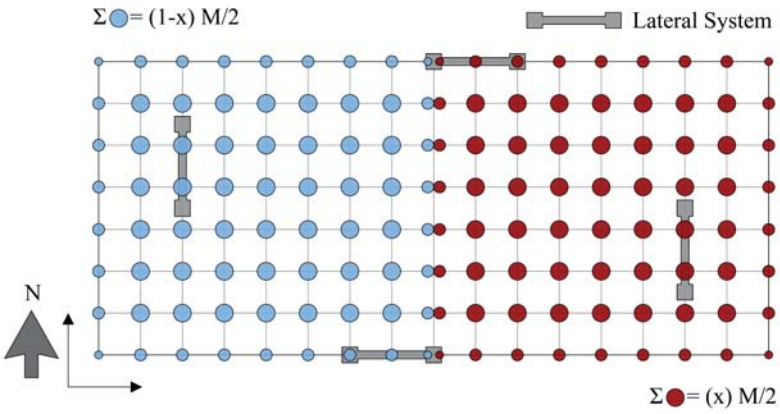

Figure 2 mass shifting eccentricity

With the base archetype configuration, several models were developed varying the plan ratio (PR) and the position of the North-South lateral system (NS-LS) respect of the building's length (L). Meanwhile, the East-West (EW) plan dimension and the lateral resistant system remains invariant for all the models. Three PR ratios were used: 2 to 1, 3 to 1, and 4 to 1. In

addition, several positions of the NS-LS were considered which are defined by the parameter α, where α represents the distance of the NS-LS from the geometric center. It is necessary to clarify that the positions of the NS lateral system are always symmetric respect to the geometric center. It means that when α is equal to 50%, the NS lateral system will be located at the perimeter, while for α equal to 0%, the NS will be located at the geometric center.

The three-dimensional elastic models were implemented using the software OpenSees [5]. Also, the models consider a 5% Rayleigh damping ratio applied on the 1st and the 3rd modes of the structure. The damping ratio was selected to be consistent with the design spectrum that uses a 5% target damping.

2.1 Equivalent Lateral Force vs. Modal Response Spectrum Analysis.

The previously defined models were used to determine the differences in design parameters and demands between the equivalent lateral force (ELF) and the modal response spectrum analysis (MRSA) design approaches. The equivalent lateral force (ELF) procedure was performed with a concentrated load corresponding to the weight of the structure (W) times the spectral acceleration ($Sa(T_1)$) consistent with the NS translational mode (i.e. 1sec.). Initially, the load was applied to an eccentricity of 5%, then at an eccentricity of A_x times 5%. Meanwhile, modal response spectrum analysis (MRSA) was performed using all the modes of the building (three), with a CQC modal combination. The design response spectrum corresponds to a D_{max} seismic risk as defined in FEMA P-695 [6] with a maximum spectral acceleration (S_d) of 1.0, and a one-second acceleration (S_1) of 0.6.

One of the initial considerations of building design is to determine if the building has torsion irregularities. The ASCE 7-16 uses the maximum story drift at a building's edge and the average story drift given a static force applied at 5% eccentricity to evaluate torsional irregularities. FEMA P-2012 defines this ratio as the Torsional Irregular Ratio (TIR). ASCE 7-16 also allows calculating the TIR with the MRSA as established in the commentary (i.e. performing a combination of the maximum and average drift for each mode). Therefore, the TIR is calculated with both methods to assess the differences under a variety of building configurations.

After computed and compared the TIR, the demands of the ELF analysis were adjusted with the amplification factor A_x to increase the torsional effects, calculated with the equation (1). The ELF final demands and the demands obtained with the MRSA were compared in terms of the maximum displacement reached in the NS direction and the maximum rotation of the rigid diaphragm. This evaluation was carried to study the initial statement of the FEMA P-2012 that MRSA leads to unconservative design for torsional sensitive buildings, and extend the study to rotational demands as a new indicator of torsional effects.

2.2 Modal Response Spectrum Analysis vs. Linear Time History Analysis.

Once the difference between the ELF and the MRSA was assessed, a comparison between the latter one and the linear time history analysis (LTHA) was performed. The demands were assessed in terms of the NS displacements and the rotation of the rigid diaphragm as well to make comments on the FEMA P-2012 recommendation about limiting the use of linear dynamic analysis.

The LTHA was conducted using 11 ground motions obtained from the Far-Field dataset provided by the FEMA P-695 document that represents a D_{max} seismic risk corresponding with the design spectrum used in the previous analyses. The 11 ground motions were matched to the spectrum using a spectral matching process [7] to reduce the variances between the ground motion response spectrum used for the LTHA and the design response spectrum used

for the MRSA. In the comparisons, the LTHA demands were considered as the average response of the 11 ground motions following the ASCE 7 code methodology.

3 RESULTS AND DISCUSSIONS

3.1 Response comparison RSA vs Static

First, the Torsional Irregular Ratio was calculated using the static method and the dynamic MRSA. The results for plan ratios 2, 3 and 4-to-1 for different locations of the NS-LS are shown in Figure 3a. It can be seen that TIR calculated with the static method increases when the NS-LS is moved towards the CoR. This is consistent with the figure shown in commentary C12.8.4.3 of ASCE 7-16, which shows the torsional amplification factor. However, when calculating the TIR with the MRSA, this value does not necessarily increase when the NS-LS is moved toward the center. This happened due to the dynamic properties when the mass is shifted to one side as will be explained in the following subsections.

Additionally, Figure 3b shows the torsional amplification factor A_x that was used to increase accidental torsion for the static method in the models. It has to be mentioned that the dynamic methods do not need to increase the demands with their corresponding A_x as is mentioned in the newest code version (ASCE7-16).

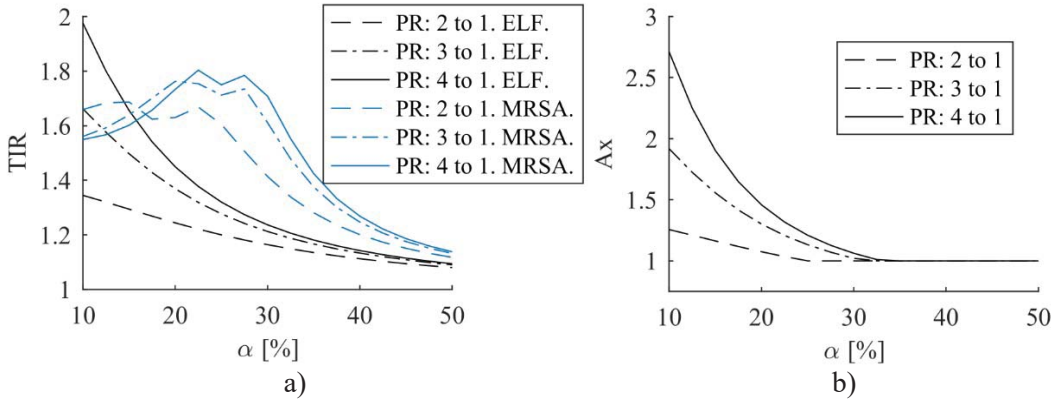

Figure 3 a) TIR calculated using ELF and MRSA and b) Torsional Amplification Factor for ELF

Figure 4 shows the drift's demands measured at the North-East and North-West corners (NE and NW, respectively) of each building configuration. Additionally, it shows the maximum drift envelope for MRSA. It should be noted the sensitivity of the demands to the location of the NS-LS and the plan-ratio. For the static method, the drift demands increase when the NS-LS is moved towards the center, and that increment rate is greater when the plan-ratio is larger. On the other hand, for MRSA, the drift demands start to increase when the NS-LS is moved towards the center but it reaches a point where the demands tend to stabilize or even decrease as happened with the TIR. Additionally, it should be noted that the increment rate remains almost the same for all building plans which drastically differs from the ELF.

Thus, it can be said that models with NS-LS at the perimeter have similar maximum responses for both methods despite their plan ratio. In contrast, when the NS-LS was moved towards the center, the calculated demands start to differ, especially for longer plan ratios (e.g. 4 to 1 plan ratio). Therefore, it can be inferred that a design based on the ELF will end up with more robust elements. This is congruent with [3] and helps to explain the findings stated in

[2], [8], where buildings designed with ELF had a better collapse performance than buildings designed with MRSA.

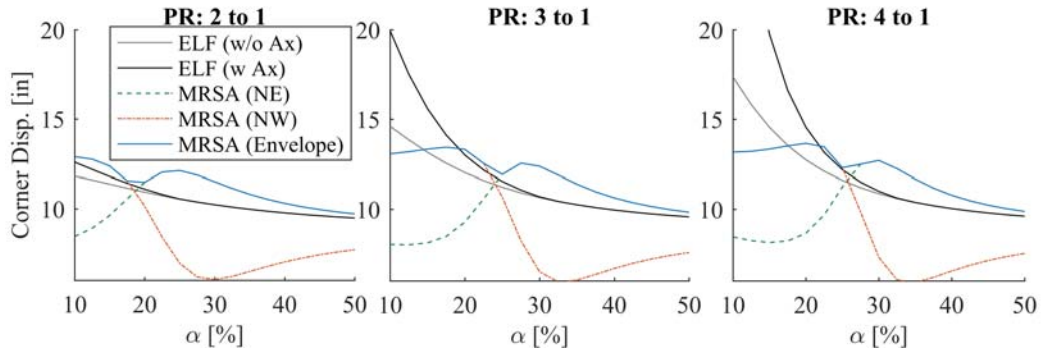

Figure 4 ELF and MRSA maximum corner displacements

Since the MRSA gives only positive results, using displacements can bias the evaluation of torsional effects. However, the diaphragm rotations can help to evaluate the torsional effects on buildings modeled with a rigid diaphragm. Rotation demands for ELF and MRSA are shown in Figure 5.

Once again, the ELF produces demands that increase with greater plan-ratios and NS-LS located towards the center. In the case of MRSA, the rotation demands increase until a given configuration and then start to decrease, similar to drift demands. It is also seen that the rotations produced by MRSA decrease with greater plan ratios, contrary to the behavior of ELF.

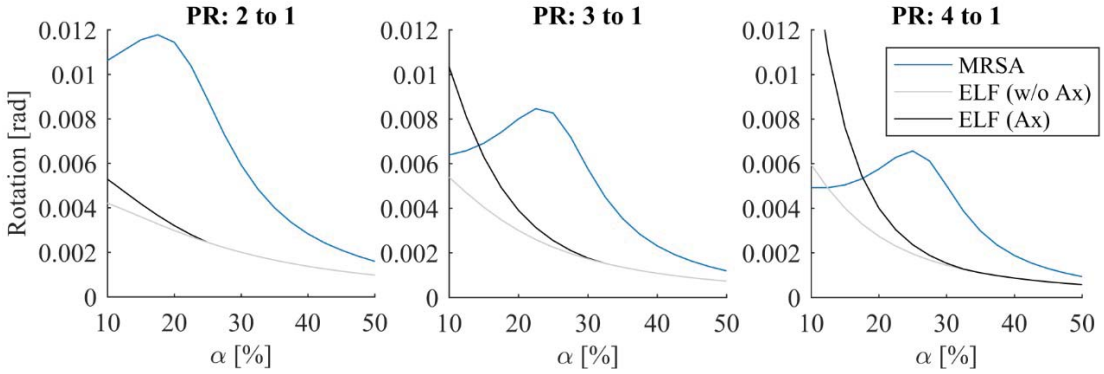

Figure 5 ELF and MRSA maximum diaphragm rotations

3.2 Response comparison LTH vs RSA

As seen before, for models sensitive to torsional effects (low alphas and larger plan ratios), the MRSA produced lower demands than the static method. This could be the reason why ELF designed buildings have a better collapse performance when compared to buildings designed with MRSA. However, it does not mean that the MRSA underestimates the elastic demands produced in those models in relation to LTH as it will be shown in this section. Figure 6 shows the maximum drift for the NE and NW corners resulting from MRSA and LTH with mass shifted 5%L to the east side. It is seen that both methods give similar absolute maximum

results. It could have been expected that when the mass is shifted into the east direction, the NE corner will have larger forces and therefore larger displacements as happens on the ELF. In agreement, the NW corner will have fewer demands and displacements. However, it can be seen that once a certain location of the NS-LS is reached, a different behavior occurred and it can be explained with the interaction of the modes and their participation factors. That mode interaction causes that for torsional sensitive configurations (i.e. with the NS-LS located toward the center) the opposite corner is subjected to higher demands. This involves that, for a given location (i.e. α=20-25% for the analyzed building) the maximum demands for both corners are the same. In the case of MRSA, the sign and the time when maximum demands occurred are lost. This can cause a misinterpretation that there are not torsional effects, and if the TIR is calculated based on the average of those values rather than the average at each mode as explained in the ASCE commentary, there would be a TIR of 1.

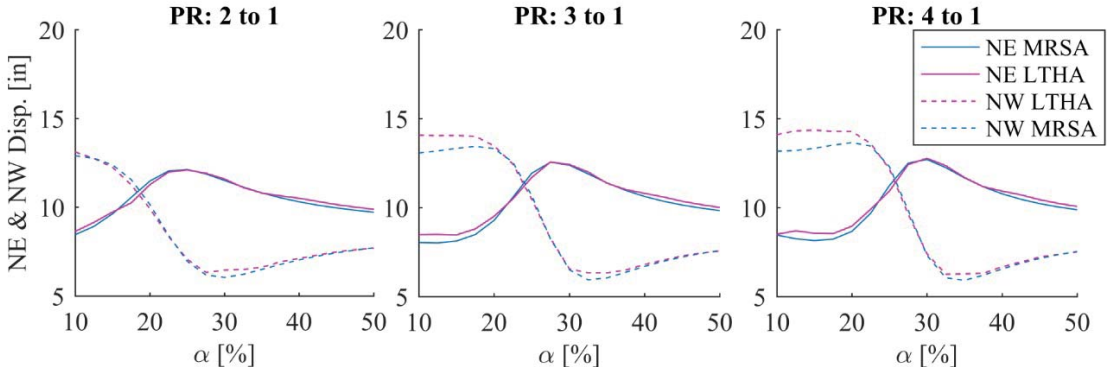

Figure 6 LTH and RSA maximum corner displacements

It must be noted that those maximum drifts don't happen at the same time as can be assessed in LTHA. Thus, when the maximum drift is reached at one of the corners, the other corner is subjected to fewer drifts than what is predicted in MRSA due to the loss of sign and time of events. This is illustrated in Figure 7 where the maximum displacements for both methods are equal but the demands of the opposite edge differ when time and sign are accounted in LTHA. When the MRSA predicts the same maximum displacement for both corners (i.e. α=20-25%), LTHA shows the bigger differences between them, even reaching displacements with different signs.

This phenomenon was studied by tracking the rotations to evaluate whether there were torsional effects or not, and in fact, it was found that the point where both corners have the same maximum displacement, the diaphragm rotation reaches its maximum value as shown in Figure 8. So, it must be noted that the maximum displacements were reported, however, they do not occur at the same time. Under this circumstance, the RSA could not be effective if torsional effects are predicted by only having the displacements as a reference but the diaphragm rotation can work as a new parameter to account for torsional effects. Once again, it is seen that both methods give almost the same results (of course, RSA requires less computational effort).

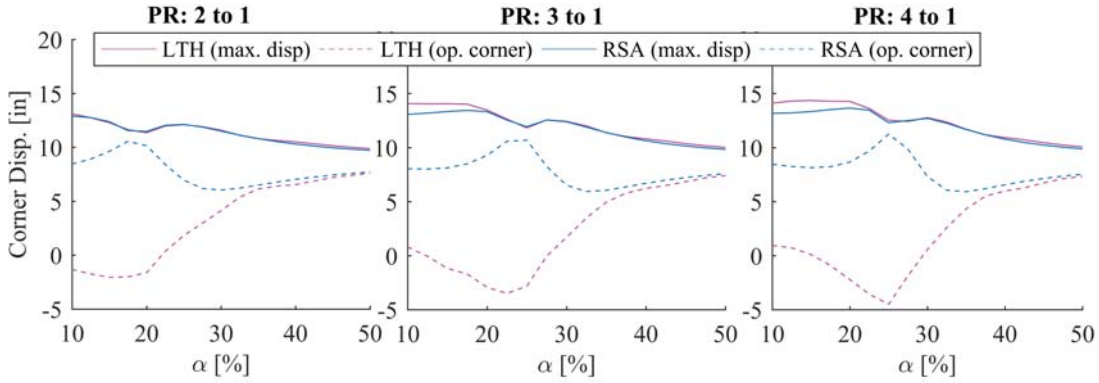

Figure 7 LTHA and RSA maximum corner displacements and displacement of the opposite corner

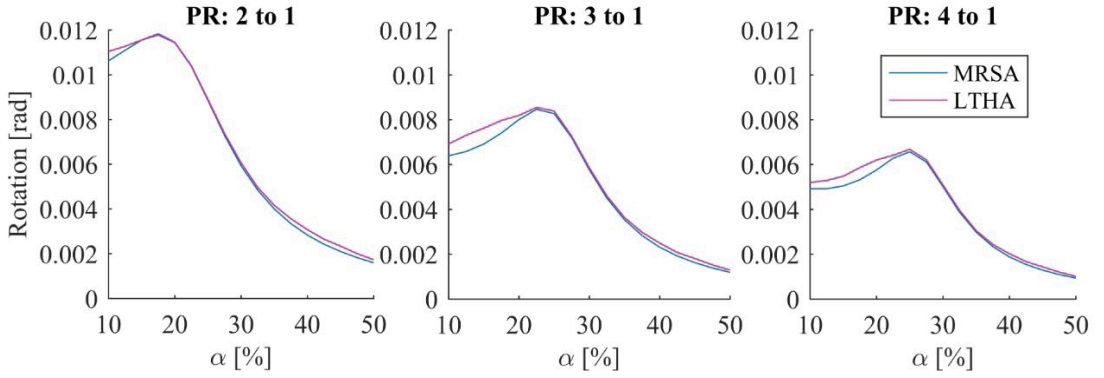

Figure 8 LTH and RSA diaphragm comparison

Now, going a step further to explain why the NW corner increased its maximum displacements, the modal shapes and participation factors for some models are shown in Figure 9. It is clear that when there is no eccentricity, each mode is purely translational or rotational (i.e. the participation factors are 100% in NS, EW or rotation). Then, when a 5% mass offset is added, there cannot be identified a purely torsional and translation mode, instead, the 1st and 3rd mode are a mix of them and it is reflected in the participation factors. For configurations where the NS-LS is located towards the perimeter (e.g. α equal to 0.5), the 1st mode takes over the NS translation while the 3rd mode takes over the torsional component. The opposite happens when the NS-LS is moved towards the center; the 1st mode starts to control the torsional response while the 3rd mode controls the NS translation. However, this implies that for some configurations, the 1st and 3rd mode shares almost the same participation over translation and torsion as happens when α is set between 0.25 and 0.30 for plan ratio 4 to 1. In this last case, the 1st mode generates a larger translation in the east corners while the 3rd mode generated larger translation in the west corners and since its period and participation are almost the same, the displacements are also similar. That is why it could be misinterpreted that since both displacements are similar, there would not be rotation when actually that is when the maximum rotation is reached due to the combined effects of modes. In the case of the 2nd mode, it always remains as translational in the EW direction.

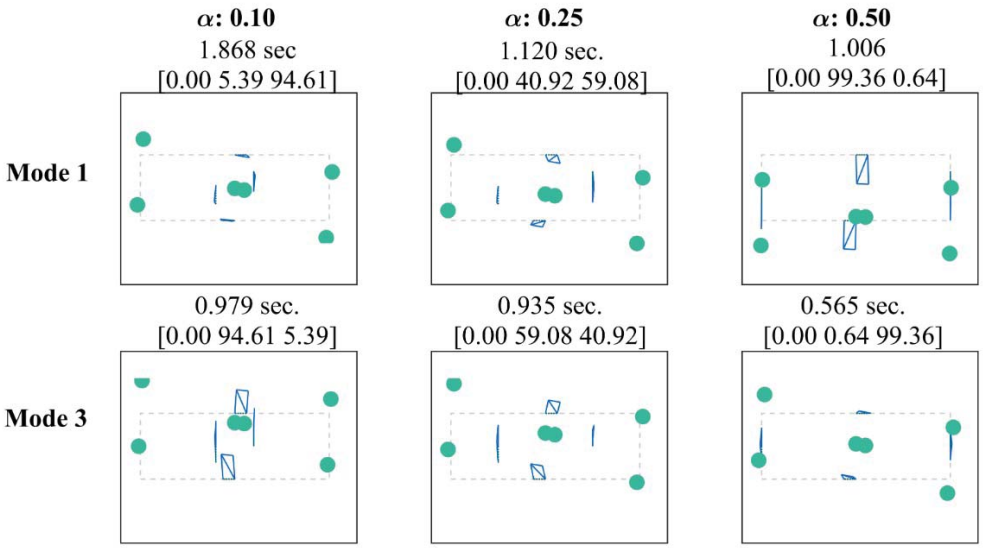

Figure 9 Modal response analysis for Plan Ratio 4 to 1 with different alpha values

4 CONCLUSIONS

The linear dynamic behavior of a structure differs from the static behavior; thus drifts and rotation demands are dependent on the method that was used.

- Starting with TIR, the static method shows an increment of the TIR when the NS LS is moved towards the center. However, MRSA causes the TIR to saturate once a given configuration is achieved, making the TIR decrease despite the NS LS is moved to-wards the center.
- Additionally, TIR calculated with static method increases for greater plan ratios for all values of alpha. MRSA produces the same behavior of the TIR but only for large values of alpha (greater than 25) before they saturate. For low alpha values, the TIR in MRSA can even decrease for greatest plan ratios but there is not much difference within the plan ratios.
- For larger values of alpha (greater than 25), the TIR calculated with MRSA is greater than the TIR calculated with the static method. It was also noted that after the saturation point, values of TIR calculated with the static method can be great than those computed with MRSA, especially for larger plan ratios.
- For large values of alpha, drifts calculated with MRSA are greater than those produced by the static procedure. However, for low alphas, the static procedure caused greater drifts demands even without the torsional amplification factor (Ax). Once again, the differences are more notorious for larger plan ratios.
- In terms of diaphragm rotations, both methods cause different behaviors. For the static procedure, rotations increased when alpha values decreased while for MRSA rotations increase up to the saturation point following what it was seen for the TIR. Additionally, it can be seen that the static method causes larger rotations for larger plan ratios. However, the MRSA behaves like the opposite; fewer rotations are expected for larger plan ratios.

This would lead to misinterpretations of the indirect forces that the orthogonal lateral system will receive due to torsion.

Linear time history analysis demands can be predicted with MRSA for all the configurations under analysis.

- The major differences between MRSA and LTH drifts and rotation demands were seen in torsional sensitive configurations (lower alphas). However, MRSA allows predicting well the demands obtained in the LTHA analysis for the prototype under study. This implies that further comments or recommendations about the mass-offset technique must apply to MRSA and LTHA in the same manner.
- Maximum rotations are reached in configurations where the modal participation factors for a 5% mass offset, in each degree of freedom, are not concentrated in one mode only. This also happens to be the configuration where both opposite edges reach the same maximum displacements.
- For configurations with large values of alpha (e.g. less torsional sensitive configurations), the displacement demands produced in the edge closer to the shifted center of mass are larger. However, due to dynamic characteristics, for low alpha values, after the saturation point, the edge in the opposite direction to the mass offset has larger displacement demands. This contra intuitive result that occurs due to inertial forces present in dynamic analyses.
- The torsional behavior of a structure can be evaluated using RSA despite it gives positive results only. For the purpose, not only drift demands must be evaluated but diaphragm rotations. It can also help to avoid results misinterpretations due to the loss of sign and time occurrence associated with MRSA. Regarding this topic, more work should be done to use the diaphragm rotations and edge lengths to be an indicator of the torsional effects.

Keywords: Structural Control, Coupled Buildings, Stochastic analysis, Passive Control

Abstract. *The structural coupling technique originated in the USA in the 70's, when Klein et al. [1] connected two adjacent structures through wire ropes to prevent pounding between them. This technique has been shown to be efficient not only to prevent the pounding phenomenon, but also to control the amplitude of vibration of coupled structures and to avoid possible severe structural damage caused by earthquakes or strong winds. The study of random vibrations arose from the need to assess the reliability structures that operate in a random environment. Stochastic dynamic analysis aims to evaluate the response of dynamic systems subject to stochastic inputs. One of the main premises of this analysis is to consider that the structure is known and deterministic, that is, its properties are not subject to random variations. The structure excitation is managed through probabilistic properties, generating the problem response as a function of variances. Thus, this paper aims to evaluate the difference between the deterministic and stochastic response in two adjacent structures, when using the structural coupling technique for vibration control. In addition, a parametric analysis is performed in order to verify the importance of the soil and filter parameters applied in the state matrix, in the stochastic analysis. Adjacent building models are used considering the shear frame structure behavior. The dampers that connect the structures are passive and their positions, quantities and mechanical properties are optimized by the particle swarm algorithm, in which the excitation in deterministic analysis is provided by the acceleration record of the 1940 El Centro earthquake. For stochastic excitation, a Gaussian stationary random process is used, in which it is applied through a filter, applied directly on the coupled system state matrix. The deterministic results of the uncoupled structures indicated the importance of choosing the base acceleration used as excitation in dynamic models. Reductions in vibration amplitude of up to 60% were observed. In the stochastic analysis, the reductions in floor vibration amplitude remained in the 50% range both structures. It has been seen that there are considerable differences when using deterministic analysis and stochastic analysis. However, the use of coupling structural control technique increases the system reliability.*

1 INTRODUCTION

The first researches on the structural coupling technique were carried out in the United States, in the 70s, when Klein *et al.* [1] connected two adjacent structures using steel cables, in order to avoid pounding between them. Later, Klein and Healy [2] developed an algorithm for semi-active control and found that to ensure that the system is controllable, the natural frequencies of adjacent buildings should be different. From these works, several researches were developed using the coupling technique, evaluating several control devices in the connection between the buildings [3-9].

The studies of random vibrations arose from the need to evaluate the reliability of structures that operate in a random environment. As examples, we can mention: winds in tall buildings and bridges, waves of the sea, earthquakes in civil structures, acceleration in satellites, among others [10]. A stochastic process, or a random process, is a mathematical model of a dynamic process in which dependence on the parameter time (t) is governed by probabilistic laws [11].

Stochastic dynamic analysis aims to evaluate the response of dynamic systems subject to stochastic inputs. One of the main premises of this analysis is to consider that the parameters of the structure are known and deterministic, that is, its properties are not subject to random variations. The excitation of the structure is managed through probabilistic properties, generating the response of the problem as a function of variances. Thus, it is possible to assess the reliability of the analysis and work, for example, with the probability of failure of a given system.

The objective of this work is to optimize the parameters of viscofluid dampers that connect two adjacent buildings through the deterministic dynamic response and the stochastic response, in order to verify the difference in the optimization results. Afterwards, a study is carried out on the importance of the parameters of the soil and filter, applied in the stochastic analysis, in the damping constant of the viscofluid dampers.

2 METHOLOGY

The models of adjacent buildings are considered to have shear frame behavior. The connection devices are of the passive type, and their positions, quantity and mechanical properties, are optimized through the particle swarm algorithm. In the deterministic analysis, an excitation provided by the acceleration record of the 1940 El Centro earthquake is used. In the stochastic analysis, a random Gaussian stationary process is considered and applied through a filter, used directly on the state matrix of the coupled system. This improved matrix contains soil and filter parameters.

3 MATHEMATICAL FORMULATION

The mathematical formulation for adjacent coupled buildings with deterministic base excitation is based on studies [7, 8, 12-13]. For stochastic excitation with white noise as an input, the formulation is based on studies [14-18].

3.1 Adjacent Coupled buildings

The adjacent buildings are considered as shear frame structures in this work, that is, the entire mass on the floor is considered concentrated in the beam, in which it is infinitely rigid in relation to the columns. In this way, rotations in the nodes are prevented and the stiffness of the structure is provided by the columns. The distance between the buildings is enough to install a connection device, however, it is not considered in the calculations. The type of control

used is a linear viscoelastic damper, that is, a device classified as passive. Finally, the movement of the ground is uniform in both structures.

Let the coupled models shown in Fig.1 in that the structure 1 contains $n+m$ floors and the structure 2, n floors. The mass, stiffness and damping properties of buildings have, respectively, the values of m_i^j, k_i^j, c_i^j, in which, i indicates the floor number and j the building $(j = 1, 2)$. The springs and dampers of the control system have the mechanical properties k_n^3 and c_n^3, being n the floor on which the elements are situated. Both structures are excited by acceleration in the ground $\ddot{X}_g$. Lastly, $x_{n+m}^1(t)$ and $x_n^2(t)$ are the displacements of models in the time domain. Thus the velocities and accelerations are, respectively, $\dot{x}_{n+m}^1(t)$, $\dot{x}_n^2(t)$, $\ddot{x}_{n+m}^1(t)$ and $\ddot{x}_n^2(t)$. The free-body diagram is shown in Fig. 2.

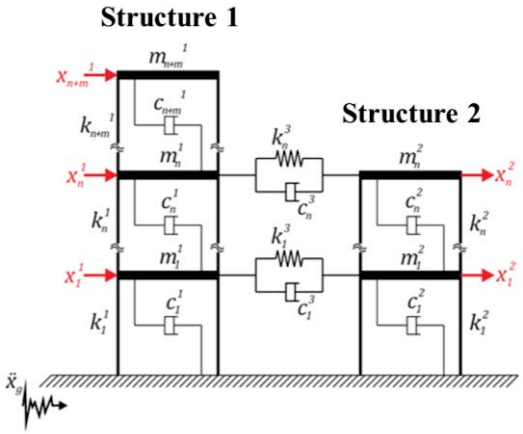

Figure 1: Model for adjacent coupled buildings.

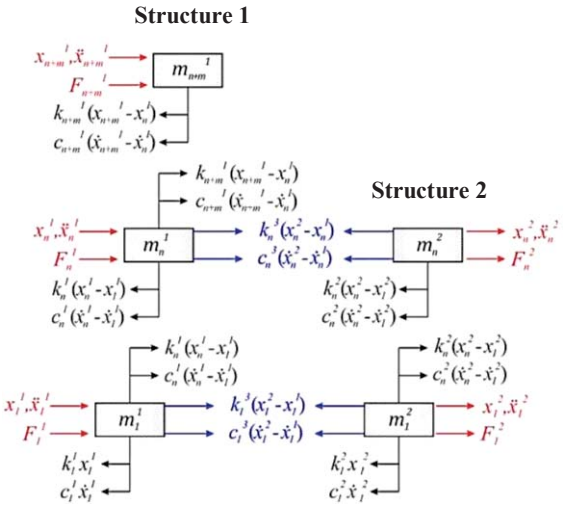

Figure 2: Free-body diagram.

Applying Newton's second law, the equation of motion for the coupled system is as follows:

$$\mathbf{M}_{ee}\,\ddot{\mathbf{x}}_{ee}(t) + \mathbf{C}_{ee}\,\dot{\mathbf{x}}_{ee}(t) + \mathbf{K}_{ee}\,\mathbf{x}_{ee}(t) = \mathbf{f}(t) \tag{1}$$

In which: $\mathbf{M}_{ee}$, $\mathbf{C}_{ee}$ and $\mathbf{K}_{ee}$ are the mass, damping and stiffness matrices of the coupled system, respectively; the vectors $\ddot{\mathbf{x}}_{ee}(t)$, $\dot{\mathbf{x}}_{ee}(t)$ and $\mathbf{x}_{ee}(t)$ are the ones that contain the values of

accelerations, velocities and displacements, respectively, in the two structures; $\mathbf{f}(t)$ is the external force vector, which in this case is the acceleration in the base.

One way to represent the above equation is by state-space. In this way, the second order differential equation (Eq. 1) is transformed into a set of first order equations. For a structural system, the state variables are displacements and velocities. If a system contains n degrees of freedom, then it is separated into $2n$ first order equations. The state vector $\boldsymbol{z(t)}$ is then given by:

$$\boldsymbol{z(t)} = \begin{bmatrix} x_{ee}(t) \\ \dot{x}_{ee}(t) \end{bmatrix} \tag{2}$$

And the first order equation is given by:

$$\dot{\boldsymbol{z}}(\boldsymbol{t}) = \boldsymbol{A}\boldsymbol{z}(\boldsymbol{t}) + \boldsymbol{B}\ddot{X}_g \tag{3}$$

In which:

$$\boldsymbol{A} = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{I} \\ -\boldsymbol{M}_{ee}^{-1}\boldsymbol{K}_{ee} & -\boldsymbol{M}_{ee}^{-1}\boldsymbol{C}_{ee} \end{bmatrix}$$

$$I = identity\ matrix \tag{4}$$

$$\boldsymbol{B} = \begin{Bmatrix} 0 \\ -1 \end{Bmatrix}$$

Matrix $\boldsymbol{A}$ is the system state matrix, the vector $\boldsymbol{B}$ represents the disturbance vector. Being $\boldsymbol{C_y}$ the system output matrix, the structure response can be obtained as:

$$\boldsymbol{y(t)} = \boldsymbol{C_y z(t)} \tag{5}$$

$$\boldsymbol{C_y} = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{I} \\ -\boldsymbol{M}_{ee}^{-1}\boldsymbol{K}_{ee} & -\boldsymbol{M}_{ee}^{-1}\boldsymbol{C}_{ee} \end{bmatrix} e\ \boldsymbol{y(t)} = \begin{Bmatrix} x_{ee}(t) \\ \dot{x}_{ee}(t) \\ \ddot{x}_{ee}(t) \end{Bmatrix}$$

3.2 Stochastic response in State-Space

In this formulation, it is considered that the system disturbance is given by a random process of white noise of average zero with power spectral density function (PSDF) of constant intensity S_0. The covariance matrix $\boldsymbol{S}$ of $\boldsymbol{y(t)}$ is given by:

$$\boldsymbol{S_{ij}} = \boldsymbol{E}[\boldsymbol{y_i y_j}] \tag{6}$$

where $E[.]$ is the expectation operator and y_i is the $i-nth$ element of the vector $\boldsymbol{y(t)}$.

As the process is random and it is considered white noise with zero mean, then $\boldsymbol{S}$ satisfies the following differential equation:

$$\dot{\boldsymbol{S}} = \boldsymbol{A}\boldsymbol{S}^{\boldsymbol{T}} + \boldsymbol{S}\boldsymbol{A}^{\boldsymbol{T}} + \boldsymbol{D} \tag{7}$$

Where $\boldsymbol{D}$ is the covariance matrix between the state and the excitation vectors and $D_{ij} = 0$ except $D_{2n,2n} = 2\,\pi S_0$.

Still, considering that the excitation is stationary, $\boldsymbol{D}$ is independent of time, so the stationary solution of Eq. (7) can be obtained by solving the Lyapunov matrix equation:

$$\boldsymbol{AS^T + SA^T + D = 0} \tag{8}$$

When using the PSDF to represent a stationary Gaussian random process $x_g(t)$, can be used a white noise filter $x_0(t)$ through two linear filters:

$$\begin{gathered}\ddot{x}_g(t) + 2\xi_g\omega_g\dot{x}_g(t) + \omega_g^2 x_g(t) = -\left(x_f(t) + x_0(t)\right) \\ \ddot{x}_f(t) + 2\xi_f\omega_f\dot{x}_f(t) + \omega_f^2 x_f(t) = -\ddot{x}_0(t)\end{gathered} \tag{9}$$

In which ω_g, ω_f, ξ_g and ξ_f are soil parameters (sub index g) and filter parameters (sub index f). Equation (9) lead to the following PSDF described by Clough and Penzien [15]:

$$G_{cp}(\omega) = S_0\left(\frac{1+4\xi_g^2\left(\frac{\omega}{\omega_g}\right)^2}{\left[1-\left(\frac{\omega}{\omega_g}\right)^2\right]^2+4\xi_g^2\left(\frac{\omega}{\omega_g}\right)^2}\right)\left(\frac{\left(\frac{\omega}{\omega_f}\right)^4}{\left[1-\left(\frac{\omega}{\omega_f}\right)^2\right]^2+4\xi_f^2\left(\frac{\omega}{\omega_f}\right)^2}\right) \tag{10}$$

Being S_0 the intensity of the process. The stochastic response of the structure is obtained through Eq. (8), in which the state vector $\boldsymbol{y(t)}$, the improved state matrix $\boldsymbol{A}$ (with the addition of the filter), are:

$$\boldsymbol{y} = \left\{\boldsymbol{x^T} \quad \boldsymbol{\dot{x}^T} \quad \boldsymbol{x_f} \quad \boldsymbol{\dot{x}_f} \quad \boldsymbol{x_g} \quad \boldsymbol{\dot{x}_g}\right\}^T \tag{11}$$

$$\boldsymbol{A} = \begin{bmatrix} [0] & [I] & \{0\}^T & \{0\}^T & \{0\}^T & \{0\}^T \\ -\boldsymbol{M}_{ee}^{-1}\boldsymbol{K}_{ee} & -\boldsymbol{M}_{ee}^{-1}\boldsymbol{C}_{ee} & -\{1\}^T\omega_f^2 & -\{1\}^T 2\xi_f\omega_f & \{1\}^T\omega_g^2 & \{1\}^T 2\xi_g\omega_g \\ \{0\} & \{0\} & 0 & 1 & 0 & 0 \\ \{0\} & \{0\} & -\omega_f^2 & -2\xi_f\omega_f & \omega_g^2 & 2\xi_g\omega_g \\ \{0\} & \{0\} & 0 & 0 & 0 & 1 \\ \{0\} & \{0\} & 0 & 0 & -\omega_g^2 & -2\xi_g\omega_g \end{bmatrix} \tag{12}$$

The elements of the covariance matrix $\boldsymbol{D}$ with dimensions $(2n+4)\,x\,(2n+4)$ are $D_{ij} = 0$ except $D_{2n+4,2n+4} = 2\pi S_0$.

With the covariance matrix $\boldsymbol{S}$ it is possible to obtain the standard deviation of root mean square (RMS) values of displacements σ_d through:

$$\sigma_d = \sqrt{diag(\boldsymbol{TST^T})} \tag{13}$$

where $\boldsymbol{T}$ is a transformation matrix, which for this case, has the form:

$$T_{2n+4,2n+4} = \begin{bmatrix} I_{n,n} & [0] \\ [0] & [0] \end{bmatrix} \tag{14}$$

For a given stochastic excitation, the maximum displacement can be obtained through the peak factor (p_f). Studies by Der Kiureghian [14], indicate that the maximum displacement (μ_{dmax}) is obtained as follows:

$$\sigma_{dmax} = \max(\sigma_d)$$
$$p_f = \sqrt{2\ln(\nu_e \tau)} + \frac{0.5775}{\sqrt{2\ln(\nu_e \tau)}} \tag{15}$$

Where σ_{dmax} is the maximum standard deviation of the displacements obtained in the stochastic analysis. In the second equation, it is the modified mean zero crossing rate and the duration of the excitation. For a degree of freedom (SDOF) system subject to white noise as excitation at the base ν_e is given by:

$$\nu_e = \begin{cases} (1.90\xi^{0.15} - 0.73)\nu & (\xi < 0.54) \\ \nu & (\xi \geq 0.54) \end{cases},$$
$$\nu = \frac{\omega}{\pi} \tag{16}$$

In the above equation ν is zero-crossing rate of the response, ω and ξ are the natural frequency and damping ratio of the SDOF structure, respectively. For multiple degrees of freedom, the natural frequency and damping rate of the dominant vibration mode should be used.

Thus, the maximum displacement is given by:

$$\mu_{dmax} = p_f \sigma_{dmax} \tag{17}$$

3.3 Particle swarm optimization (PSO)

The PSO was used to obtain the positions, quantity and optimum properties of the dampers in the analysis. The PSO algorithm was developed by Kennedy and Eberhart [19] and is based on a population of individuals that adapt and stochastically return to previously well-defined regions.

The objective function used is formed by two parts. The first consists of minimizing the square of the RMS of the maximum interstory drift of the two adjacent buildings (Eq. 17). The second is intended to decrease the value of the sum of squares of these RMS (Eq. 18).

$$f_{obj1} = \max\{\max(\{\Delta\}^1)^2 \quad \max(\{\Delta\}^2)^2\} \tag{18}$$

$$f_{obj2} = \sum_{i=1}^{n+m}\left(\{\Delta\}_i^1\right)^2 + \sum_{i=1}^{n+m}\left(\{\Delta\}_i^2\right)^2 \tag{19}$$

$$f_{objtotal} = f_{obj1} + f_{obj2} \tag{20}$$

$$\begin{cases} \{\Delta\}_i^j = x_i^j \\ \{\Delta\}_i^j = x_i^j - x_{i-1}^j \qquad 1 < i \leq n_{floor} \end{cases} \tag{21}$$

where $\{\Delta\}^j$ is the vector that contains the RMS of the interstory drift of each building ($1 \leq j \leq 2$) and x_i^j is the RMS of the absolute displacement calculated on each floor.

4 NUMERIC STUDY

One model of adjacent structures was chosen, containing the largest, 8 floors and the smallest, 4 floors, as shown in Fig. 3.

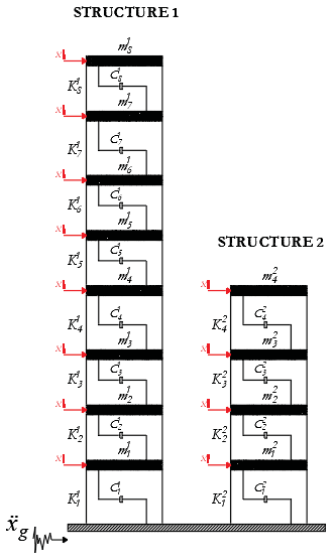

Figure 3: Models of adjacent buildings.

The floor mass considered is m_i^j = 30 t, floor-to-floor height H_i^j = 3.0 m and stiffness per floor k_i^j = 12.58 MN/m. The damping matrices were calculated using the Rayleigh method, considering a 3% damping ratio for all modes. In the deterministic analysis, accelerations on the ground of the 1940 El Centro earthquake were used, whose record of accelerations is shown in Fig. 4.

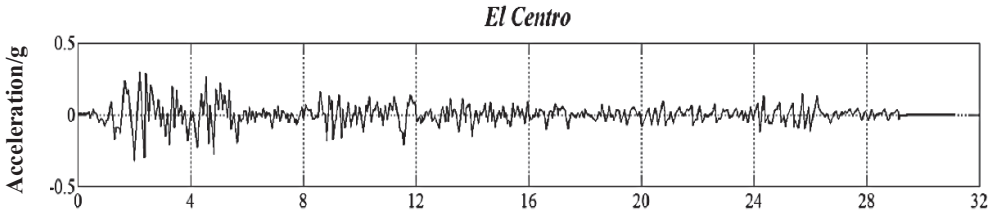

Figure 4: Record of 1940 El Centro earthquake accelerations.

The stiffness and damping values of the connection device between adjacent buildings vary from zero to 10.10^6 Ns/m. These devices are based on passive dampers available on the market (Taylor Device, Inc).

On first stochastic analysis, for comparison with the deterministic analysis, Clough and Penzien's PSDF was used, as described in Eq. (10). The soil parameters are based on the work of [20-22] and are described in Table 1.

ω_g (rad/s)	ξ_g	ω_f (rad/s)	ξ_f
5π	0.6	0.5π	0.6

Table 1: Parameters of PSDF.

For the process intensity S_0, a value suggested by Clough and Penzien [15] representing the NS component of the 1940 El Centro earthquake was used, and has the value of

$S_0 = 0.0047937\ m^2/s^3$. Fig. 5 shows the spectrum using the parameter values described above.

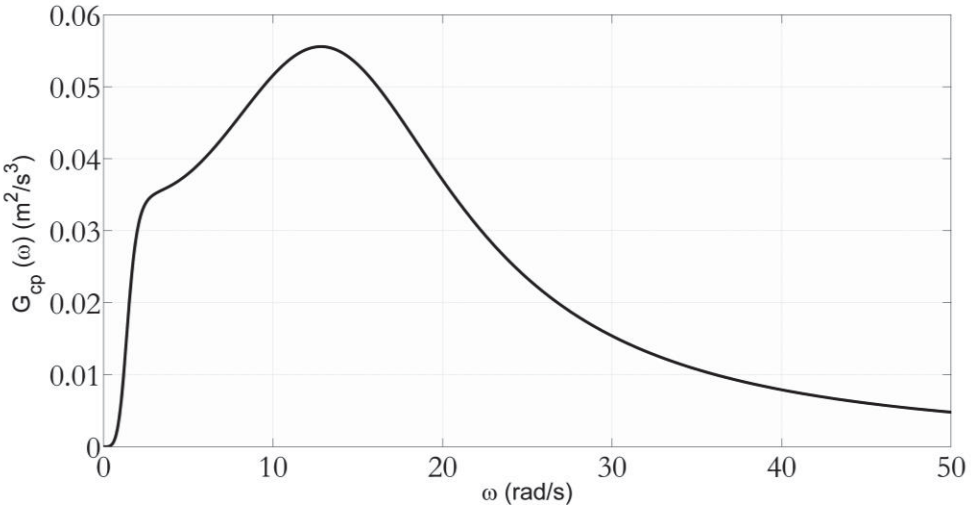

Figure 5: Clough and Penzien PSDF.

5 RESULTS AND DISCUSSIONS

The results are separated into two parts. The first part presents the results of the comparative analysis of the performance of the control technique by structural coupling using deterministic and stochastic analysis. The second part presents the results of the parametric analysis of the influence of soil and filter parameters on the structural coupling technique performance using stochastic analysis.

5.1 Comparative study

The first two natural frequencies (ω) in both structures are shown in Table 2. In parentheses are the frequencies f in Hertz, where $f = \omega/2\pi$.

Structure	First frequency (rad/s)	Second frequency (rad/s)
1	3.78 (0.60)	11.21 (1.78)
2	7.11 (1.13)	20.48 (3.26)

Table 2: Natural frequencies of adjacent structures.

In this stage, three analyses are performed. The first analysis (RMS-D) consists of optimizing the parameters of the viscofluid damper, which connects the two structures, through a deterministic analysis using the objective function of Eq. (20). In the second analysis (RMS-S), optimization is performed through stochastic responses with the same objective function as the first analysis. In the third analysis (MD-D), optimization is performed, in a deterministic analysis, with the objective function (Eq. 20) modified. The values of Δ (Eq. 18 and Eq. 19) are now the absolute values of interstory drift and no longer the RMS of those displacements.

The Eq. (20) with absolute values of interstory drift is used by [7, 9, 12]. The results of optimization are shown in Table 3. Table 4 shows the results of the interstory drift RMS. The results of the maximum interstory drift are shown in Table 5 and the maximum displacement values are shown in Table 6. The values in parentheses are those of the coupled system.

Analysis	Objective Function	Damping Constant (Ns/m)	Position (floor)
RMS-D	0.00052986	1,816,143.80	3
RMS-S	0.00038953	305,282.23	1 and 4
MD-D	0.004551	505,569.80	1 and 4

Table 3: Optimization results.

Analysis	Structure	RMS Interstory Drift (mm)	Reduction
RMS-D	1	13.38 (6.95)	48%
	2	16.40 (6.25)	62%
RMS-S	1	17.70 (8.39)	53%
	2	25.50 (7.10)	72%
MD-D	1	13.38 (6.95)	48%
	2	16.40 (5.87)	64%

Table 4: RMS of Interstory drift results.

Analysis	Structure	Maximum Interstory Drift (mm)	Reduction
RMS-D	1	37.65 (21.91)	42%
	2	60.57 (24.22)	60%
RMS-S	1	48.06 (22.81)	52%
	2	37.20 (19.28)	48%
MD-D	1	37.65 (22.25)	41%
	2	60.57 (23.83)	61%

Table 5: Maximum Interstory drift results.

Analysis	Structure	Maximum Displacement (m)	Reduction
RMS-D	1	0.180 (0.134)	26%
	2	0.176 (0.077)	56%
RMS-S	1	0.255 (0.133)	48%
	2	0.106 (0.059)	44%
MD-D	1	0.180 (0.132)	27%
	2	0.176 (0.078)	56%

Table 6: Maximum displacement results.

For the uncoupled system, in the deterministic analysis, the structure 2 has a greater amplitude of interstory drift than the larger structure (structure 1) and also, both have similar max-

imum amplitudes. This is due to the energy content in the frequency range of the 1940 El Centro earthquake, as shown in Fig. 6.

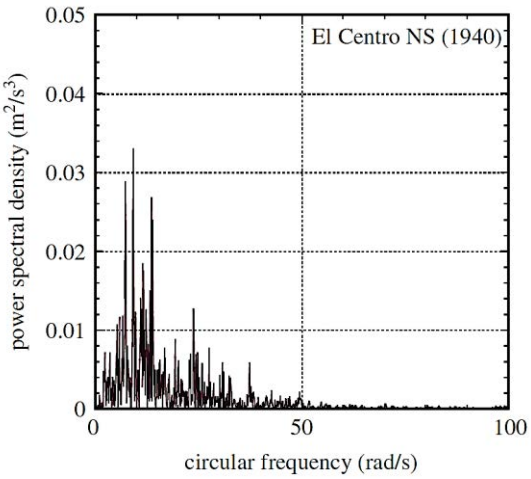

Figure 6: Power density function of the 1940 El Centro earthquake [23].

Stochastic analysis resulted in more economical dampers when compared to deterministic analysis. Also, the maximum displacements are higher (29%) for structure 1 and smaller (66%) for structure 2, in comparison with the deterministic analysis. Even so, the efficiency of the coupling technique was better in the stochastic analysis, in which the randomness of earthquakes is considered.

5.2 Parametric study

This study aims to verify the influence of the soil and filter parameters, applied in the state matrix $\boldsymbol{A}$ (Eq. 12), on the damping coefficient (C^3) of the dampers. The parameters are ω_g, ω_f, ξ_g e ξ_f. Each parameter was varied one by one, keeping the other three constants with values described in Table 1.

The results for natural soil frequency ω_g are shown in Fig. 7. The parameter was varied from 0.1π to 10π.

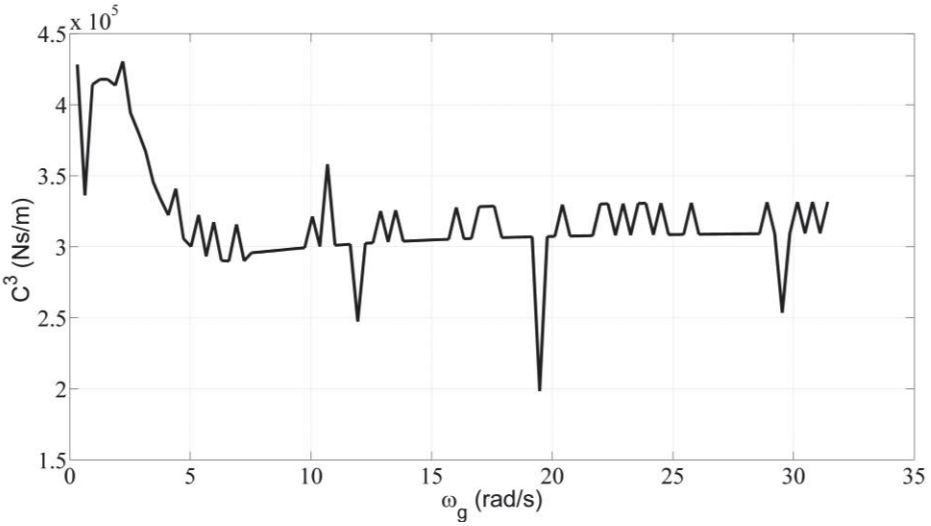

Figure 7: Influence of the ω_g on the damping coefficient.

There is an influence of the soil natural frequency in the optimization of the damper. The C^3 value changes around 300,000 Ns/m, close to the answer of the previous comparative study. This means that this parameter generates a little variation in the optimization, that is, its values are not significant in the analysis. The number of dampers varied between 1 and 2. For the filter frequency ω_f, the results are shown in Fig. 8. The frequency was varied from 0.1π to 10π.

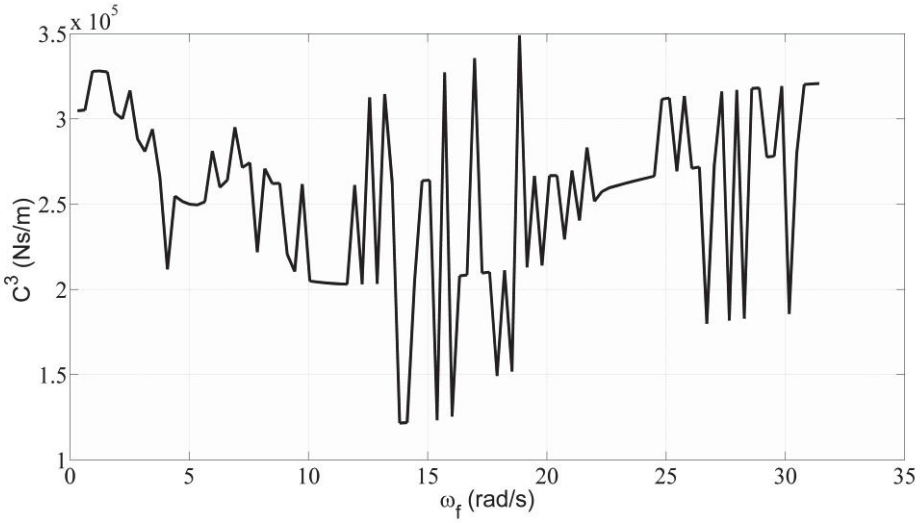

Figure 8: Influence of the ω_f on the damping coefficient.

The filter frequency generated a more intense variation on the damping coefficient. Thus, it is important that the frequency is carefully chosen, since this parameter strongly influences the dampers that connect the two structures.

The responses for the soil ξ_g and filter ξ_f damping ratio are shown in Fig. 9 and Fig. 10. The damping ratios varied from 0.01 to 1.

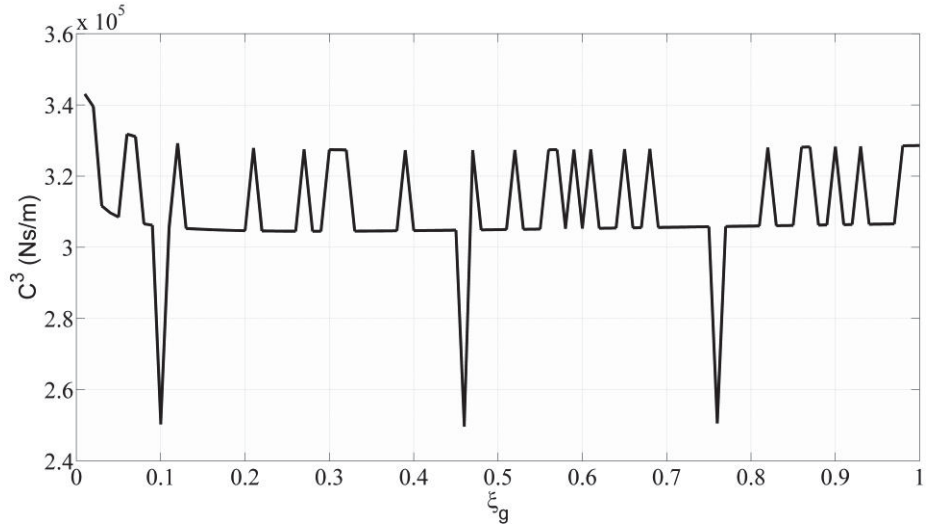

Figure 9: Influence of the ξ_g on the damping coefficient.

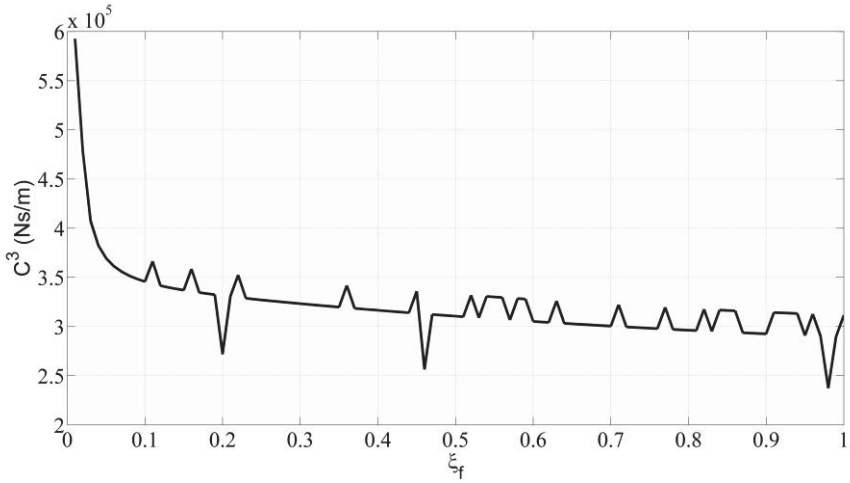

Figure 10: Influence of the ξ_f on the damping coefficient.

The soil damping ratio has a greater influence in the damping constant of the control system that connects the two structures. Even so the values are close to the average, showing a low standard deviation, thus, it has a low influence in the optimization.

6 CONCLUSIONS

This work aimed to study the vibration control technique through structural coupling using different perspectives in the optimization. In addition, a parametric study was carried out to verify the influence of soil and filter parameters on the damping constant of the control device that connects the two adjacent structures.

The deterministic results of the uncoupled structures indicated the importance of choosing the base acceleration used as excitation in dynamic models. In this analysis, for example, the more rigid structure (structure 2) obtained amplitudes of vibrations similar to the more flexible structure (structure 1).

The efficiency of the control technique by structural coupling was observed in both deterministic and stochastic analysis. In the deterministic analysis, there were reductions of up to 60% in the vibration amplitudes in the structure 1. For the structure 2, a 42% reduction on the maximum interstory drift was observed. In the stochastic analysis, the reductions on the vibration amplitudes of the floors, remained in the range of 50% in the structures. In the more flexible structure, the reduction on the vibration amplitudes was more efficient than in the rigid structure, different from that observed in deterministic analysis.

Comparing the results between the two analysis, the maximum displacements in the structure 2 were greater in the stochastic analysis. For structure 1, the displacements were smaller. It was observed that the maximum interstory drift are higher in the structure 2 in the deterministic analysis. In the stochastic analysis, these displacements demonstrate the opposite behavior, with the interstory drift being smaller in the structure 2. However, the interstory drift RMS maintained the same behavior in the three analysis. The use of the structural coupling technique approximated the maximum response between the three analysis.

The difficulty in predicting the real characteristics of earthquakes, makes the stochastic analysis important in the evaluation of the maximum response in dynamic problems. It has been shown that there are considerable differences when using deterministic and stochastic analysis. However, the use of the coupling structural control technique increases the reliability of the system, since it approximates the responses of the analysis performed.

In the parametric analysis, the influence of the soil and filter constants on the mechanical characteristics of the damper that connects the two structures was verified. The parameter that generated the greatest variation in the damping coefficient was the filter frequency. As the optimum properties of the dampers depend on the response of the structures, it makes the choice of these variables a crucial point in the analysis. Since the characteristics of the earthquake and the real behavior of the structure during the earthquake are not known, this analysis demonstrated that the value of the optimal damping constant has a low standard deviation for the soil parameters, however, this deviation is considerable for filter parameters. Thus, for this analysis, changes in soil characteristics can be discarded.

Keywords: Tuned mass damper, Vibration, Inverted pendulum, Hybrid control, PID controller.

Abstract. *Tuned mass dampers are devices well known in the literature. It is an auxiliary mass system that correctly tuned when connected to the structure vibrates out of phase with it, having the energy transferred to itself and thus reducing the vibration level of the main system. Among the geometries of this type of damper stands out the pendular one. However, recent studies show that inverted pendulum configuration would be more appropriate and efficient. The inverted pendulum problem itself is widely discussed in the literature, but its application as a structural control device acting as a tuned mass damper has not been sufficiently studied. The originally passive control device can be designed to operate in a hybrid manner with the addition of an active controller to the system. This configuration has the advantage of being more robust than passive, which only works well in the design frequency range, and requires lower control forces than purely active control. In this work a hybrid inverted pendulum mass damper (TMD-HIP) is proposed, where in addition to tuning it from the pendulum length and mass, an active control device is added. The active force used is designed as a PID controller with optimized gains. Numerical simulations are performed using the MATLAB computational package and its SIMULINK control toolbox. Several forms of external excitation are considered in the analysis. From the results it appears that the TMD-HIP is a good alternative for reducing excessive vibration. Although it is a preliminary model, it is a basis for studies in this area to evolve to more sophisticated model and full-scale applications.*

1 INTRODUCTION

The design and construction of slender and flexible structures, such as wind turbines, observation towers and high buildings, have increased in recent years. These structures are subjected to dynamic actions such as: wind, earthquakes, waves, heavy traffic, human occupation and rotating machines. These vibrations are undesirable both from the point of view of safety and environmental comfort, since they can reach the ultimate limit state, that is, collapse of the structure, or the service limit state, caused by excessive vibrations causing discomfort to the occupants [1].

One of the solutions to reduce undesirable levels of vibration in structures is the so-called structural control. It is a technology that promotes changes in the structure stiffness and damping properties, both by adding external devices and by applying external forces [2, 3]. It can be classified as passive, active, hybrid and semi-active [2].

Passive control already has several applications implemented in practice in structures around the world [4]. One of the most used devices is the so-called Tuned Mass Damper (TMD), it is an auxiliary mass attached to the structure, which properly tuned, vibrates out of phase, thus reducing the dynamic response of the main system [2, 5-12].

Among the possible geometric configurations used for TMD we have the simple pendulum [12-20]. Alternatively, Ahn *et al.* [21] proposed a TMD type as inverted pendulum (TMD-IP). The authors showed that equivalent performance of a simple pendulum can be achieved, but with shorter inverted pendulum lengths.

Despite being a problem widely studied in the control literature [22], the inverted pendulum system functioning as a TMD has not been adequately explored in the literature yet [4, 7, 23-28].

Resende *et al.* [26] presented an experimental-numerical study of an inverted pendulum system to control a reduced model of one degree of freedom. The study concluded that, based on experimental results, the TMD-IP showed satisfactory reductions of more than 50% in the response amplitudes of the main system, indicating good potential for the development of future practical applications.

Passive control, however, has deficiencies, as it does not function properly outside the design frequency range. The active control, which is a more robust control in relation to the passive, requires external energy supply, high magnitudes actuator forces and eventual stability problems. In this way, hybrid control, which combines passive and active control, presents itself as a more robust alternative and requires lower magnitude force than those of purely active control [1]. In the literature proposals for hybrid mass dampers can be found [29-34]. It is the combination of a passive TMD with an active control actuator, having already been implemented in practice [35].

In this work, the originally passive TMD-IP can be designed to operate in a hybrid manner with the addition of an active controller to the system. A hybrid inverted pendulum mass damper (TMD-HIP) is proposed, where in addition to tuning it from the pendulum length and mass, an active control device is added. The active controller used is a PID controller with optimized gains. From the analysis of the results it appears that the TMD-HIP is a good alternative for reducing excessive vibrations. Although being a preliminary model, it could be a basis for future studies in this area, to evolve to more sophisticated modelling and full-scale applications.

2 MATHEMATICAL MODEL

The system of two degrees of freedom (2DoF) studied in this work is shown in Figure 1. It represents the main system with a translational degree of freedom with an inverted coupled pendulum having a rotational degree of freedom. Considering small displacements, where $\mathbf{sin}\,\boldsymbol{\theta} \cong \boldsymbol{\theta}$, the hypothesis is of a linear system and the equations of motion are given by:

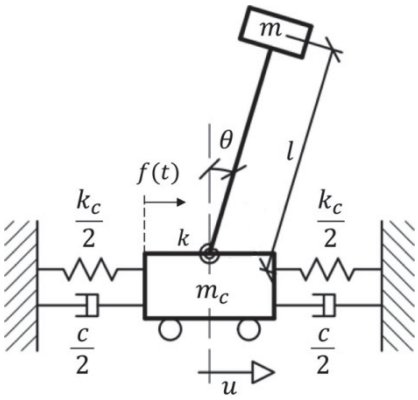

Figure 1: Mass-spring-damper model with inverted pendulum [26].

$$\begin{aligned}&(m_c + m + \rho l)\ddot{u} + \left(ml + \frac{\rho l^2}{2}\right)\ddot{\theta} + c\dot{u} + k_c u = f(t)\\&\left(ml + \frac{\rho l^2}{2}\right)\ddot{u} + \left(ml^2 + \frac{\rho l^3}{3}\right)\ddot{\theta} + \left(k - mgl - \frac{\rho g l^2}{2}\right)\theta = 0\end{aligned} \tag{1}$$

where:

m_c *is* the mass of the main system;
k_c is the stiffness of the main system;
c is the damping of the main system;
ρ is the linear specific mass of the pendulum;
l is the length of the pendulum;
m is the pendulum top mass;
k is the pendulum rotational stiffness;
g is the gravity acceleration;
$f(t)$ is the external dynamic force.

Applying the Laplace transform to each equation and solving the system with two algebraic equations, the transfer functions for the translational and rotational displacement are obtained and given, respectively, by:

$$\begin{aligned}G_u(s) &= \frac{(4\rho l^3 + 12ml^2)s^2 + (12k - 6\rho g l^2 - 12mgl)}{As^4 + Bs^3 + Cs^2 + Ds + E}\\G_\theta(s) &= \frac{-(6\rho l^2 + 12ml)s^2}{As^4 + Bs^3 + Cs^2 + Ds + E}\end{aligned} \tag{2}$$

where:

$$
\begin{aligned}
A &= \rho^2 l^4 + 4\rho\, l^3 (m_c + m) + 12 m_c m l^2 \\
B &= 4cl^2 (3m + \rho l) \\
C &= 4k_c l^2 (3m + \rho l) + 12k(\rho l + m_c + m) - 6\rho g l^2 (\rho l + m_c + 3m) - 12mgl(m_c + m) \\
D &= 12kc - 6cgl(\rho l + 2m) \\
E &= 12kk_c - 6k_c gl(\rho l + 2m)
\end{aligned}
\tag{3}
$$

3 PID CONTROLLER

The PID controller is a combination between the proportional derivative control (PD) and the proportional integral control (PI). The combination of these two types of control combines the increased damping provided by the PD control with the improvement of the system stability and the steady state error generated by the PI control [36]. Therefore, from the PID control it is possible to obtain a significant improvement in the behaviour of the system for both the transient and steady state behaviour.

The block diagram of the system with hybrid PID control consists of adding a sensor, a PID controller and a reference input as shown in Figure 2. The sensor captures the output signal and converts it to the same unit as the reference signal in order to compare these values. However, as the system response and the reference signal already have the same unit, then the transfer function of the sensor is unitary. As the aim is to reduce the displacements, the reference is taken equal to zero. The actuator force is applied at the translational main system.

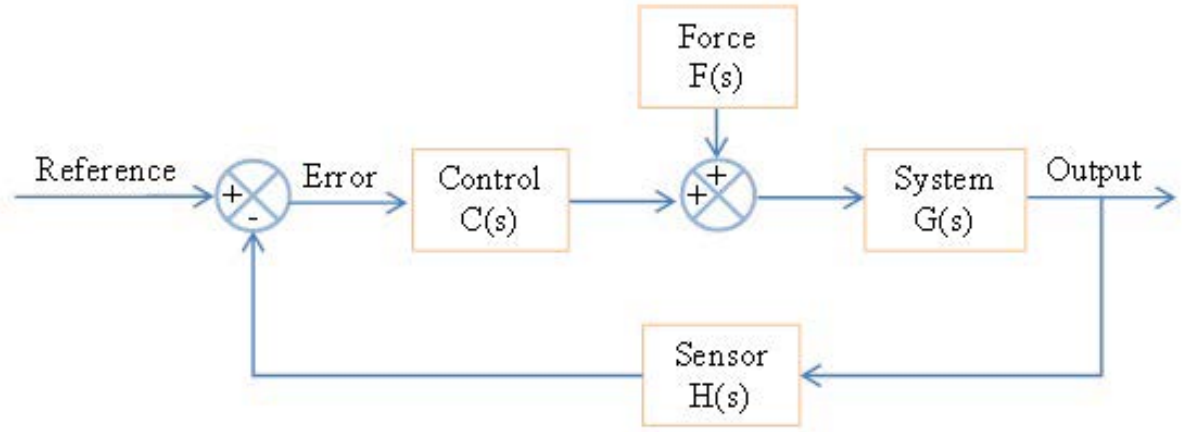

Figure 2: Block diagram of closed-loop system.

The controller transfer function is obtained from the optimization of P, I, D and N values, where N is a filter coefficient. The controller transfer function is given by:

$$
C(s) = P + I\frac{1}{s} + D\frac{N}{1 + N\frac{1}{s}} \tag{4}
$$

In order to verify the performance of the PID controller, a preliminary result of the vibration control is obtained through an inverted pendulum system analysis as shown in Figure 3.

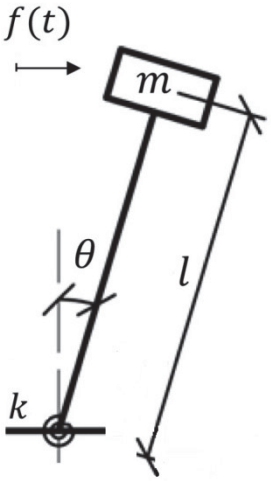

Figure 3: Inverted pendulum system.

The motion equation for this system is given by:

$$\left(ml^2+\frac{\rho l^3}{3}\right)\ddot{\theta}+\left(k-mgl-\frac{\rho g l^2}{2}\right)\theta=f(t)l \tag{5}$$

Applying the Laplace transform, the following system transfer function is obtained:

$$G_\theta(s)=\frac{1}{\left(ml+\frac{\rho l^2}{3}\right)s^2+\left(\frac{k}{l}-mg-\frac{\rho g l}{2}\right)} \tag{6}$$

The physical parameters adopted for the model are: ρ=0.24 kg/m, l=0.24 m, m=0.097 kg, k=2.23 N.m/rad and g=9.781 m/s^2.

The loading is a harmonic force with amplitude equal to 0.10 N and frequency of 15.7 rad/s. The evolution of angular displacement over time for the system without control and with PID control is shown in Figure 4.

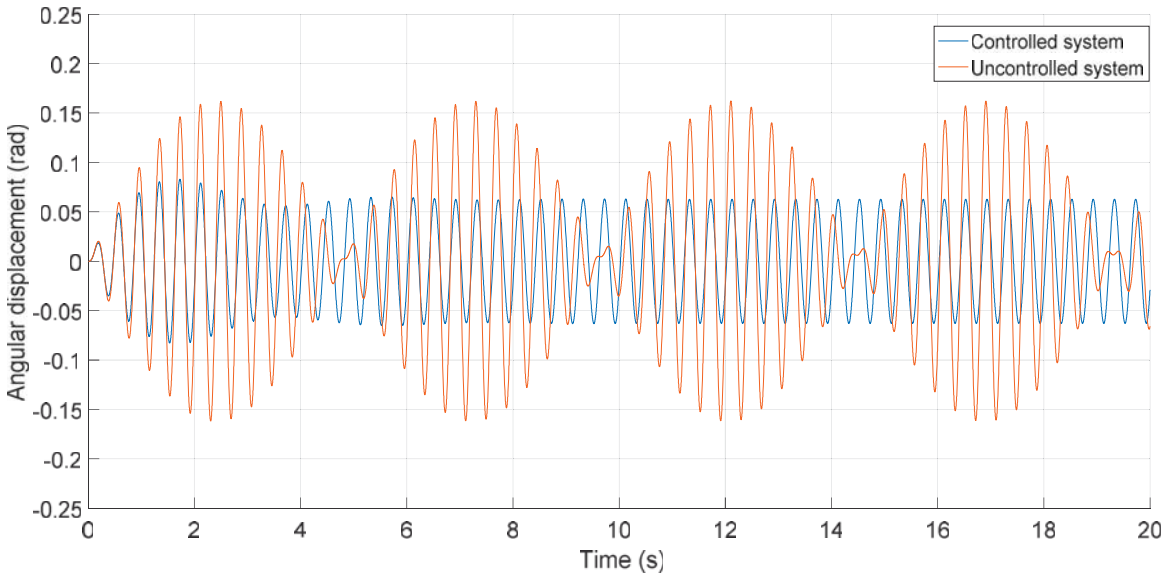

Figure 4: Angular displacement time history of an inverted pendulum subjected to harmonic loading.

It is verified that the maximum displacement of the system without control is 0.162 rad, while for the system with active control the maximum displacement is 0.083 rad, that is, there is a reduction of 48.76% in the value of the angular displacement of the inverted pendulum. In addition, the displacements are below 0.174 rad (10°), so the hypothesis that the system has a linear behaviour is met.

Then, a step excitation with amplitude equal to 0.10 N and duration of 5 s is applied. The response of the structure in the time domain in this case is shown in Figure 5 both for the system without control and for the system with PID control.

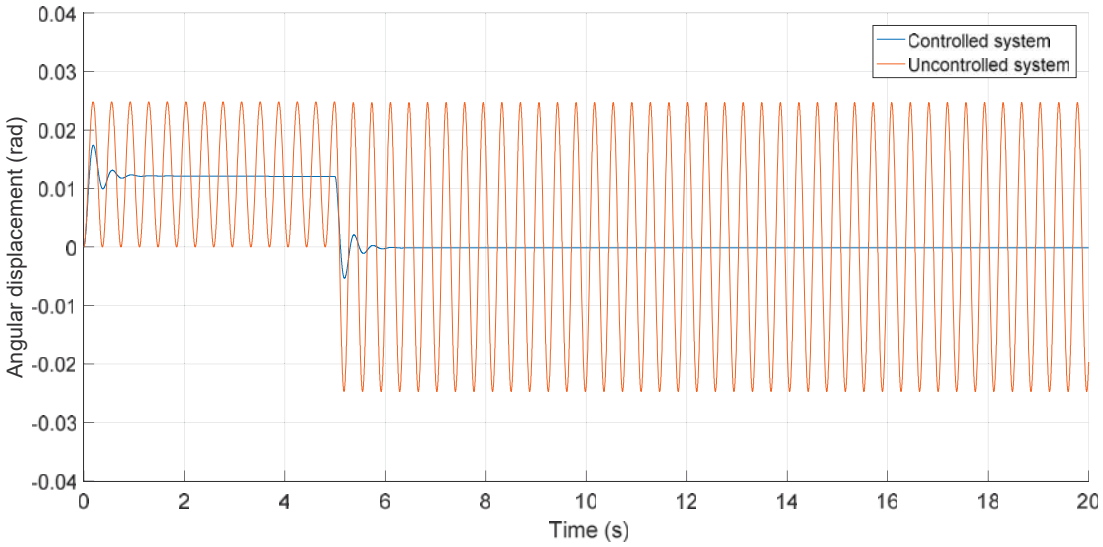

Figure 5: Angular displacement time history of an inverted pendulum subjected to step loading.

The maximum displacement of the system without control is 0.025 rad, while the system with active control shows a maximum displacement of 0.017 rad, that is, there is a reduction of 32%. As the displacements are below 0.174 rad (10°), the hypothesis that the system has a linear behaviour is met.

Therefore, it is verified that the control by means of PID presents satisfactory performance in reducing the dynamic response of the inverted pendulum presented.

4 RESULTS AND DISCUSSIONS

The parameters considered for the 2DoF model are: m_c=1.13317 kg, c=0.546 N.s/m, k_c=328.34 N/m, ρ=0.24 kg/m, l=0.24 m, m=0.097 kg, k=2.23 N.m/rad and g=9.781 m/s^2. Two loading cases were analyzed: harmonic loading $f(t)=f_o\sin(\omega t)$ where f_o =0.32 N and ω=15.7 rad/s and step loading with amplitude equal to 0.32 N and duration of 5 s. It is worth noticing that all the parameters above are the ones of the experimental model presented by Resende *et al.* [26].

4.1 Modal analysis and frequency analysis

It was developed a modal analysis of the following cases: system without control, applying passive control, active control and hybrid control.

The natural frequency of system without control is 17.02 rad/s. The addition of an inverted pendulum introduces one extra degree of freedom at the system and influences the modal parameters of the structure, leading to new values of natural frequencies, which are 14.27 rad/s and 20.12 rad/s. The mode shapes for passive control model are given by the following eigen-

vectors: [10.75 1.00] for the first mode of vibration and [-15.78 1.00] for the second mode of vibration, where the first column represents the angular displacement and the second column represents the translational displacement.

As the addition of a PID controller acts applying a control force at the system in order to reduce vibrations and it does not change the physical properties of the system, the mass and stiffness matrixes remain the same and consequently the modal proprieties too. Thus, natural frequencies and mode shapes of the without control model are the same of active control model, as well as these modal proprieties of the passive control model are the same of those of the hybrid control model. Therefore, PID controller does not produce any change in the modal parameters of the system.

Besides that, it is developed a frequency analysis of the same study of modal analysis: without control, passive control, active control and hybrid control. Figure 6 shows the frequency response function for an amplitude force of 0.32 N.

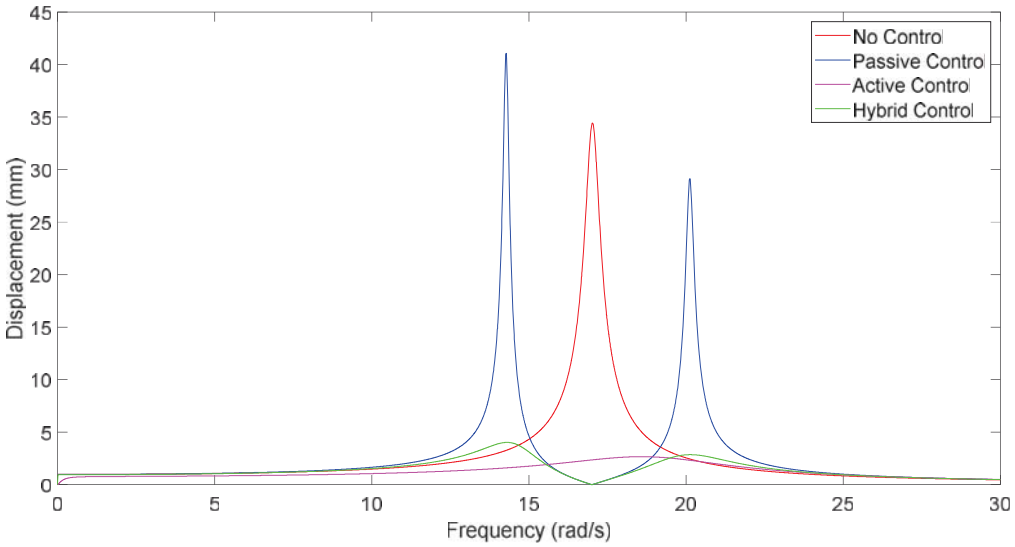

Figure 6: Displacement response in frequency domain (without control, TMD-IP, AC, TMD-HIP).

Table 1 summarizes the values of natural and resonant frequencies and peak response for all the case studied.

	No control	Active control	Passive control	Hybrid control
Natural Frequency (rad/s)	17.02	17.02	14.27 and 20.12	14.27 and 20.12
Resonant Frequency (rad/s)	17.02	18.58	14.27 and 20.12	14.31 and 20.15
Peak Response (mm)	34.43	2.67	41.07 and 29.13	4.02 and 2.86

Table 1: Natural and resonant frequencies and peak response.

The resonant frequency of the system without control is 17.02 rad/s. The addition of an inverted pendulum as passive control changes resonant frequencies. In this model, the resonant frequencies are the same of natural frequencies: 14.27 rad/s and 20.12 rad/s. Besides that, it is verified that for frequencies between 15.02 rad/s and 19.18 rad/s, the permanent response of the passive control model is less than the without control model. Therefore the passive control works well only in a range of frequency pre-established in the design.

The addition of PID controller changes slightly the resonant frequency which for the active control model is 18.58 rad/s and for hybrid control model are 14.31 rad/s and 20.15 rad/s. It can be seen a little difference for resonant frequencies between without control model and active control model, and between passive control model and hybrid control model. This little difference happens because although PID controller acts applying a control force to the system, it works improving damping which changes the bandwidth frequency and consequently resonant frequencies.

Besides that, it is verified that active control model presents the minimum peak response when compared with the other models. On the other hand, the amplitude response of the hybrid control model is lower than active control model in a frequency range between 15.62 rad/s and 18.92 rad/s. Therefore, depending on the frequency range of external exciting force, it can be better to design using active or hybrid control in order to minimize peak permanent response.

4.2 Response due to harmonic loading

Figure 7 shows the time domain response for harmonic loading using passive control and PID hybrid control. The optimization of the values of P, I, D and N is performed using the Simulink/MATLAB toolbox and limiting the control forces to 50% of the magnitude of the dynamic excitation forces. The values of the parameters found are P = 7.5, I = 0.9, D = 5.0 and N = 1720. The hybrid control shows a rise time equal to 851 s and a settlement time equal to 1430 s.

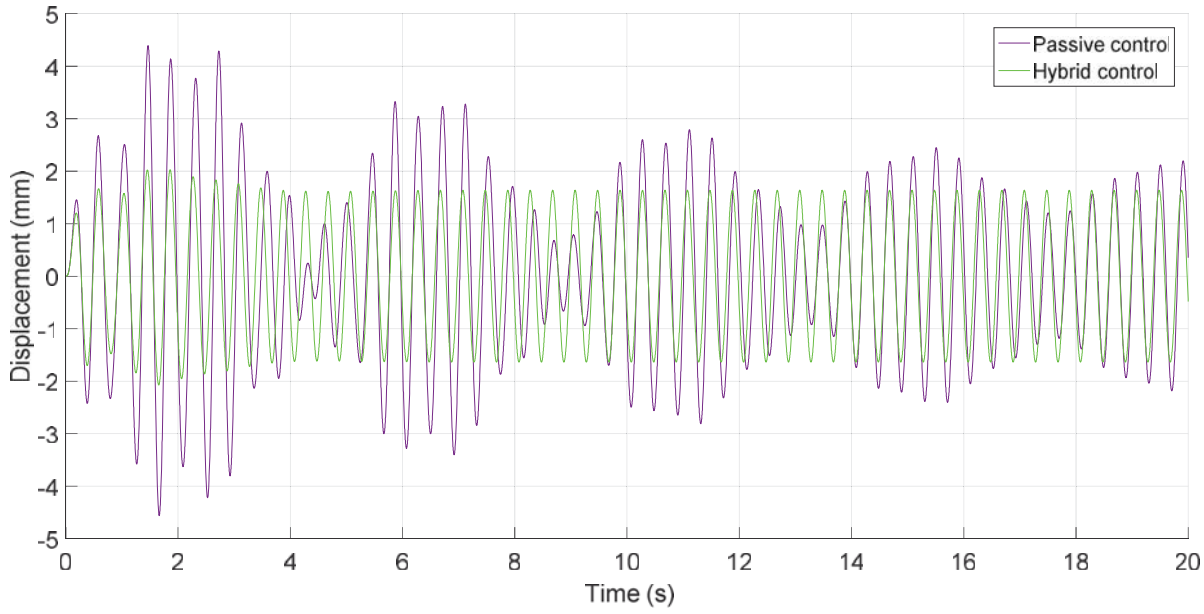

Figure 7: Displacement time history of the main system for harmonic loading (TMD-IP and TMD-HIP).

Figure 8 shows the time domain response for harmonic loading using PID active control and PID hybrid control. The optimization of the values of P, I, D and N for active control is performed using the Simulink/MATLAB toolbox and equalling the maximum displacements from the two PID controllers. The values of the parameters found for PID active control are P = 81.3, I = 97.3, D = 6.1 and N = 2337. The active control shows a rise time equal to 8.74 s and a settlement time equal to 15.5 s.

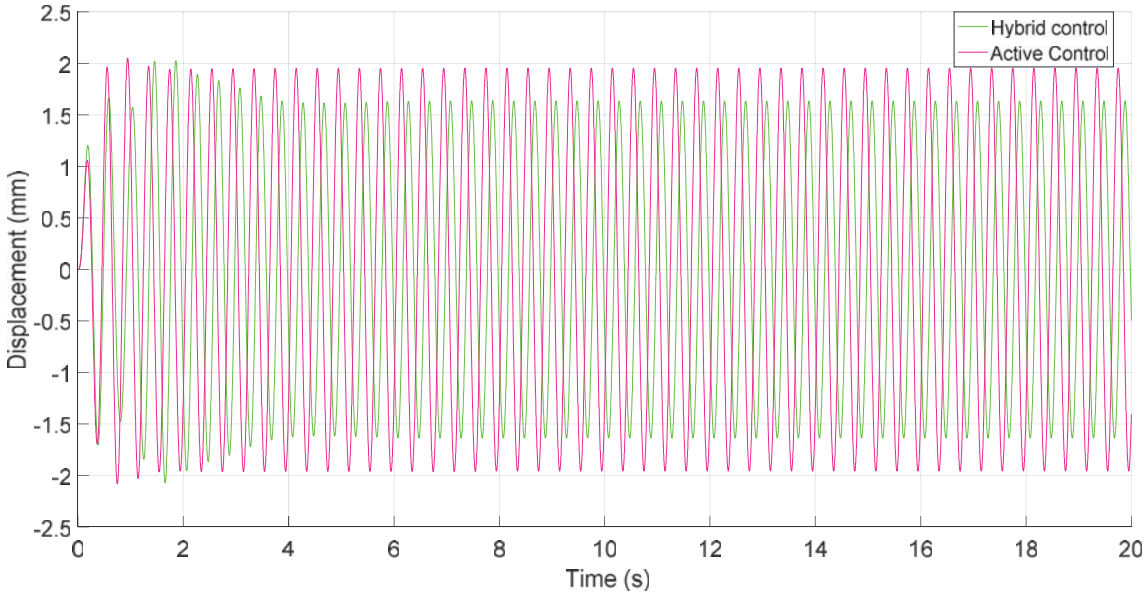

Figure 8: Displacement time history of the main system for harmonic loading (AC and TMD-HIP).

Figure 9 shows the comparison of displacement time history between the uncontrolled system and the system with TMD-HIP because this was the one that shows the smallest displacements compared to passive control and PID active control.

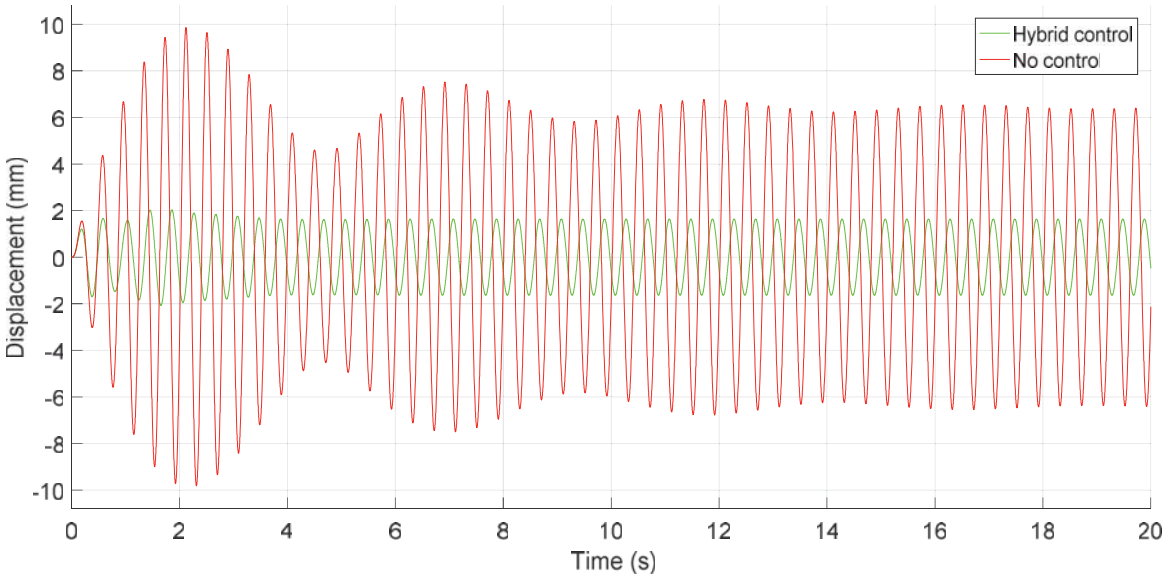

Figure 9: Displacement time history of the main system for harmonic loading (without control and TMD-HIP).

Table 2 shows the maximum and RMS displacement values of the main system for the harmonic loading case.

	No control	Passive control	Active control	Hybrid control
U_{max} (mm)	9.76	4.36	2.08	2.07
RMS(mm)	5.60	2.45	1.38	1.26

Table 2: Displacements due to harmonic loading.

The system with passive control shows a reduction of 55.3% in the maximum displacement of the structure in relation to the system without control. The system with hybrid control shows a reduction of 78.8% and 52.5%, respectively, in relation to the system without control and the system with passive control. It is verified that there are time ranges where the response with passive control is lower than the one with hybrid control.

Although the maximum displacement results comparing the active hybrid control are approximately the same, there is a reduction of 8.7% of the response regarding the hybrid control in relation to the active control during the steady state phase.

Regarding the RMS response, the system with passive control shows a reduction of 56.2 % compared to the system without control, while the system with hybrid control presents a reduction of 77.5% and 48.57%, respectively, in relation to the system without control and the system with passive control. Regarding the RMS of the systems with PID controller, the system with hybrid control shows a reduction of 8.7% in relation to the system with active control.

The control force is limited to 50% of amplitude value of the external action, and therefore the hybrid control shows to be feasible in practice. In the case of active control, it is found that to maintain the same maximum displacement obtained through the hybrid control during the transient response, a control force of 0.26 N is required, which corresponds to 81.2% of the amplitude of the external excitation. Therefore, it is verified that the capability of the actuator when using active control is 62.5% higher than when using hybrid control.

The maximum angular displacement of the system with passive control is equal to 0.081 rad, which allows using the small displacement hypothesis, as this value is less than 0.174 rad (10^o).

4.3 Response due to step loading

Figure 10 shows the time history response of the structure for a step load considering the system with passive control and with hybrid control. The values of P, I, D and N found were P = 47.0, I = 12.6, D = 3.6 and N = 1716. The hybrid control shows rise time equal to 64.6 s and settlement time equal to 113 s.

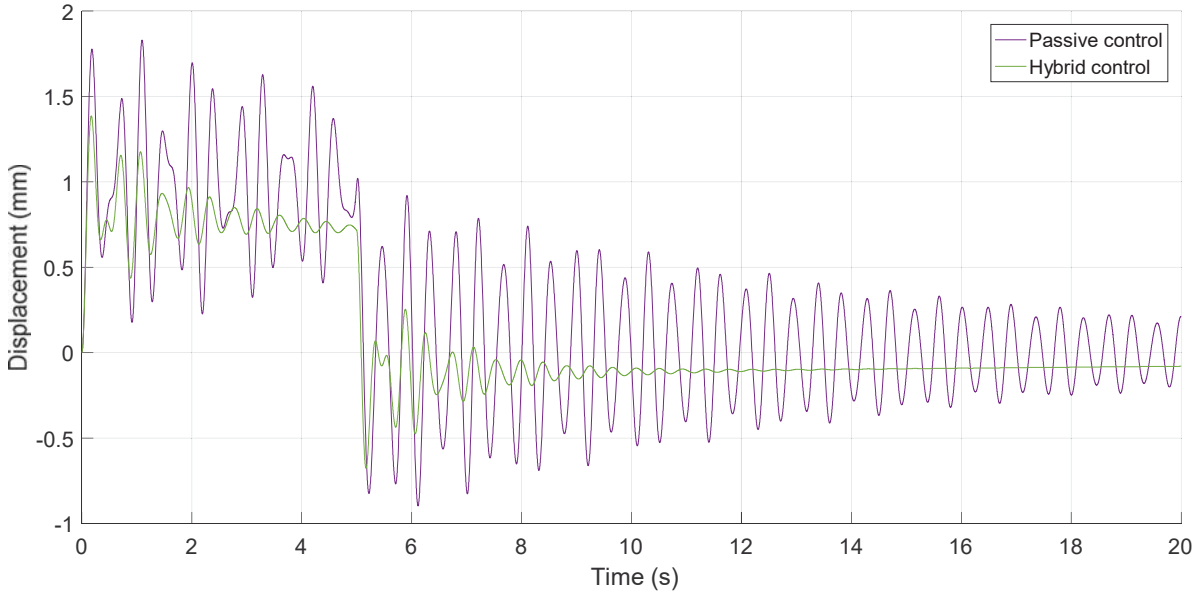

Figure 10: Displacement time history of the main system for step loading (TMD-IP and TMD-HIP).

Figure 11 shows the time history response using PID active control and PID hybrid control. The optimization of P, I, D and N values for active control is performed using the Simulink/MATLAB toolbox in order to approach the maximum response obtained using the two PID controllers. The values of the parameters found for PID active control are P = 49.8, I = 24.7, D = 3.5 and N = 2177. The active control shows a rise time equal to 33.1 s and a settlement time equal to 57.7 s.

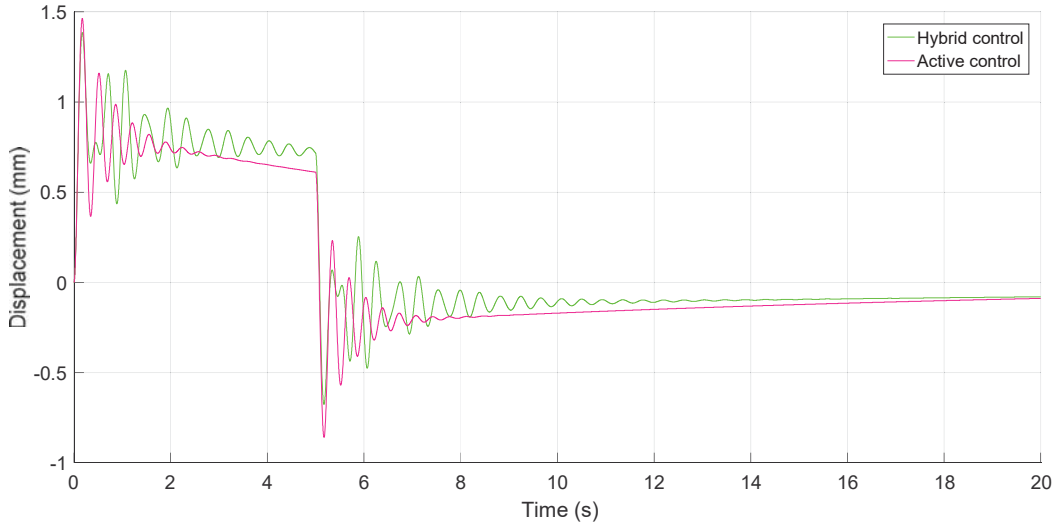

Figure 11: Displacement time history of the main system for step loading (AC and TMD-IP).

As the hybrid control shows better results than the passive control and PID active control, the response in the time domain is compared considering the system without control and with hybrid control as shown in Figure 12.

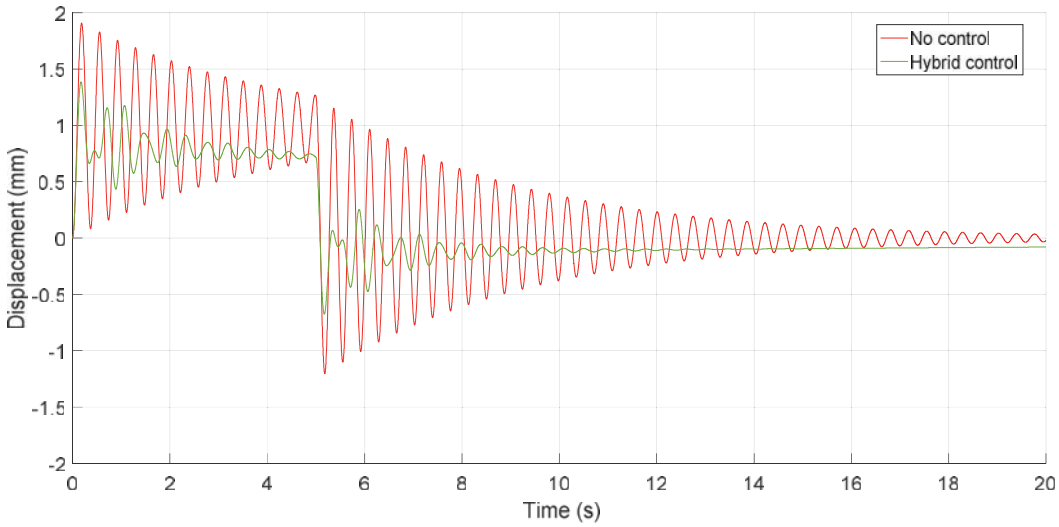

Figure12: Displacement time history of the main system for step loading (without control and TMD-IP).

Table 3 shows the maximum and RMS displacement values of the main system for the step loading case.

	No control	Passive control	Active control	Hybrid control
U_{max}(mm)	1.95	1.83	1.46	1.39
RMS(mm)	1.34	1.27	1.05	1.01

Table 3: Displacements due to step loading.

The system with passive control shows a reduction of 6.1% in the maximum displacement of the structure in relation to the system without control. The system with hybrid control presents a reduction of 28.7% and 24.0% in the displacement, respectively, compared to the system without control and the system with passive control. It is verified that there are ranges of time that the response of the system with passive control is lower than that of the hybrid control.

As for the PID controllers, although the maximum displacement between the active control and the hybrid control diverges by 3.96% during the transient phase, the hybrid control goes to zero faster than active control for longer times.

Despite the reduction in the amplitude response due to the step loading, when using the hybrid control, it is less than of the one due to the harmonic loading, the hybrid control is still an efficient alternative to attenuate vibrations due to step loadings.

Regarding to the RMS response, the system with passive control shows a reduction of 5.2% in relation to the system without control, while the system with hybrid control shows a reduction of 24.6% and 20.4%, respectively, in relation to the system without control and to the system with passive control.

The maximum control force obtained for the hybrid control is 0.09 N which represents only 27.5% of magnitude of external excitation. Therefore, the use of external energy is lower and because of this, the hybrid control system to minimize vibrations is a viable alternative in structures subjected to step loads. In the case of active control, it is found that to maintain the maximum displacement approximately equal to the one obtained with the hybrid control during the transient response, a control force of 0.12 N is required, which corresponds to 37.5% of the amplitude of the external excitation. Therefore, it is verified capability of the actuator needed when using active control is 33.3% higher than when using hybrid control.

The maximum angular displacement of the system with passive control is equal to 0.012 rad, being therefore less than 0.174 rad and allowing the use of the linear regime hypothesis for angular displacement.

5 CONCLUSIONS

In this work, the use of a TMD-HIP is studied, in order to verify the potential of this device. The analyses are performed using the parameters of the passive experimental model presented by Resende *et al.* [26]. Two loading cases are considered and the active control force is obtained through a PID controller.

Installing an inverted pendulum influences the modal proprieties of the system, while the addition of a PID controller does not change them. On the other hand, PID controller changes slightly resonant frequencies.

Passive control model reduces permanent response only in a frequency range when compared to the without control model. Although active control model presents the minimum peak permanent response, there is a specific frequency range where permanent amplitude response of the hybrid control is lower than that corresponding to the active control model.

Verifying the response in terms of maximum displacement, the use of hybrid control is shown as an efficient alternative, since it manages to reduce the maximum response by almost 85% when compared to the system without control.

In regard to RMS response, the hybrid control manages to reduce the response by almost 80% when compared to the system without control.

The required control forces vary from just 25% to 50% of amplitude of external actions, which can be considered satisfactory and feasible in practice.

The hybrid control shows better results to reduce the response of structures subjected to harmonic loading than to impulse loading, since in the case of step loads the structure needs an additional time to accommodate the response due to this type of excitation.

It is found that the TMD-HIP performs satisfactorily in reducing the translational response of the main system, with more significant reductions than the passive TMD-HIP presented by Resende *et al.* [26].

Compared to purely active control, the TMD-HIP leads to greater response reductions requiring small actuator force amplitudes.

For future work it is intended to implement this hybrid control in the experimental model. It is also worth mentioning that this device shows potential, based on more in-depth future studies for use on a real scale.

Keywords: Closed-loop model updating, output feedback, gain design

Abstract. *A conventional procedure for structural model updating is to solve an inverse problem with the aim of minimizing the discrepancy between an experimental target feature vector and a model-predicted one. The inverse problem to be solved is often ill-posed as the number of model parameters to be updated typically exceeds the number of target features. One way to confront this issue is to expand the target feature vector through closed-loop model updating, where gains are used to form multiple closed-loop eigenstructures from which target features are obtained. Besides confronting the ill-posedness of the inverse problem, the closed-loop model updating procedure also allows one to tailor the sensitivities of the target features by adequate design of the feedback gains. The present paper offers a comparative study in which the merit of different gain design criteria is examined for closed-loop sensitivity-based model updating. More specifically, the gains will be designed through eigenstructure assignment in an optimization setting where different cost functions, including the nuclear norm and the condition number of the sensitivity matrix, will be tested. Updating results will be shown for a numerical model of a shear building.*

1 INTRODUCTION

Within the fields of civil and mechanical engineering, numerical models are used extensively for structural design, analysis, health monitoring, and so forth [1]. In order to ensure adequate models, a selected subset of their parameters are updated to minimize the discrepancy between target features from the physical structure—for example, system poles, which are used in this paper—and the corresponding features predicted by the model. In this setting, the updating procedure involves solving an inverse problem, and an issue in this regard is that the number of updating parameters typically exceeds the number of identified poles, hence resulting in an under-determined system of equations. Furthermore, the sensitivities of the poles to the updating parameters are often relatively low [2, 3].

A suggested procedure to expand the target space, and hereby obtain a determined or over-determined system of equations, is to test the structure under known perturbations [4]. However, this approach suffers from its often limited practicality. In order to avoid testing under known perturbations, the use of output feedback to form multiple closed-loop systems has been proposed [5, 6, 7]. Different studies have examined the use of randomly generated gains to over-determine the system of equations [8, 9, 10], while another approach enables one to tailor the sensitivities through gain design in an eigenstructure assignment setting [11, 12]. The present paper addresses the latter by exploring the merit of different gain design criteria for sensitivity-based closed-loop updating of structural models. Specifically, four different criteria are examined; namely, maximization of three different norms of the sensitivity matrix and minimization of the condition number of the sensitivity matrix. The incentive for using each of the four criteria is outlined from a theoretical outset, and the performance is evaluated in the context of a comparative study with a numerical shear building model.

The paper is organized as follows: Section 2 presents the background theory of output feedback and eigenstructure assignment. The model updating procedure is outlined in section 3, section 4 describes the four gain design criteria, and section 5 contains a numerical examination of the merit of using the different criteria in closed-loop model updating. Finally, section 6 closes the paper with a conclusion.

2 OUTPUT FEEDBACK

A discrete-time, linear, and time-invariant state-space representation of a structural system is given by

$$x_{k+1} = A_d x_k + B_d u_k, \tag{1a}$$

$$y_k = C x_k, \tag{1b}$$

where $x_k \in \mathbb{R}^n$ is the state, $u_k \in \mathbb{R}^r$ the input, and $y_k \in \mathbb{R}^m$ the output, while $A_d \in \mathbb{R}^{n\times n}$, $B_d \in \mathbb{R}^{n\times r}$, and $C \in \mathbb{R}^{m\times n}$ are the system matrices. It should be noted that (1b) is only valid when measurements are displacements, velocities, non-collocated accelerations, or collocated accelerations if the direct transmission term is subtracted. Throughout this paper, it is assumed that one of the stated conditions is met.

When system (1) operates under static output feedback, the input is given by

$$u_k = -G y_k + v_k, \tag{2}$$

where $G \in \mathbb{R}^{r\times m}$ is the gain matrix and $v_k \in \mathbb{R}^r$ is some unmeasured excitation. Plugging (2) into (1) yields the closed-loop system

$$x_{k+1} = (A_d - B_d G C) x_k + B_d v_k, \tag{3}$$

with the non-defective closed-loop state matrix defined as $\bar{A} = A_d - B_d G C$.

2.1 Eigenstructure assignment

Let $\begin{Bmatrix} \lambda_1 & ... & \lambda_p \end{Bmatrix}$ denote a subset of $p \leq n$ closed-loop poles that are to be placed and $\Psi = \begin{bmatrix} \psi_1 & ... & \psi_p \end{bmatrix} \in \mathbb{C}^{n \times p}$ the corresponding eigenvectors. The eigenvalue problem of the closed-loop system (3) is given by

$$(A_d - B_d G C)\psi_j = \psi_j \lambda_j, \tag{4}$$

which can be rewritten into

$$\begin{bmatrix} A_d - I\lambda_j & -B_d \end{bmatrix} \begin{Bmatrix} \psi_j \\ GC\psi_j \end{Bmatrix} = 0. \tag{5}$$

By defining $Z = C \begin{bmatrix} \psi_1 & ... & \psi_p \end{bmatrix} \in \mathbb{C}^{m \times p}$ and $\Gamma = GC \begin{bmatrix} \psi_1 & ... & \psi_p \end{bmatrix} \in \mathbb{C}^{r \times p}$, it follows that

$$GZ = \Gamma, \tag{6}$$

so when the number of placed poles is equal to the number of outputs, the gain follows as

$$G = \Gamma Z^{-1}. \tag{7}$$

In the case of homogeneous sensing, Z is poorly conditioned, which will typically result in a subset of the unplaced poles being unstable [7]. To resolve the instability issue, (6) is over-determined by setting $p = n$ and then

$$GZW^{1/2} = \Gamma W^{1/2}, \tag{8}$$

where $W \in \mathbb{R}^{n \times n}$ is a diagonal weighting matrix with $\alpha_i > 1$ assigned to the subset of poles used in the updating and ones assigned to the rest. The weighted least-squares solution is then given by

$$G = \Gamma W^{1/2}(ZW^{1/2})^{\dagger} = \Gamma W Z^H (ZWZ^H)^{-1}, \tag{9}$$

where superscripts † and H denote the pseudo-inverse and Hermitian transpose, respectively.

3 MODEL UPDATING FORMULATION

Let $\Lambda_{\mathcal{S}}, \Lambda_{\mathcal{M}} \in \mathbb{C}^{qp}$ denote physically estimated and model-predicted poles for q different closed-loop systems, then the unknown parameters $\theta \in \mathbb{R}^s$ are estimated through the following constrained optimization problem:

$$\begin{aligned} &\arg\min_{\theta \in \mathbb{R}^s} ||\Lambda_{\mathcal{S}} - \Lambda_{\mathcal{M}}(\theta)||_2^2 \\ &\text{subject to} \quad \forall i \in [1, s] : \tau_i \leq \theta_i \leq \eta_i, \end{aligned} \tag{10}$$

where τ and η are lower and upper bounds on θ. The procedure is to form enough closed-loop systems to ensure that $qp \geq s$, such that the optimization problem is well-posed. Worth of explicit note is that the number of poles selected for each of the q gain can differ, but a fixed number, p, is assumed here to promote simplicity.

4 GAIN DESIGN

In order to obtain a determined or over-determined system of equations, q gains are designed and gathered in the compound gain matrix

$$\mathcal{G} = \begin{bmatrix} G_1 & G_2 & ... & G_q \end{bmatrix} \in \mathbb{R}^{r \times qm} \tag{11}$$

from which we place the poles

$$\Lambda = \begin{Bmatrix} \Lambda_{G_1} & ... & \Lambda_{G_q} \end{Bmatrix} \in \mathbb{C}^{qp}. \tag{12}$$

The design of $\mathcal{G}$ can be carried out on the basis of different criteria; of which the four outlined in subsection 4.2 are examined in the present paper. Regardless of what criterion one opts for, the general aim is to maximize the Fisher information that the target features carry on the model parameters to be updated.

4.1 Fisher information on updating parameters

For an observable variable, λ, that carries information on θ, the Fisher information matrix is defined as [13]

$$\mathcal{F} = -E\left(\frac{\partial^2 \ln(p(\lambda_i;\theta))}{\partial\theta_i \partial\theta_j}\right), \tag{13}$$

in which $E(\bullet)$ denotes the expected value of $\bullet$. Assuming that λ_i is Gaussian and that the covariance, Σ, does not depend on θ, the Fisher information matrix can be expressed as

$$\mathcal{F} = J_{\mathcal{G}}^H \Sigma^{-1} J_{\mathcal{G}}, \tag{14}$$

where $J_{\mathcal{G}} \in \mathbb{C}^{qp \times s}$ is the non-defective sensitivity matrix

$$J_{\mathcal{G}} = \begin{bmatrix} J_{G_1} \\ \vdots \\ J_{G_q} \end{bmatrix} = \begin{bmatrix} \frac{\partial \Lambda_{G_1}}{\partial \theta} \\ \vdots \\ \frac{\partial \Lambda_{G_q}}{\partial \theta} \end{bmatrix}. \tag{15}$$

4.2 Gain design criteria

The present subsection outlines four gain design criteria that aim to maximize the model parameter estimation accuracy by increasing the inherent Fisher information. The merits of the criteria are explored and compared in a numerical example in section 5.

4.2.1 Nuclear norm

If $\Sigma = \gamma I$, which is often assumed with $\gamma \in \mathbb{R}^+$, then $\mathcal{F} \propto J_{\mathcal{G}}^H J_{\mathcal{G}}$. This suggests to design the gains such that

$$\tilde{\mathcal{G}} = \arg\max_{\mathcal{G}} \|J_{\mathcal{G}}\|_*, \tag{16}$$

where $\tilde{\mathcal{G}}$ is the optimal gain based on the cost function and $\|J_{\mathcal{G}}\|_*$ is the nuclear norm,

$$\|J_{\mathcal{G}}\|_* = \text{trace}\left(\sqrt{J_{\mathcal{G}}^H J_{\mathcal{G}}}\right) = \left\| \begin{matrix} \sigma_1 \\ \vdots \\ \sigma_{qp} \end{matrix} \right\|_1 \tag{17}$$

with σ_i being the i'th singular value of $J_{\mathcal{G}}$. It is worth mentioning that this norm promotes sparsity.

4.2.2 Frobenius norm

The Frobenius norm, which is given by

$$\|J_{\mathcal{G}}\|_F = \sqrt{\text{trace}(J_{\mathcal{G}}^H J_{\mathcal{G}})} = \left\| \begin{matrix} \sigma_1 \\ \vdots \\ \sigma_{qp} \end{matrix} \right\|_2, \tag{18}$$

also contains the dot product of the sensitivity matrix, thus a cost function is formulated as

$$\tilde{\mathcal{G}} = \arg\max_{\mathcal{G}} \|J_{\mathcal{G}}\|_F. \tag{19}$$

Note that, unlike the nuclear norm, the Frobenius norm does not promote sparsity.

4.2.3 Individual gain evaluation

The cost functions based on the nuclear and Frobenius norms aim to increase the sensitivity by maximizing the ℓ_1- and ℓ_2-norms of the singular values of the sensitivity matrix. Another approach is to design gains individually, where each gain increases sensitivity to a specific parameter by maximizing the ℓ_2-norm of the associated column in the sensitivity matrix. Hence,

$$\tilde{G}_i = \arg\max_{G_i} \|J_{G_{i_{\bullet i}}}\|_2, \tag{20}$$

such

$$\tilde{\mathcal{G}} = [\tilde{G}_1 \dots \tilde{G}_q]. \tag{21}$$

4.2.4 Condition number

The model updating formulation (10) is solved iteratively on the basis of the linearized Taylor approximation

$$J_{\mathcal{G}}(\theta^{(i+1)} - \theta^{(i)}) = \Lambda_{\mathcal{S}} - \Lambda_{\mathcal{M}}^{(i)}. \tag{22}$$

Evidently, the parameter estimation involves (pseudo-)inversion of $J_{\mathcal{G}}$, thus a cost function is defined as

$$\tilde{\mathcal{G}} = \arg\min_{\mathcal{G}} \kappa(J_{\mathcal{G}}), \tag{23}$$

where $\kappa(J_{\mathcal{G}})$ is the condition number of the sensitivity matrix.

5 NUMERICAL EXAMPLE

The merit of the four cost functions for gain design is tested numerically by comparing model updating results for the 10-level shear building shown in figure 1. We refer to a *target model* and *nominal model*, with the latter being the one to be updated. Mass, damping, and stiffness values for the nominal model are shown in figure 1. The target model, which in this example replaces a physical system, is identical to the nominal model except for inter-story stiffness reductions of 10 % and 5 % at the first and second floor, respectively. Two sine sweep inputs, which only excite the first open-loop mode, are applied at floor one and two, while outputs are taken as displacements at floor two, four, six, and eight with a sampling frequency of 100 Hz. The outputs are imposed with 2 % Gaussian white noise, and the system identification is performed

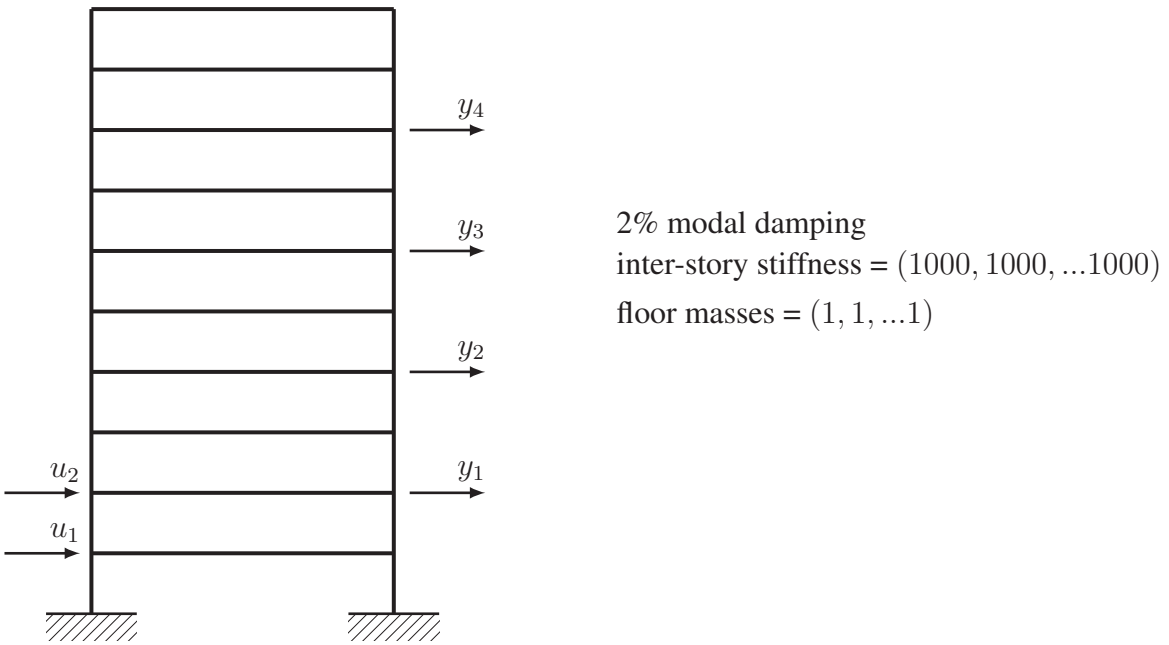

Figure 1: Nominal model of the structure for the numerical example.

using a subspace identification algorithm [14]. The model updating analysis is performed in a Monte Carlo setting with 1000 simulations, where the first closed-loop pole is extracted as target feature. The inter-story stiffnesses between floor one, two, and three are chosen as the updating parameters, thus three gains are designed in order to obtain a determined system of equations for the model updating. The gains are designed with the cost functions defined in section 4.2, and the optimization is carried out using a genetic algorithm (GA). For more information on GAs, the reader is referred to [15].

The closed-loop poles are placed using (9), where the constraints listed below are applied. The first constraint ensures stability, the second ensures that the poles can be estimated, the third limits the damping, and the fourth provides the lower and upper bounds on θ. For the selected τ and η, it has been numerically verified that the nominal and target models both comply with the other constraints.

- $\mathbb{R}(\lambda_{\mathcal{S}}) < 0$
- $|\mathbb{I}(\lambda_{\mathcal{S}})| > 1$
- $\frac{-\mathbb{R}(\lambda_{\mathcal{S}})}{|\lambda_{\mathcal{S}}|} < 0.1$
- $\tau = 0.80$ and $\eta = 1.20$.

The model updating is carried out by minimization of (10) using the "fmincon"-algorithm in MATLAB®. Converged parameter estimation results are shown in figure 2 and listed in tables 1-2 for the under-determined open-loop formulation and the determined closed-loop formulations using each of the four gain design criteria. Evidently, the model parameters do not converge to the exact values for the open-loop formulation or the closed-loop ones based on the nuclear and Frobenius norms as gain design criteria. The parameter estimation fails when using either the nuclear or Frobenius norm to design $\mathcal{G}$, because a subset of the closed-loop poles are approximately equal, which results in an ill-conditioned sensitivity matrix. For the

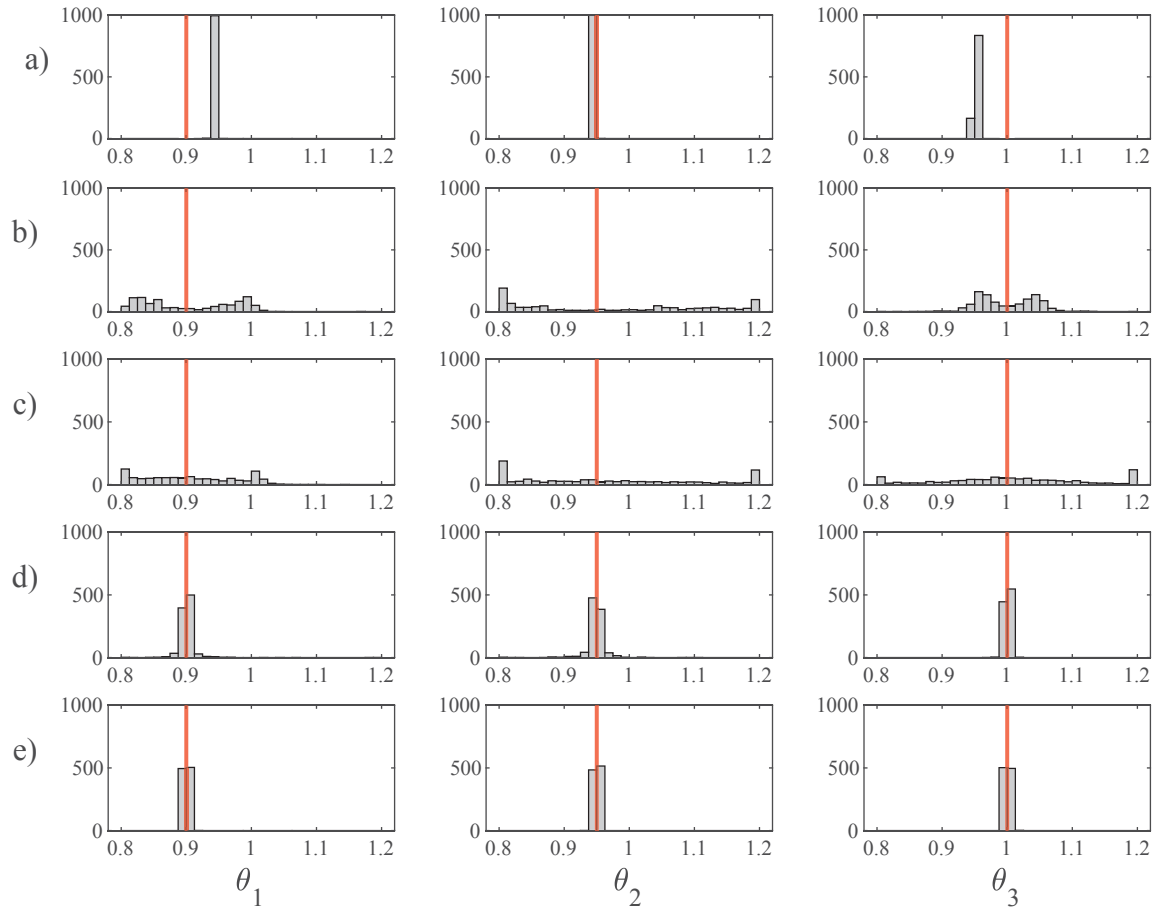

Figure 2: Estimation results for θ_i in a) open loop and in closed loop using gains designed based on b) nuclear norm, c) Frobenius norm, d) individual, and e) condition number. The exact θ_i-values are indicated with a red vertical line.

cost function that minimizes the condition number of the sensitivity matrix, the mean values are converged to the exact θ_i-values and with standard deviations comparable to those obtained in open loop. Evidently, the condition number-based cost function allows for the most accurate parameter estimation.

	E(θ_i)				
	Open-loop	Nuclear	Frobenius	Individual	Condition number
θ_1	0.943	0.904	0.907	0.902	0.900
θ_2	0.945	0.976	0.969	0.949	0.950
θ_3	0.950	0.999	1.010	1.000	1.000

Table 1: Mean values for the updated θ_i-values. The exact values are $\theta_1 = 0.9$, $\theta_2 = 0.95$, and $\theta_3 = 1$.

	std.(θ_i)				
	Open-loop	Nuclear	Frobenius	Individual	Condition number
θ_1	0.001	0.071	0.073	0.019	0.001
θ_2	0.001	0.146	0.137	0.018	0.002
θ_3	0.001	0.045	0.112	0.002	0.002

Table 2: Standard deviations for updated θ_i-values.

6 CONCLUSION

The paper offers a comparative study in which the merit of different gain design criteria is examined for closed-loop model updating. Gains are designed through eigenstructure assignment in an optimization setting where different cost functions are tested numerically in the context of a 10-level shear building. The gains are designed in order to maximize the parameter estimation accuracy, and the numerical example shows that, out of the four gain design criteria explored in this study, minimizing the condition number of the sensitivity matrix yields the most accurate parameter estimates.

Keywords: seismic rotational components, seismic torsional component, seismic rocking components, r/c structures, seismic damage, eccentricity effects

Abstract. *The influence of the torsional component of earthquake excitations on the response of reinforced concrete (R/C) structures is the aim of this work. The structure that is going to be examined is asymmetric in plan and regular in elevation 5-storey R/C building. In most studies, seismic input is modeled only using the translational components of the ground acceleration, while the torsional one is ignored. This is due to the observation that the torsional component has minimal effect on low-rise buildings. Hence, the accelerometers used would not measure it, leading to a lack of records. Nowadays, technology provides such instruments and relative records have been made available. Indicative of this is that design response spectra for rotational components are introduced in the design codes. In this paper, nonlinear dynamic time history analyses of the selected R/C building are performed (a) considering the torsional component of the excitation and (b) without it. From the numerical results it is shown that the impact of torsional component in structural response must be taken into account. Moreover, the extracted results indicate that the provided by Eurocodes values for the accidental eccentricity can effectively capture the effects of the torsional component on the seismic damage.*

1 INTRODUCTION

Generally, the seismic analysis and design of new buildings, as well as the assessment of the seismic performance of existing ones, are only conducted by applying the translational components of earthquakes, thus ignoring the effects of the rotational components on the structural response. The main reason for the above assumption is the fact that earthquake records that include rotational components were not available since the last years, because these components are difficult to be recorded by accelerographs in the free field. Thus, some researchers attempted to derive rotational components by combining mathematical equations with the properties of surface and body waves and geological parameters of soil. Nevertheless, during the last years it has been made feasible to record real ground motion with rotational components too. The rotational components of an earthquake record consist of the torsional component, which is the rotation about vertical axis, and the other two rocking components, which are the rotations about the two horizontal axes. The effects of these components of earthquakes on structures have been studied by a number of investigators and it was found that their contribution may significantly affect the seismic response and the damage of structures.

A lot of seismology scientists focus on rotational records over the last years. Droste and Teisseyre [1] using the signals taken from an array of seismographs calculated the rotational excitations. Takeo [2] using a gyro-sensor with combination of inertial angular displacement sensor measure the rotation motion during an earthquake happened in April 1998 in Japan. Advances in rotational seismology about instrumentation, theory and observations are presented in the work of Igel et al. [3]. More cheaper sensors based on electrochemical magnetohydrodynamic technology used from Liu et al. [4] and Wassermann et al. [5]. There are a lot of procedures that calculate rotational time series from translational recordings. A Single Station Procedure (SSP), is one of them. A number of researchers such as Lee and Trifunac [6], Castellani and Boffi [7], Li et al. [8] and Basu et al. [9], presented their work based on SSP. Site soil conditions are connected with rotations earthquake excitations. This link is proposed in the work of Sbaa et al. [10]. Perron et al. [11] show that the interaction of translation and rotation records seems to be useful, for engineering seismology applications and for investigation of the composition of the wavefield and this has a result to avoid a deployment of dense arrays.

Considering the torsional component, current seismic code provisions allow to ignore it when conducting the seismic analysis (with the exception of special structures e.g. towers, masts and chimneys, see [12]), but they recommend the shifting of mass center in order to account for the effects of this component on the seismic response. The shifting of mass center is achieved with the aid of the accidental eccentricity. Bozev et al. [13], performed analysis accounting the rotational components of seismic action on towers, masts and chimneys according to EN1998-6. Zembaty [14], work on rotational seismic code definition in EN1998-6, for slender tower-shaped structures. Zembaty and Boffi [15], apply response spectrum analysis using horizontal and rotational spectra described in Eurocode, and show the effect of rotational excitation to moments diagram along the height of a tall tower.

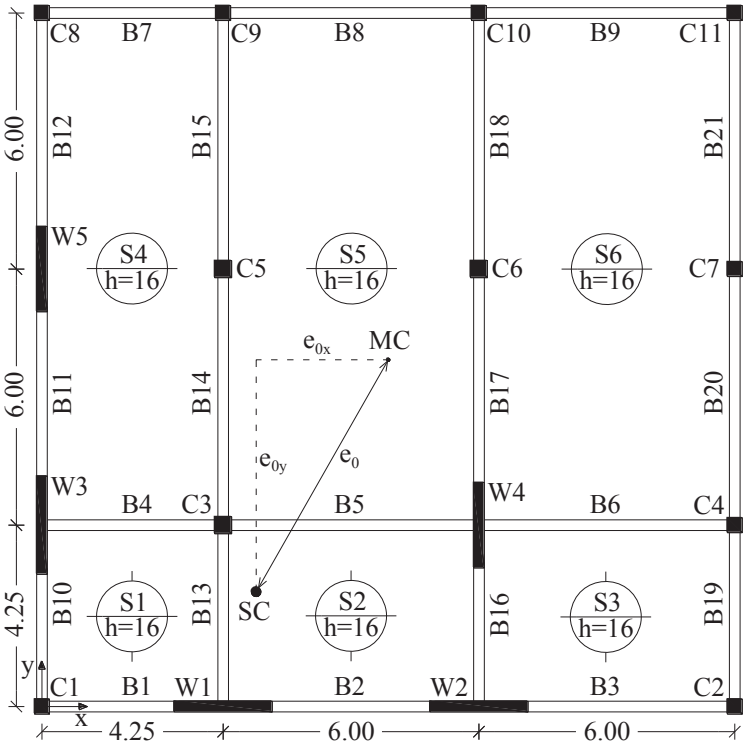
A lot of works investigated the effect of rotational components of ground motion on structural response. The influence of rotational components on a base-isolated nuclear power plant was investigated by Wolf et al. [16]. Furthermore, rotational components of near-fault earthquakes effects on triple concave friction pendulum base-isolated asymmetric structures is investigated by Tajammolian et al. [17]. Another application of rotational excitation in a base-isolated building and the rocking mode identification was done by Politopoulos [18]. A simplified relation for the application of rotational components to seismic design codes and calculation of response of multiple-support structures subjected to horizontal and rocking components are presented in references [19], [20]. Basu et al. [21], [22], suggests an equivalent accidental eccentricity to account for the effects of torsional ground motion on structures.

Torsion in building due to base rotational excitation was investigated by De-La-Llera and Chopra, [23]. Yin et al. performed earthquake time history analysis using recorded rotation ground excitation at a structure [24]. A parametric study on the effect of rotational ground motions on building structural responses is also examined by Vicencio and Alexander [25].

In the present paper the adequacy of the accidental eccentricity as a parameter to capture the effects of the torsional component on the seismic damage is further investigated. For this purpose, one 3D asymmetric 5-storey R/C building with structural system consisting of frames and walls is examined. The building is analyzed with the aid of nonlinear time-history analysis using an adequate number of real ground motions with translational and torsional components. Two different categories of structural models for the building and the seismic excitation are investigated: a) a model taking into account the translational and the torsional components of the seismic motion applied to the mass center of the building and b) models taking into account only the translational components of the seismic motion, but using different values of the accidental eccentricity. Then, a comparison between the above models is carried out in order to examine the effectiveness of the accidental eccentricity in capturing the effects of torsional component of seismic motion. Useful results are derived concerning the effectiveness of the specific Eurocode provisions as regards the proposed values for accidental eccentricities.

2 THE EXAMINED BUILDING: DESCRIPTION - MODELING - DESIGN

The data of the building which was used in the present investigation are outlined in Fig. 1. This building is asymmetric in plan but regular in elevation according to the EN1998-1 [26].



Dimensions of the cross-sections of R/C members (b/h):

Storey	Height	Beams (in cm)
1^{st}-2^{nd}	3.2m	25/55
3^{rd}-4^{th}	3.2m	25/50
5^{th}	3.2m	20/45

Storey	Columns	Walls
1^{st}-3^{rd}	35/35 (C3,C5, C6: 40/40)	W1,W2, W3: 230/25
4^{th}-5^{th}	30/30	W4,W5: 200/25

Behavior factor: q=3.0

Structural eccentricities e_{0x}, e_{0y}, torsional radii r_x, r_y, and Radius of gyration l_s:

e_{0x}(m)	e_{0y}(m)	r_x(m)	r_y(m)	l_s(m)
3.1	5.44	7.87	9.44	6.7

MC: Mass Center
SC: Stiffness Center

Structural type / Ductility class	Ductile Wall System / Medium (DCM)
Concrete / Steel	C20/25 / S500B
Slab loads	Dead G=1.0kN/m^2, Live Q=2.0kN/m^2
Masonry loads	Perimetric beams 3.6kN/m^2, Internal beams 2.1kN/m^2
Design spectrum for elastic analysis (§2.2.2.5 of EN1998-1)	Reference PGA a_{gR}=0.24g; Importance class: II $\rightarrow \gamma_I$=1 $\rightarrow a_g$=0.24g (Ground type: C)

Figure 1: Data of the examined 5-storey R/C building

In the framework of design the examined building was analyzed for static loads (1.35G+1.50Q) and for seismic loads (G+0.3Q±E, taking into consideration the accidental torsion effects) using the elastic modal response spectrum analysis, as defined in EN1998-1 [26]. The R/C members were designed following the provisions of EN1992-1-1 [27] and EN1998-1 [26]. As regards the modeling of building the following assumptions (compatible to the provisions of EN1988-1) were made:

- The floor slabs were assumed to act as rigid diaphragms,
- The beam-wall joints were modeled as perfectly rigid,
- The building was considered to be fully fixed to the ground,
- The infill walls were considered only as vertical loads and not as seismic resistant structural elements,
- The flexural and shear stiffness properties of the R/C members' cross-sections were considered to be equal to one-half of the corresponding stiffness of the uncracked ones.

As regards the modeling in the framework of the nonlinear time history analyses, for the R/C structural elements' nonlinear behavior force-based beam-column elements were implemented in OpenSees software [28], using a 5-point Gauss – Lobato integration scheme. Fiber sections, describing exactly the reinforcement detailing were assigned to the beam, column and wall elements. In addition, appropriate material constitutive laws (according to EN1992-1-1 and EN1998-1) were utilized for the steel rebar, the unconfined and confined concrete regions respectively.

3 THE SEISMIC RECORDS

The building models were subjected to the 6.4 moment magnitude, M_w, earthquake excitation (mainshock) which happened at 2015/11/17 in Kefalonia Island, Greece, as well as to six of the aftershocks of the seismic sequence (in total 7 earthquake records according to provisions of EN1998-1). The mainshock's epicenter latitude and longitude were 38.16^o and 20.50^o degrees respectively. The event depth was 10.7 km. The record history of translational and torsional component was provided by by Argonet project, a 3D accelerometric array implemented on the island of Kefalonia in Greece, [10], [[11] and is ostensive shown in Fig. 2.

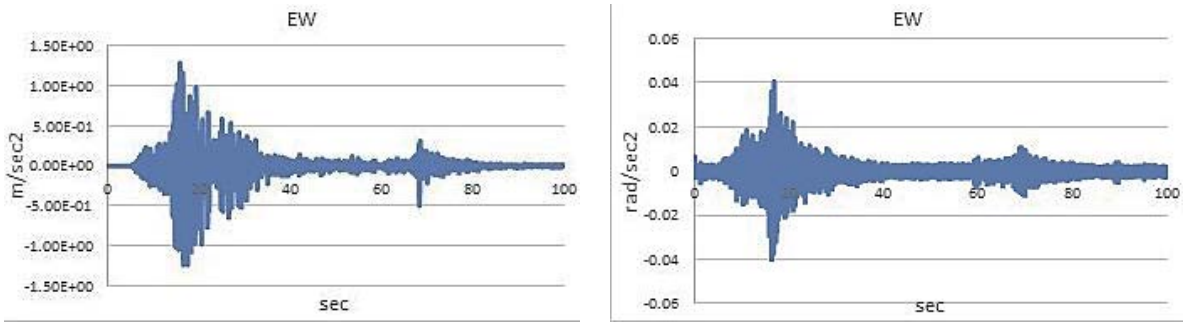


Figure 2: Two components of the mainshock: translational and torsional ones.

4 DESCRIPTION OF THE PARAMETRIC INVESTIGATION

The procedure followed in order to accomplish the aim of the present study comprises of a series of analyses of the selected building, according to the following characteristics:

- Nonlinear time history analyses using the 7 selected seismic records with 2 (only translational) or 3 (2 translational and 1 rotational) components.
- Application of the (2 or 3) seismic components of each record to the Mass Center of the building (MC), as well as to positions at distances from the MC equal to the following

values of accidental eccentricity: e_a=±0.025L, e_a=±0.05L, e_a=±0.1L και e_a=±0.2L. The aforementioned distances are measured along the line that connects the MC with the Stiffness Center (SC) of the building, whereas L denotes the building's dimension along the diagonal of its plan view. The description of the abovementioned distances is given in Fig. 3.

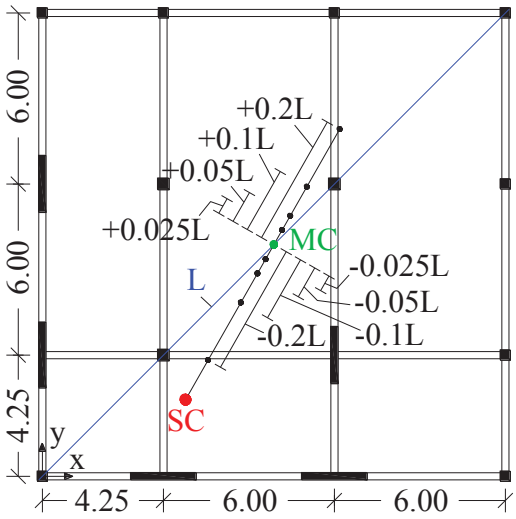

Figure 3: Positions of application of the 2 (or 3) components of the seismic records

- In order to account for two different seismic intensities corresponding to certain performance levels suggested by EN1998-3 (§2.1) [29], the accelerograms were scaled to two different values of Peak Ground Acceleration (PGA). More specifically, the scaling factors adopted in the present study correspond to the following performance levels:

a) Performance level of Significant Damage (SD). According to EN1998-3 (§2.1(3)P) this performance level corresponds to a reference return period of 475 years, which, in turn, corresponds to PGA=a_g·S=0.276g, where a_g=0.24g and S=1.15 are the design ground acceleration and the soil factor respectively used for the elastic analysis of the buildings (EN1998-1 (§3.2.1(3) and §2.1(4)) and the Greek National Annex). So, in this case the 7 selected records were scaled to PGA=0.276g.

b) Performance level of Near Collapse (NC). According to EN1998-3 (§2.1(3)P) this performance level corresponds to a reference return period of 2475 years, which, in turn, corresponds to PGA=1.72·a_g·S=0.475g (EN1998-1 (§3.2.1(3) and §2.1(4)) and the Greek National Annex). So, in this case the selected 7 records were scaled to PGA=0.475g.

For each one of the 7 seismic records the following analyses were conducted (Table 1):

A/A	Accidental Eccentricity e_a	Number/Type of excitations
1,2	±0.025L	3 / (2 translational + 1 torsional)
3,4	±0.05L	3 / (2 translational + 1 torsional)
5,6	±0.10L	3 / (2 translational + 1 torsional)
7,8	±0.20L	3 / (2 translational + 1 torsional)
9,10	±0.025L	2 / (2 translational)
11,12	±0.05L	2 / (2 translational)
13,14	±0.10L	2 / (2 translational)
15,16	±0.20L	2 / (2 translational)
17	0	2 / (2 translational)
18	0	3 / (2 translational + 1 torsional)

Table 1: Parameters of analyses for each one of 7 selected records and performance levels (NC and SD)

Consequently, in total 252(=7·18·2) nonlinear time history analyses were conducted.

With regard to the damage measures that were used, the following parameters were chosen, the use of which has been well documented in the relative literature:

- Maximum interstorey drift ratios along building's axes X, Y (Fig. 1).
- Maximum roof rotations about the vertical axis of the building (axis Z).
- Maximum roof accelerations along building's axes X, Y (Fig. 1).

5 RESULTS

In the current section the main results extracted from the parametric investigation (section 4) are presented and discussed. The Figures 4, 5 and 6 illustrate the ratios of maximum values of the examined seismic Response Parameters (RP), (i.e. the values of interstorey drifts along the axes X (DrX) and Y (DrY), the rotations of floors considered as rigid diaphragms about the vertical axis Z (Rz) and the accelerations of floors along the axes X (AccX) and Y (AccY)) extracted from analyses performed considering 3 components of seismic excitation (the two translational and the torsional) applied to MC(e_a=0) and the corresponding values exported from analyses performed considering the 2 translational components of seismic excitation and several values for the accidental eccentricity (e_a≠0, see Fig. 3). More specifically, the values of the ratios of the examined RP in Figs. 4, 5, 6 are calculated by means of Eq. (1).

$$\frac{RP(e_a=0)}{RP(e_a\neq 0)}=\frac{(1/7)\cdot\sum_{i=1}^{7}\left\{\max\left[RP_{storey1,\dots},RP_{storey5}\right]_{i,e_a=0}\right\}}{(1/7)\cdot\sum_{i=1}^{7}\left\{\max\left[RP_{storey1,\dots},RP_{storey5}\right]_{i,e_a\neq 0}\right\}} \quad \left[\begin{array}{l}RP=DrX,\ DrY,\ Rz,\ AccX,\ AccY,\\ \max(Drx,DrY),\max(Accx,AccY)\end{array}\right] \tag{1}$$

Where: i is the seismic record (i=1÷7), e_a=0 indicates the analyses of the building considering 3components of excitation (the two translational and the torsional) applied to MC, and e_a≠0 indicates the analyses of the building considering 2 components of excitation (only the translational components) and several values for the accidental eccentricity (i.e. e_a=±0.025L, ±0.05L, ±0.10L and ±0.20L).

It is obvious that when the values of these ratios tend to 1.00 then the analyses in which the 2 translational seismic components and accidental eccentricities are considered (e_a≠0) export almost equal values of RPs with the corresponding analyses in which 3 seismic components are considered in MC (e_a=0).

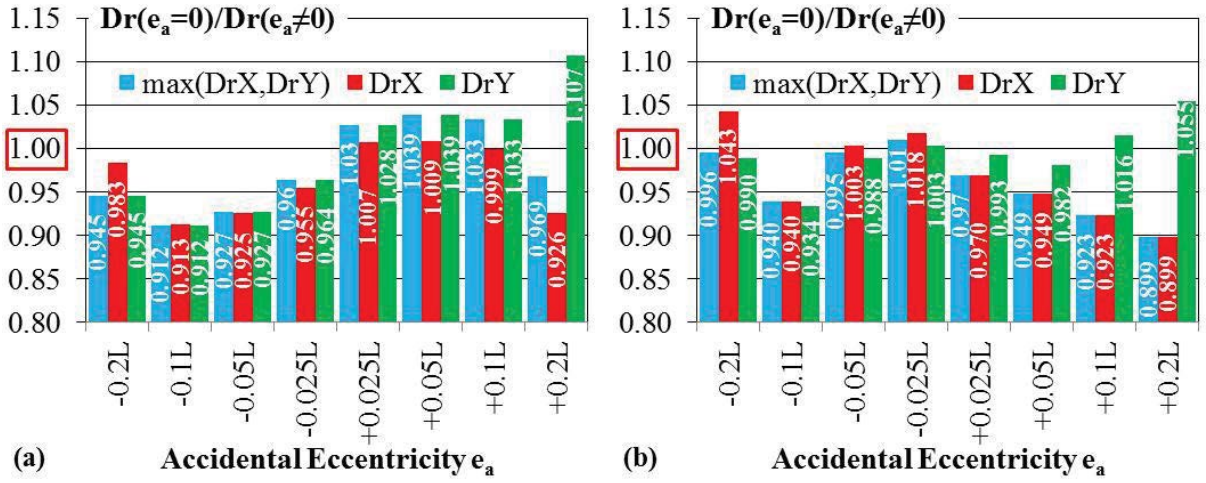

Figure 4: Ratios of the maximum interstorey drifts along the direction of X (DrX), Y (DrY) axes and max(DrX, DrY) extracted by analyses performed considering 3 seismic components applied to MC (e_a=0) and those extracted by analyses performed considering 2 seismic components in several distances from MC (e_a≠0): (a) Performance level SD, (b) Performance level NC

Fig. 4 illustrates the ratios of interstorey drifts DrX, DrY and the maximum values between them max(DrX,DrY). More specifically, the Fig. 4(a) presents the ratios which correspond to analyses conducted considering the performance level SD, whereas the Fig. 4(b) presents the ratios extracted considering the performance level NC. The study of this figure leads to the following main conclusions:

- The values of accidental eccentricity e_a for which the analyses conducted considering the two translational seismic components lead to ratios $Dr(e_a=0)/Dr(e_a\neq0)$ close to 1 fluctuate between +0.025L and +0.1L in case of performance level SD. The corresponding range of values of e_a in case of analyses for performance level NC is between -0.05L and -0.025L.
- Generally, the higher values of $e_a(=\pm0.2L)$ fail to lead to values of ratios $Dr(e_a=0)/Dr(e_a\neq0)$ close to 1. Exception to this conclusion is the value -0.2L in case of performance level NC.

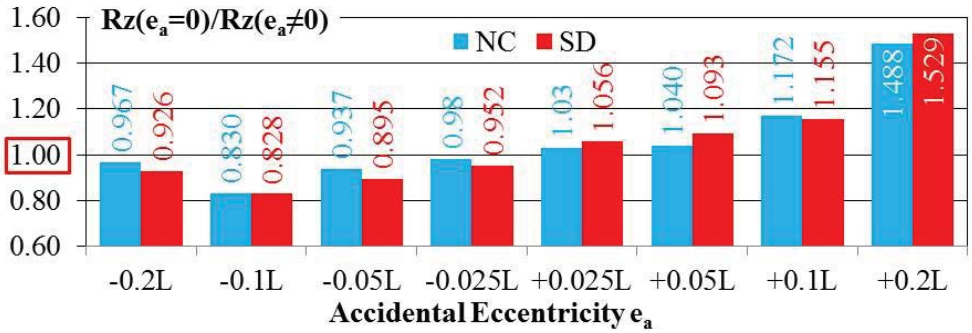

Figure 5: Ratios of the maximum floor rotations about the vertical axis Z (Rz) extracted by analyses performed considering 3 seismic components applied to MC ($e_a=0$) and those extracted by analyses performed considering 2 seismic components in several distances from MC ($e_a\neq0$).

Fig. 5 illustrates the ratios of the floor rotations about the vertical axis Z ($Rz(e_a=0)/Rz(e_a\neq0)$) extracted from analyses for performance levels NC and SD. The main conclusions that can be drawn from this figure are the following:

- The values of accidental eccentricities e_a which lead to values of ratios $Rz(e_a=0)/Rz(e_a\neq0)$ closer to 1 are located between -0.025L and +0.05L. Thus, as in case of ratios $Dr(e_a=0)/Dr(e_a\neq0)$ the smaller values of e_a are more effective than the larger ones.
- No significant diversification is observed between the results of analyses for performance levels NC and SD as regards the relation e_a–$Rz(e_a=0)/Rz(e_a\neq0)$.

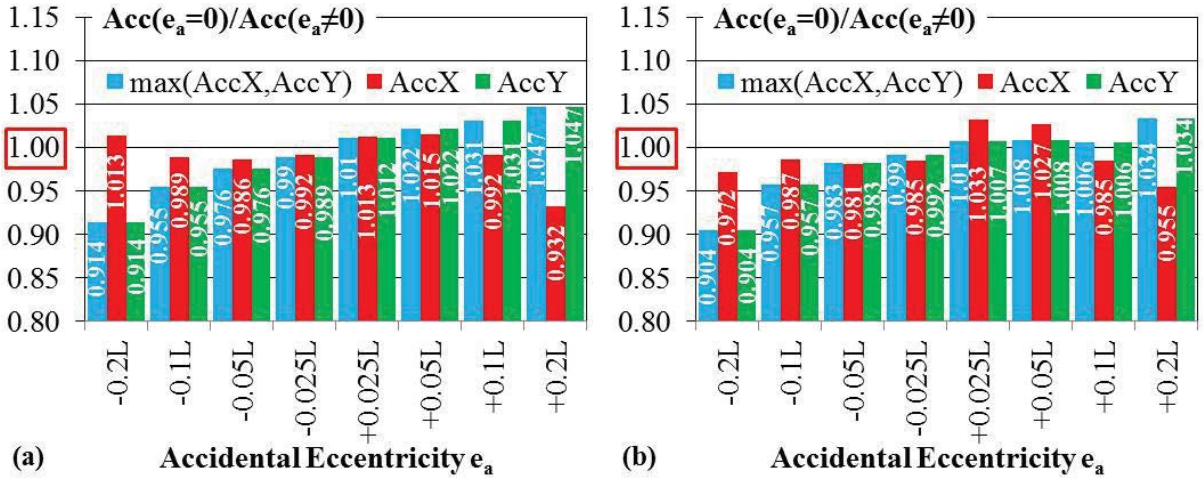

Figure 6: Ratios of the maximum floor acceleration along the direction of X (AccX), Y (AccY) axes and max(AccX, AccY) extracted by analyses performed considering 3 seismic components applied to MC ($e_a=0$) and those extracted by analyses performed considering 2 seismic components in several distances from MC ($e_a\neq0$): (a) Performance level SD, (b) Performance level NC

Fig. 6 illustrates the ratios of floor accelerations AccX, AccY and the maximum values between them max(AccX, AccY). The Fig. 6(a) presents the ratios which correspond to analyses conducted considering as performance level the level SD, whereas the Fig. 6(b) presents the ratios extracted considering the performance level NC. The study of Fig. 6 leads to the conclusion that while the convergence of $Acc(e_a=0)/Acc(e_a\neq0)$ ratio values to 1 is achieved using mainly low values of e_a as in the case of $Dr(e_a=0)/Dr(e_a\neq0)$ ratios the range of these values is greater in the current case. More specifically, in both examined cases of performance level (i.e. NC and SD) the values of e_a which lead to $Acc(e_a=0)/Acc(e_a\neq0)$ ratio values closer to 1 fluctuate between -0.05Land +0.05L.

The Figures 7 and 8 illustrate the variation along the height of the values of interstorey drifts along axes X (DrX) and Y (DrY) extracted from analyses considering performance levels SD and NC. These are the mean (according to EN1998-1) values of DrX and DrY all over the used seismic records (Eq. 2).

$$\text{meanDrX}_j(\%)=\frac{1}{7}\cdot\sum_{i=1}^{7}\left\{\text{DrX}_{j,i}(\%)\right\}\ ,\ \text{meanDrY}_j(\%)=\frac{1}{7}\cdot\sum_{i=1}^{7}\left\{\text{DrY}_{j,i}(\%)\right\}\quad (j=1\div5) \tag{2}$$

Where: i is the seismic record (i=1÷7) and j (j=1÷5) is the storey.

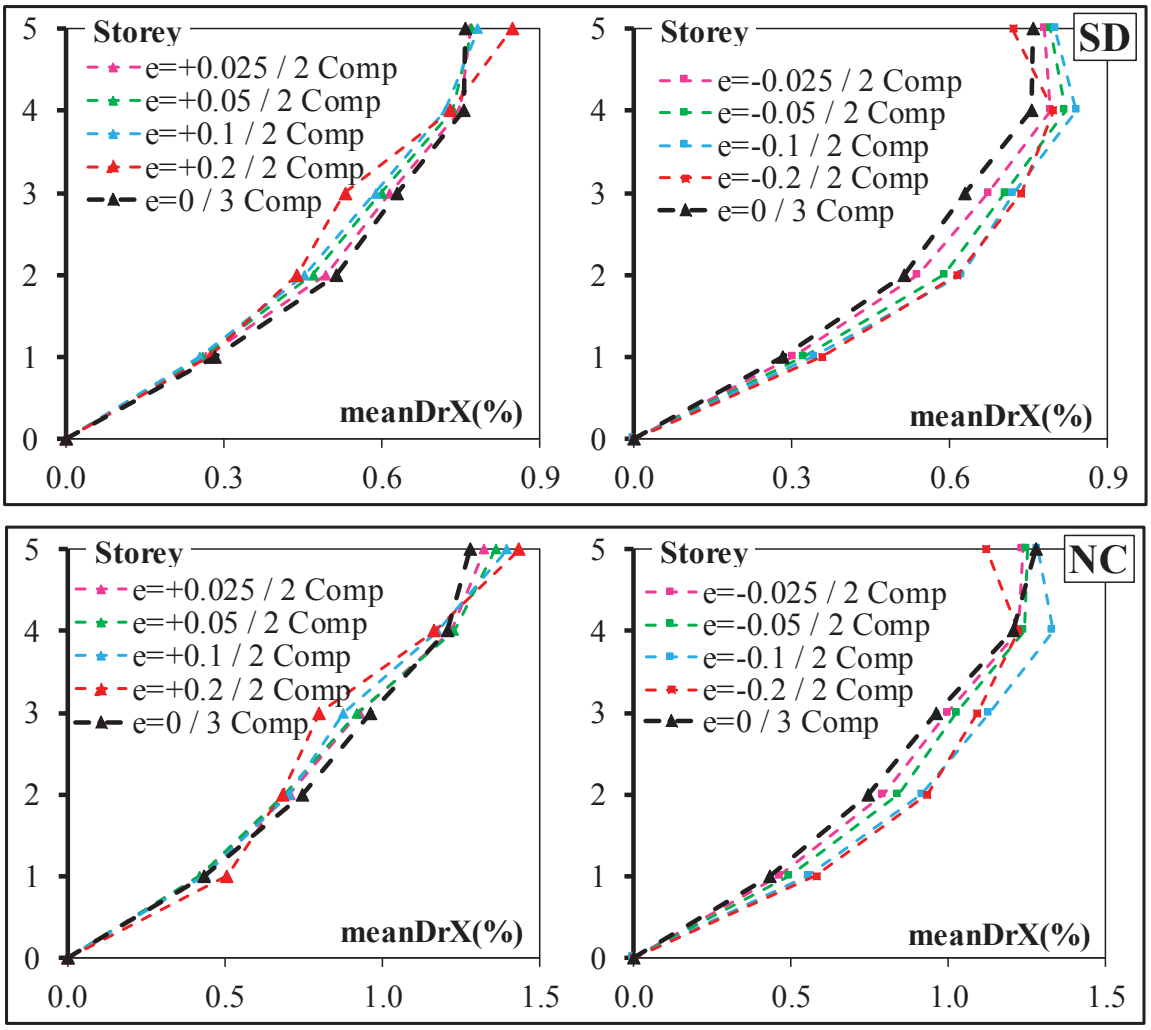

Figure 7: Variation along the height of the interstorey drift mean values along axis X all over the used seismic records

The presentation of diagrams of Figs. 7 and 8 aims to illustrate in more details the comparison between the results extracted from analyses conducted using 3 seismic components applied to MC and the corresponding results extracted from analyses conducted using 2 seismic components and several values for accidental eccentricity (Fig. 3).

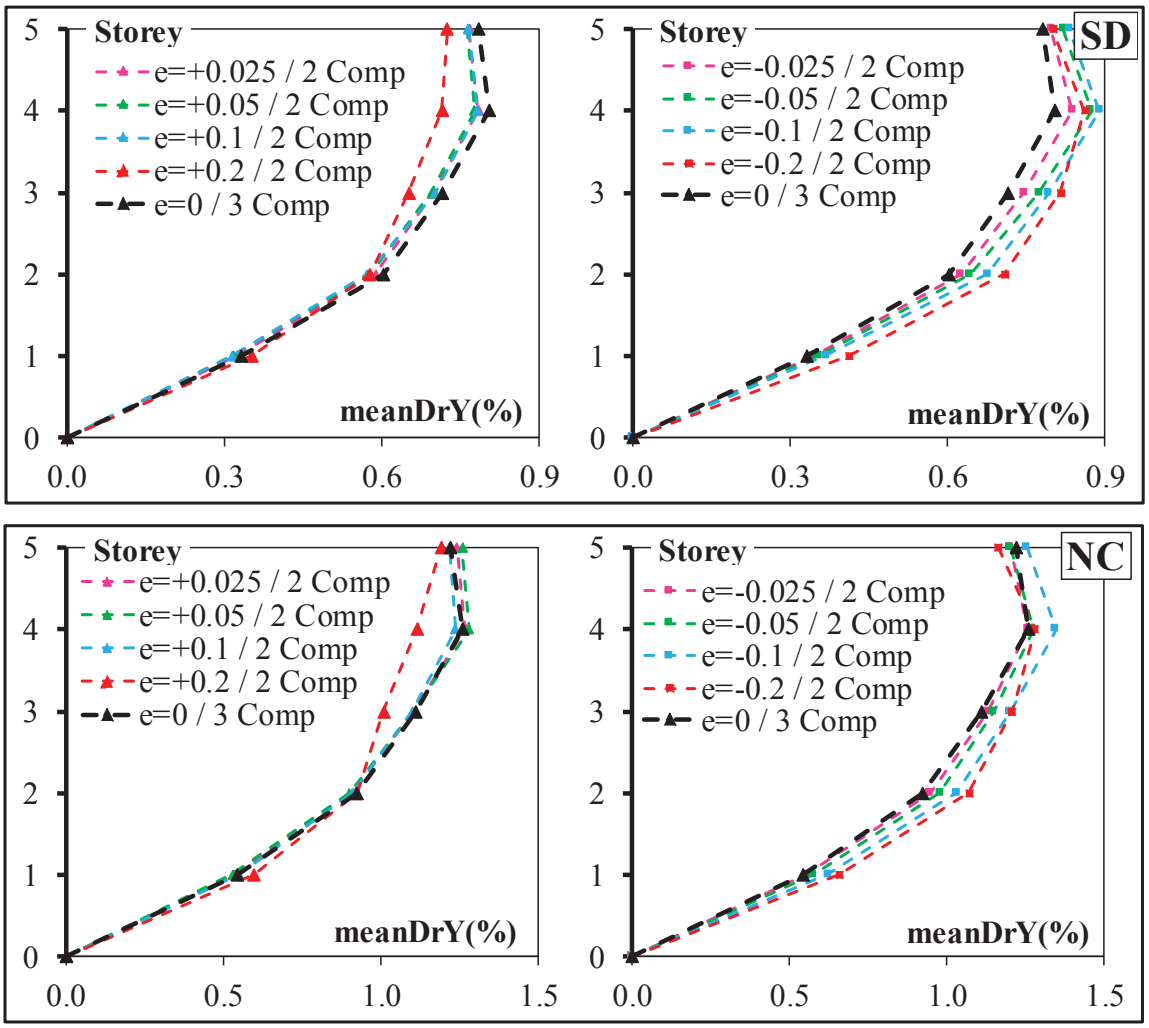

Figure 8: Variation along the height of the interstorey drift mean values along axis Y all over the used seismic records

The study of Figs. 7 and 8 confirms the main conclusion which was extracted from the study of Fig. 4. Thus, it is confirmed that the mean DrX (and DrY) values extracted from analyses conducted considering 2 (translational) seismic components and low values for accidental eccentricity e_a are closer to the corresponding values extracted from analyses conducted considering 3 seismic components applied to the MC.

6 CONCLUSIONS

The current paper deals with the investigation of the adequacy of the accidental eccentricity as a parameter to capture the effects of the torsional seismic component on the seismic damage. To this end, an 3D asymmetric 5-storey R/C building with structural system consisting of frames and walls is analysed using nonlinear time-history analysis and seven real ground motions with translational and torsional components. These ground motions were scaled to PGA values which correspond to performance levels indicated by Eurocodes. In order to achieve the goals of investigation two different categories of models for the building

and the seismic excitation were used: a) a model in which the translational and the torsional components of the seismic motion are applied to the mass center of the building and b) models in which only the translational components of the seismic motion are considered in different distances of building's mass center (i.e. consideration of several values for the accidental eccentricity). For the comparison of the above models three different seismic response parameters were used. These parameters are the interstorey drifts and the accelerations of floors along the two building's principal axes as well as the rotations of floors considered as rigid diaphragms about the its vertical axis, which are well-known damage indices.

The main conclusion which was extracted from the aforementioned investigation is that the results of the two categories of models converge generally for values of accidental eccentricity equal or lower of the 5% of building's floor length. This is an indication that the accidental eccentricity which is provided by the Eurocodes is capable to capture adequately the effects of the torsional seismic component on the seismic damage. However, the above conclusion is based on only one building and for this reason is essentially an initial conclusion which requires extended investigation.

Keywords: Building vibrations; Railway traffic; Sub-structuring approach; dynamic stiffness method.

Abstract. *This paper presents a sub-structuring approach to predict the building vibrations generated by railway traffic. The three-dimensional building is simulated by rectangular plates supported by a distribution of columns and is modelled by the dynamic stiffness method. The building model is coupled with the layered half-space by using the continuity condition. The building vibrations generated by surface railways and underground railways are examined by two case studies. In the two cases, the analytical models are applied to calculate the incident wave field generated by railway traffic. The proposed method shows sufficient efficiency, making it suitable for performing many types of parametric studies and large-scale vibration predictions. It is found that the building vibration levels decrease as the distance from the building to the railway line increases, which is induced by the attenuation of the waves due to geometrical spreading in the soil. The floating slab can significantly reduce the building vibration levels starting from its cut-off frequency.*

1 INTRODUCTION

Ground-borne vibrations induced by railway traffic can make annoyance to the dwellers and interrupt the usage of sensitive equipment in the nearby building [1–3]. Therefore, a correct prediction method for those vibrations is important, which decides whether or not a vibration mitigation countermeasure should be used. In the past decades, the prediction of building vibrations generated by railway traffic has been paid much attention. A series of approaches, either numerical or (semi) analytical, have been proposed.

The numerical approach has the advantage in simulating the complex geometry of the building and ground. Since it requires a large amount of computational efforts and storage, various kinds of methods were proposed to improve the efficiency. In terms of the building vibrations generated by the surface railway traffic, Jean and Villot [4] proposed a two-dimensional (2D) finite element–boundary element (FE-BE) model, while Fiala et al. [5] developed a three-dimensional (3D) FE-BE model. Villot et al. [6] proposed a two-and-a-half dimensional (2.5D) methodology to predict the building vibrations induced by surface trains. There were also some studies focusing on the building vibrations induced by underground railway traffic by using numerical approaches. Lopes et al. [7–8] proposed a sub-structuring approaches, in which a 2.5D finite element-Perfectly Matched Layers (FE–PML) method was used to simulate the track–tunnel–ground system, while a 3D FE method was applied to model the building. Coulier et al. [9] developed a 2.5-D FE-BE model for the coupled tunnel-soil-building system. Recently, a two-step time-frequency numerical method was develop by Yang et al. [10] to calculate the vibrations of a large-scale building induced by underground railway traffic. A train-track coupled dynamic model proposed by Zhai [11–12] was applied to calculate the rail supporting forces in the first step, while a 3D FE model was developed to predict the building vibrations in the second step.

Despite the rapid advances in computing technology, the numerical approach is still not a feasible solution for the prediction of large-scale vibrations. On the contract, the (semi) analytical method is quite efficient and suitable for predicting large-scale vibrations and performing certain parametric studies. Although a number of analytical models were proposed to predict the ground vibrations induced by surface railway traffic [13–16] and underground railway traffic [17–21]. However, less attention was paid to analytical modelling of the building vibrations induced by railway traffic. Recently, an efficient method was proposed by Hussein et al. [22] to compute the building vibrations from underground tunnels, in which the PiP model was used to calculate the incident waves generated by underground railway traffic, and a 2D framed structure composed of horizontal and vertical beams was applied to simulate the building response. Clot et al. [23] proposed a 3D analytical method to predict the vertical building vibrations generated by a harmonic load acting on the ground surface.

This paper proposes an efficient method to calculate the vertical vibrations of buildings induced by railway traffic by using sub-structuring approach. A multi-story building constructed on a multi-layered half-space is considered. The 3D building is simplified as rectangular plates supported by columns and simulated by the dynamic stiffness method. By using the continuity condition between the building foundations and ground, the building is coupled with the stratified soil. Two case studies on building vibrations generated by surface railways and underground railways are presented to demonstrate the high efficiency of the proposed approach.

2 MODELLING METHOD

In this section, the modelling method for the vertical building vibrations generated by incident waves is proposed. A building with N story is located on a multi-layered half-space (Fig-

ure 1). The building floors are simplified as rectangular floors, while the supported columns are simulated as rods, as shown in Figure 2. The columns on each floor are distributed in an $N_x \times N_y$ grid pattern. The shallow foundations are considered in this study to support the building.

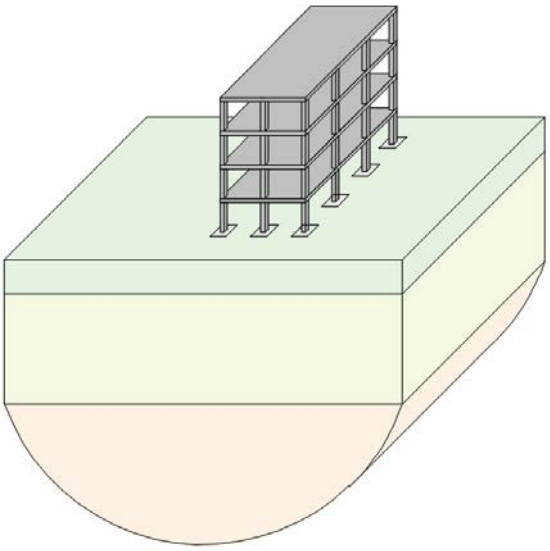

Figure 1: A building constructed in a milti-layered half-space.

2.1 DYNAMIC STIFFNESS MATRIXES FOR COLUMNS AND FLOORS

For a rod with a length L_c and cross-sectional area A_c, the relationship between the forces and displacements at the two edges can be obtained in the frequency domain as:

$$\hat{F}_{jk}^{2n} = c_{11}^{n}\hat{u}_{jk}^{2n} + c_{12}^{n}\hat{u}_{jk}^{2n+1},\ \hat{F}_{jk}^{2n+1} = c_{12}^{n}\hat{u}_{jk}^{2n} + c_{11}^{n}\hat{u}_{jk}^{2n+1}, \tag{1}$$

with

$$c_{11}^{n} = \mathrm{i}\xi E_c A_c \frac{1+\mathrm{e}^{-\mathrm{i}2\zeta L_c}}{1-\mathrm{e}^{-\mathrm{i}2\zeta L_c}},\ c_{12}^{n} = -2\mathrm{i}\xi E_c A_c \frac{\mathrm{e}^{-\mathrm{i}\zeta L_c}}{1-\mathrm{e}^{-\mathrm{i}2\zeta L_c}}, \tag{2}$$

where $\xi = \omega(\rho_c/E_c)^{1/2}$ is the axial wavenumber, with E_c and ρ_c being Young's modulus and density of the column.

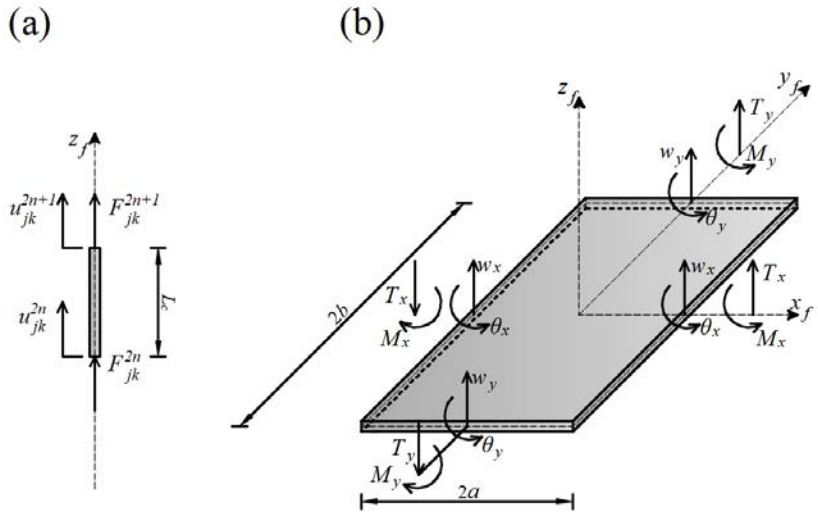

Figure 2: (a) Supported column (j, k) and sub-plate j for the story n.

The dynamic stiffness method is applied to calculate the vertical vibration of a rectangular plate. According to the superposition method [24], the plate displacement consists of four parts: symmetric-symmetric (SS), antisymmetric-antisymmetric (AA), symmetric-antisymmetric (SA), and antisymmetric-symmetric (AS):

$$\hat{w}(x_f, y_f) = \hat{w}_{SS}(x_f, y_f) + \hat{w}_{AA}(x_f, y_f) + \hat{w}_{SA}(x_f, y_f) + \hat{w}_{AS}(x_f, y_f) \tag{3}$$

A triangular series expansion is subsequently applied to those displacement and force components. Taking the symmetric-symmetric part as an example, the corresponding displacement components $\hat{\mathbf{u}}_{SS}$ and force components $\hat{\mathbf{t}}_{SS}$ are expressed as:

$$\begin{aligned} \hat{\mathbf{u}}_{SS} &= \left[\hat{w}_{xSS},\quad \hat{\theta}_{xSS},\quad \hat{w}_{ySS},\quad \hat{\theta}_{ySS}\right]^{\mathrm{T}} = 2\hat{\mathbf{U}}_{SS0}\mathbf{H}_{SS0} + \sum_{m=1}^{M}\hat{\mathbf{U}}_{SSm}\mathbf{H}_{SSm}, \\ \hat{\mathbf{t}}_{SS} &= \left[\hat{T}_{xSS},\quad \hat{M}_{xSS},\quad \hat{T}_{ySS},\quad \hat{M}_{ySS}\right]^{\mathrm{T}} = 2\hat{\mathbf{Q}}_{SS0}\mathbf{H}_{SS0} + \sum_{m=1}^{M}\hat{\mathbf{Q}}_{SSm}\mathbf{H}_{SSm}, \end{aligned} \tag{4}$$

where the rotations θ_x, θ_y, shear forces T_x, T_y, and moments M_x, M_y are shown in Figure 2, whose expressions were given in Ref. [25]. $\hat{\mathbf{U}}_{SS} = [\hat{\mathbf{U}}_{SS0}, \hat{\mathbf{U}}_{SS1}, ..., \hat{\mathbf{U}}_{SSM}]^{\mathrm{T}}$ and $\hat{\mathbf{Q}}_{SS} = [\hat{\mathbf{Q}}_{SS0}, \hat{\mathbf{Q}}_{SS1}, ..., \hat{\mathbf{Q}}_{SSM}]^{\mathrm{T}}$ are the projections of the displacement $\hat{\mathbf{u}}_{SS}$ and force $\hat{\mathbf{t}}_{SS}$, with

$$\mathbf{H}_{SS0} = 0.5\mathbf{I}_4, \quad \mathbf{H}_{SSm} = \begin{bmatrix} \cos\dfrac{m\pi y_f}{b_f} & 0 & 0 & 0 \\ 0 & \cos\dfrac{m\pi y_f}{b_f} & 0 & 0 \\ 0 & 0 & \cos\dfrac{m\pi x_f}{a_f} & 0 \\ 0 & 0 & 0 & \cos\dfrac{m\pi x_f}{a_f} \end{bmatrix}, \tag{5}$$

Following the procedure proposed by Nefovska-Danilovic [24], the dynamic stiffness matrix for a rectangular plate can be subsequently obtained, which is given by:

$$\mathbf{K}_f = \frac{1}{2}\mathbf{T}_1 \begin{bmatrix} \mathbf{K}_{SS} & 0 & 0 & 0 \\ 0 & \mathbf{K}_{AA} & 0 & 0 \\ 0 & 0 & \mathbf{K}_{SA} & 0 \\ 0 & 0 & 0 & \mathbf{K}_{AS} \end{bmatrix} \mathbf{T} \tag{6}$$

where $\mathbf{K}_{SS}$, $\mathbf{K}_{AA}$, $\mathbf{K}_{SA}$, and $\mathbf{K}_{AS}$ represent the dynamic stiffness matrixes for each symmetric part, while $\mathbf{T}$ and $\mathbf{T}_1$ are the transformation matrixes. The expressions of those matrixes were given by Nefovska-Danilovic [24].

The external force can only be applied to the edges of the plate in the dynamic stiffness method. Therefore, each floor may consist of multiply plates. Considering each plate as an element with four nodes that corresponds to the four edges, an assembly procedure that is used in the FE method can obtain the system equation for each building floor n:

$$\begin{bmatrix} \hat{\mathbf{Q}}_I^n \\ \hat{\mathbf{Q}}_R^n \end{bmatrix} = \begin{bmatrix} \mathbf{K}_{II}^n & \mathbf{K}_{IR}^n \\ \mathbf{K}_{RI}^n & \mathbf{K}_{RR}^n \end{bmatrix} \begin{bmatrix} \hat{\mathbf{U}}_I^n \\ \hat{\mathbf{U}}_R^n \end{bmatrix}, \tag{7}$$

where $\hat{\mathbf{U}}_I^n$ and $\hat{\mathbf{Q}}_I^n$ are the projections of the displacements and forces at the edges supporting by columns, while $\hat{\mathbf{U}}_R^n$ and $\hat{\mathbf{Q}}_R^n$ are those at other edges.

2.2 COUPLING OF THE FLOOR AND COLUMN

To couple the building floor with the supported column, the continuity condition at the connect positions is applied, which gives

$$\begin{cases} \hat{\mathbf{T}}_j^n = \dfrac{-1}{b}\mathbf{E}\mathbf{H}_j^n(\hat{\mathbf{F}}_j^{2n-1} + \hat{\mathbf{F}}_j^{2n}), \quad \hat{\mathbf{u}}_j^{2n-1} = \hat{\mathbf{u}}_j^{2n} = \left[\mathbf{H}_j^n\right]^{\mathrm{T}}(\hat{\mathbf{w}}_j^n), \quad n = 1, \ \ldots, N-1 \\ \hat{\mathbf{T}}_j^N = \dfrac{1}{b}\mathbf{E}\mathbf{H}_j^N(\hat{\mathbf{F}}_j^{2N-1}), \quad \hat{\mathbf{u}}_j^{2N-1} = \left[\mathbf{H}_j^N\right]^{\mathrm{T}}(\hat{\mathbf{w}}_j^N), \qquad n = N \end{cases} \tag{8}$$

where $\hat{\mathbf{u}}_j^l = \left[\hat{u}_{j1}^l, \ \hat{u}_{j2}^l, \ \ldots, \ \hat{u}_{jN_y}^l\right]^{\mathrm{T}}$ and $\hat{\mathbf{F}}_j^l = \left[\hat{F}_{j1}^l, \ \hat{F}_{j2}^l, \ \ldots, \ \hat{F}_{jN_y}^l\right]^{\mathrm{T}}$ (l = 1, 2, …, 2N − 1) represent the displacement and force components of the supported columns, respectively. $\mathbf{E}$ is a (2M + 1) × (2M + 1) diagonal matrix with E(1, 1) = 0.5 and E(m, m) = 1 ($m \geq 2$). $\mathbf{H}_j^n$ has the following expression:

$$\mathbf{H}_j^n = \begin{bmatrix} 1 & 1 & \cdots & 1 \\ \cos\dfrac{\pi y_1}{b_j^n} & \cos\dfrac{\pi y_2}{b_j^n} & \cdots & \cos\dfrac{\pi y_2}{b_j^n} \\ \sin\dfrac{\pi y_1}{2b_j^n} & \sin\dfrac{\pi y_2}{2b_j^n} & \cdots & \sin\dfrac{\pi y_{N_y}}{2b_j^n} \\ \vdots & \vdots & \ddots & \vdots \\ \cos\dfrac{M\pi y_1}{b_j^n} & \cos\dfrac{M\pi y_2}{b_j^n} & \cdots & \cos\dfrac{M\pi y_{N_y}}{b_j^n} \\ \sin\dfrac{(2M-1)\pi y_1}{2b_j^n} & \sin\dfrac{(2M-1)\pi y_2}{2b_j^n} & \cdots & \sin\dfrac{(2M-1)\pi y_{N_y}}{2b_j^n} \end{bmatrix}, \tag{9}$$

Substituting Eq. (1) into Eq. (8) gives the following relationship:

$$\begin{cases} \hat{\mathbf{Q}}_I^1 = \mathbf{K}_c^{11}\hat{\mathbf{U}}_I^1 + \mathbf{K}_c^{12}\hat{\mathbf{U}}_I^2 + \mathbf{G}^0\hat{\mathbf{F}}^0 + \mathbf{D}^0\hat{\mathbf{u}}^0, \qquad n = 1 \\ \hat{\mathbf{Q}}_I^n = \mathbf{K}_c^{n,n-1}\hat{\mathbf{U}}_I^{n-1} + \mathbf{K}_c^{n,n}\hat{\mathbf{U}}_I^n + \mathbf{K}_c^{n,n+1}\hat{\mathbf{U}}_I^{n+1}, \quad n = 2, \ \ldots, N-1 \\ \hat{\mathbf{Q}}_I^N = \mathbf{K}_c^{N,N-1}\hat{\mathbf{U}}_I^{N-1} + \mathbf{K}_c^{N,N}\hat{\mathbf{U}}_I^N, \qquad n = N \end{cases} \tag{10}$$

where $\hat{\mathbf{u}}^0$ and $\hat{\mathbf{F}}^0$ are the vertical displacements and forces between the columns and the foundations, respectively. Since the buildings are assumed to be directly fixed the foundation, the continuity condition between the columns and foundations gives:

$$\hat{\mathbf{u}}^0 = \hat{\mathbf{u}}^{fs}, \ \hat{\mathbf{F}}^0 = \hat{\mathbf{F}}^{fs}, \tag{11}$$

The Combination of Eqs. (7), (10) and (11) gives the system equation for the whole building:

$$\begin{bmatrix} \hat{\mathbf{F}}^{fs} \\ \mathbf{0} \end{bmatrix} = \begin{bmatrix} \mathbf{K}^{ss} & \mathbf{K}^{sb} \\ \mathbf{K}^{bs} & \mathbf{K}^{bb} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{u}}^{fs} \\ \hat{\mathbf{U}}^b \end{bmatrix} \tag{12}$$

2.3 BUILDING VIBRATIONS INDUCED BY INCIDENT WAVES

When an incident wave acts on the shallow foundations, the induced vibrations can be determined by:

$$\hat{\mathbf{u}}^{fs} = \hat{\mathbf{u}}^s = -\hat{H}^s\mathbf{I}\hat{\mathbf{F}}^{fs} + \hat{\mathbf{u}}^{s,iw} \tag{13}$$

where $\hat{\mathbf{u}}^s$ denotes the vertical displacements of soils at the geometric center of each foundation; $\hat{\mathbf{u}}^{s,iw}$ is the corresponding incident displacement field. $\hat{H}^s$ is the soil compliance that represents the vertical displacement at the driving point induced by a rectangular distribute load. The transfer matrix method [14] is used to calculate the soil compliance in this study.

Substituting Eq. (13) into Eq. (12) gives the system equation for the calculation of the building vibrations induced by the incident waves:

$$\begin{bmatrix} 1/\hat{H}^s \mathbf{I}\hat{\mathbf{u}}^{s,iw} \\ \mathbf{0} \end{bmatrix} = \begin{bmatrix} \mathbf{K}^{ss} + \mathbf{K}^s & \mathbf{K}^{sb} \\ \mathbf{K}^{bs} & \mathbf{K}^{bb} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{u}}^0 \\ \hat{\mathbf{U}}^b \end{bmatrix} \tag{14}$$

3 APPLICATION

3.1 BUILDING VIBRATIONS FROM SURFACE RAILWAY

In the first numerical case, the proposed method is used to calculate the vertical building vibrations generated by surface railways. As shown in Figure 3, the track system consists of the rails, pads, sleepers and ballast. The rails in this model are simulated as Euler-Bernoulli beams, while the rail pads are modelled as continuous spring. The sleepers are simplified as a continuous mass and the ballast is modelled as a continuous distributed vertical spring and mass. A harmonic load acting on the rails is considered as the excitation. An analytical model proposed by Sheng et al. [14] is used to calculate the incident displacement field $\hat{\mathbf{u}}^{s,iw}$ generated by a harmonic load acting on a railway track.

In this case, the UIC60 rail with a bending stiffness $E_rI_r = 6.3 \times 10^6$ N/m^2 and a mass per unit length $m_r = 60.34$ kg/m is considered. The equivalent stiffness of the rail pads per unit length k_{rp} is 3.5×10^8 N/m^2, and its loss factor $\eta_{rp} = 0.15$. The Mass of sleepers per unit length m_s is 490 kg/m, while the mass of ballast per unit length m_b is 1200 kg/m. the ballast has a smeared stiffness $k_b = 3.15 \times 10^8$ N/m^2 and a loss factor $\eta_b = 1$. The contact width of railway and ground is 2.7 m.

The soil consists of a layer with a depth of 2 m on top of a homogeneous half-space. The first layer has a shear wave velocity $C_s = 150$ m/s, a compression wave velocity $C_p = 306$ m/s, and density $\rho_s = 1900$ kg/m^2. The bottom half-space has a shear wave velocity $C_s = 230$ m/s, a compression wave velocity $C_p = 443$ m/s and a density $\rho_s = 2023$ kg/m^2. The material damping ratio β_s for the two layers are 0.05 and 0.04, respectively.

A four-story building with two spin is located in the vicinity of the railway line. The distance between the centerline of the track to the nearest column alignment of the building d = 10 m, 20 m, and 30 m is considered. The geometry of the building is shown in Figure 4. The building floors with a length of 8 m, a width of 4 m, and a thickness of 0.3 m are supported by square columns with a side length of 0.3 m and a height of 3 m. the material of the building floors and columns are concrete with Young's modulus of 35 GPa, a density of 2500 kg/m^3, and a Poisson's ratio of 0.2.

Four observation points are considered, as shown in Figure 4. The observation points A and C are located at the center of each spin of the first floor, while the observation points B and D are at the center of each spin of the fourth floor.

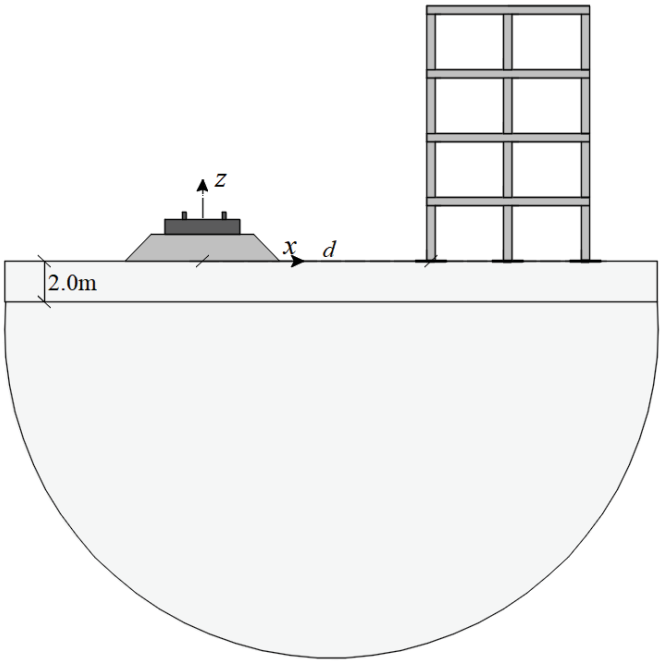

Figure 3: Geometry of the surface railway-soil-building system.

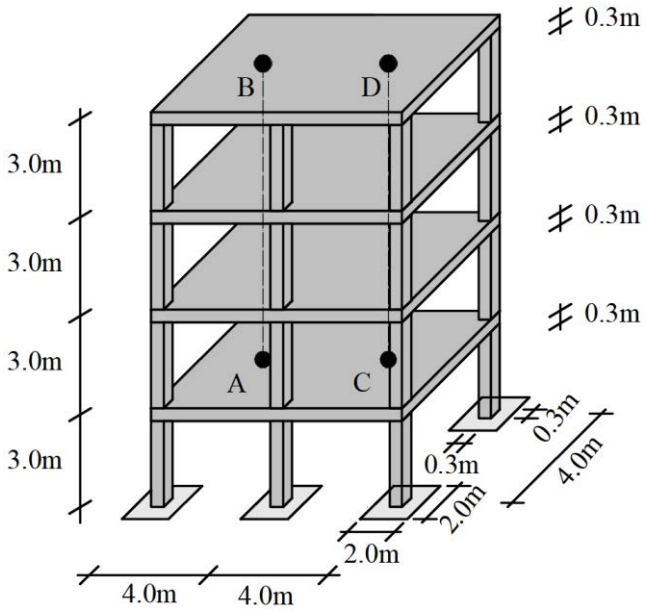

Figure 4: Geometry of the building.

Figure 5 shows the vertical displacements of the building at the four observation points induced by a harmonic load acting on the rails of the surface railway. As expected, the displacement amplitude decreases as the distance from the building to the railway line increases. Since the attenuation of the waves due to geometrical spreading in the soil is slow in the low-frequency range, the magnitude of the displacement decreases slightly as distance from the building to the railway line increases. When the distance *d* increases from 10m to 20 m and 30m, the vibration levels decrease approximately 5 dB and 8dB, respectively. However, as the frequency increases, the attenuation due to geometrical spreading accelerates. The vibration level of the building decreases significantly as the distance increases.

A personal computer with 8 GB RAM and 2.6 GHz processor is used to calculate the results in this case. The average calculation times for each frequency (f) is 2.5 minutes, which shows its advantage of high computational efficiency.

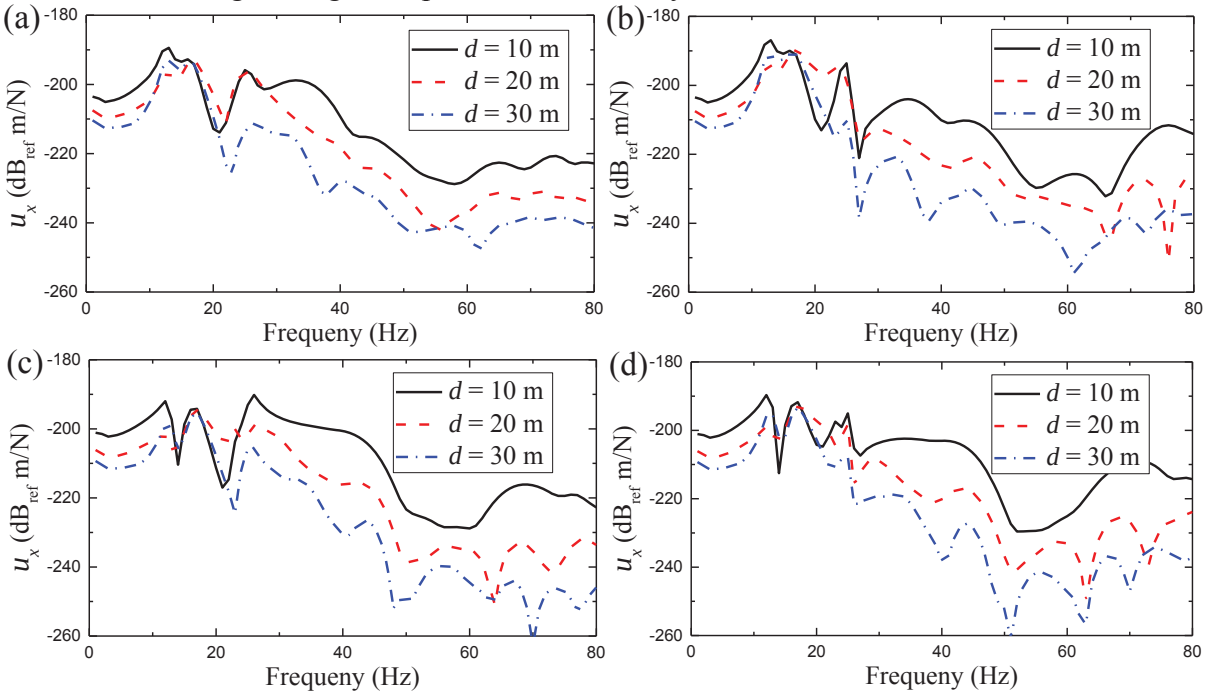

Fig. 5. Vertical displacements of the building at the observation point (a) A, (b) B, (c) C, and (d) D induced by a harmonic load acting on the rails of the surface railway.

3.2 BUILDING VIBRATIONS FROM UNDERGROUND RAILWAY

This section investigates the building vibrations induced by underground railways. As shown in Figure 6, a circular tunnel embedded in a two layered half-space is considered. A fully-coupled analytical method [19] is used to calculate the incident displacement field $\hat{\mathbf{u}}^{s,iw}$. The tunnel is simulated as a cylindrical thin shell. The soil is considered as a layered elastic half-space and simulated by the transfer matrix method [26–28]. A model of a double-beam is used to model the track slab and rails. A harmonic load acting on the rails is considered as the excitation. The derivation of this method was proposed in detail by He et al. [19].

In this study, the tunnel with an out radius of 3.0 m and a thickness of 0.25 m is made of concrete with Young's modulus E_t = 50 GPa, a density ρ_t = 2500 kg/m^3, and a Poisson's ratio ν_t = 0.2. The depth of the tunnel is 10 m below the ground surface. The UIC 60 rails is considered in this case. The rail pads in this case have a smeared stiffness k_{rp} = 116 MN/m^2. Two kinds of slabs are considered. The first one is a directly-fixed slab, and the second one is a floating slab with the isolation frequency f_n = 10 Hz and 20 Hz being considered. Two kinds of slabs have a mass per unit length of 3500 kg/m and a bend stiffness of 1430 MNm^2. The properties of the soil and building are the same as those in Section 3.1.

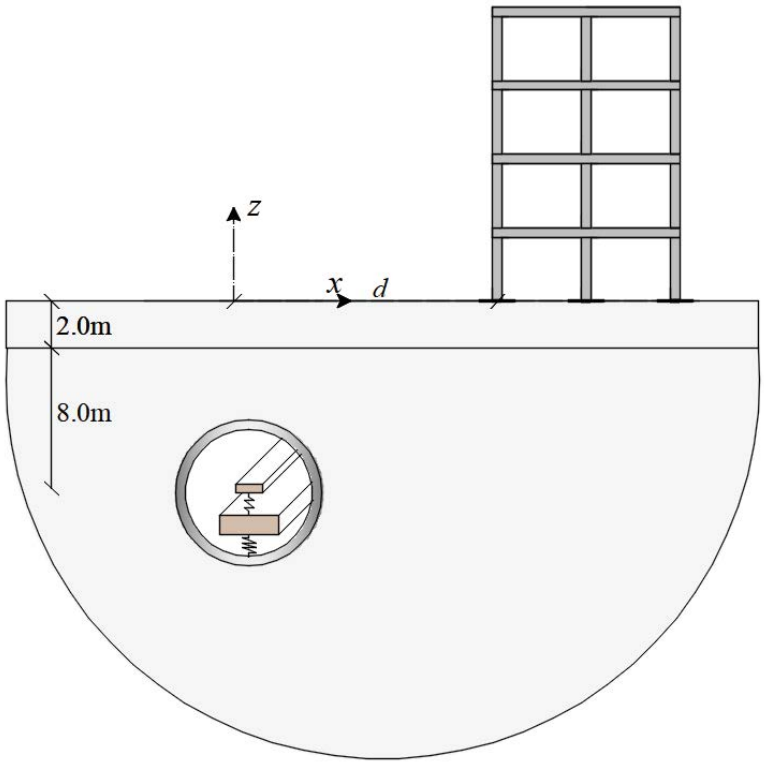

Figure 6: Geometry of the underground tunnel-soil-building system.

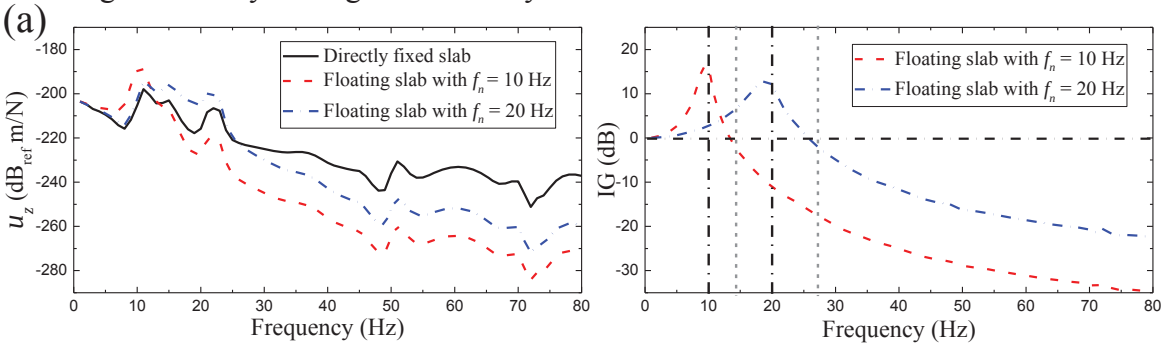
Figure 7 presents the vertical displacements of the building at the four observation points induced by a harmonic load acting on the rails of the underground railway. The insert gain (IG) that represents the difference of the building vibration levels between the two kinds of slabs is calculated and presented. By comparing the building responses for the directly-fixed slab with those for the floating slab, we can find that the floating slab has a good isolation effectiveness after the cut-off frequency $\sqrt{2}f_n$. However, the floating slab also can increase the vibration levels for the frequency that is less than the cut-off frequency. Especially at the isolation frequency of the floating slab track, a major peak can be observed at the IG curves.

The calculation times for each frequency (f) is 9 minutes in this numerical case, indicating that the proposed method has a high computational efficiency when calculating the building vibrations generated by underground railway traffic.



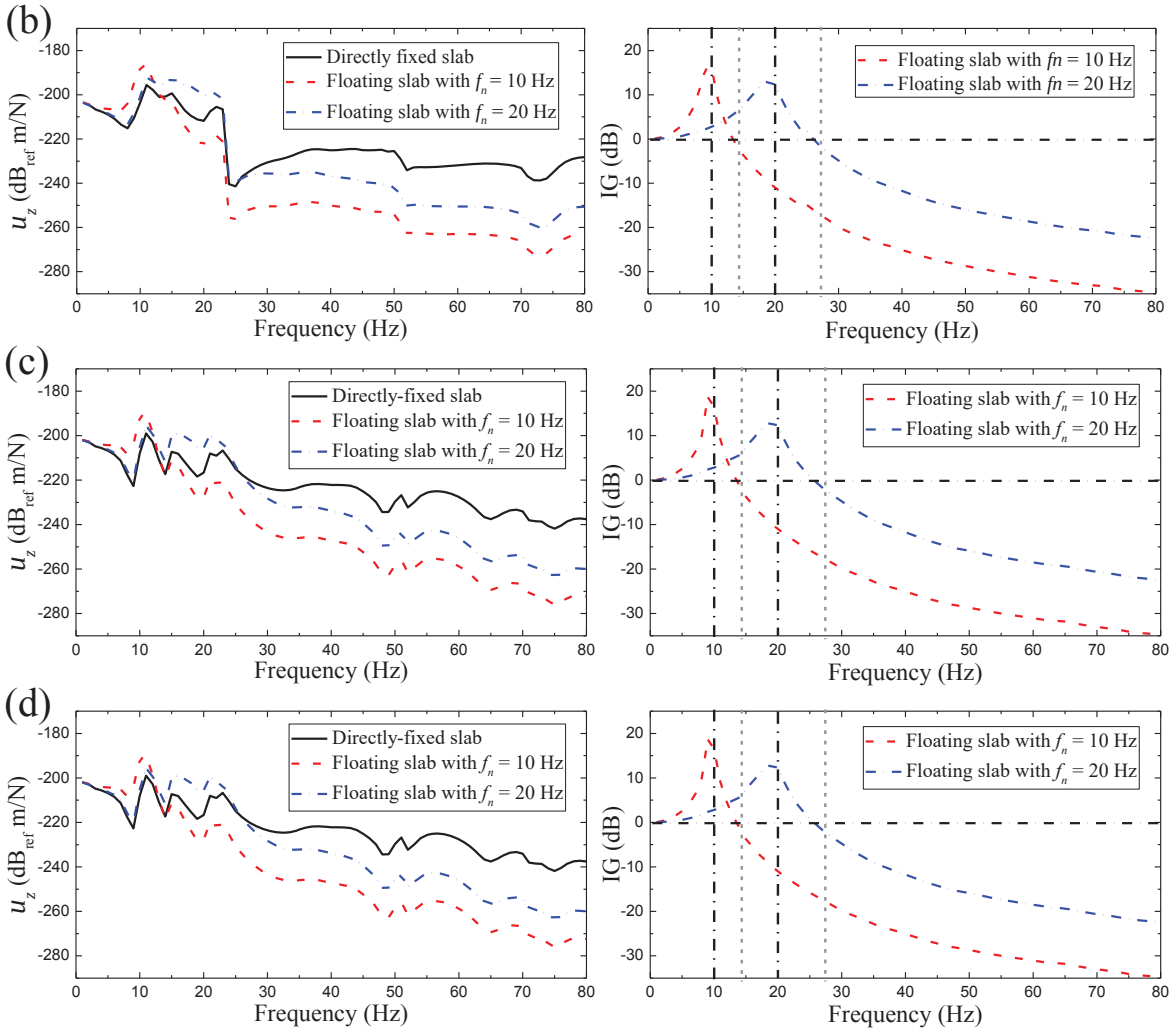


Figure 7: Vertical displacements of the building at the observation point (a) A, (b) B, (c) C, and (d) D induced by a harmonic load acting on the rails of the underground railway.

4 CONCLUSIONS

A sub-structuring method was proposed to calculate the vertical building vibrations induced by railway traffic. The 3D building is simulated by rectangular plate supported by a distribution of columns. The dynamic stiffness method was used to obtain the solution for rectangular plates and columns. The 3D building model was subsequently obtained by coupling the plate model with the column model. The building model was coupled with the layered half-space by satisfying equilibrium and compatibility condition at the building foundations.

Two case studies on building vibrations generated by surface railways and underground railways are proposed. In this first case, an analytical model was used to calculate the incident wave filed generated by surface railway traffic. In the second case, the tunnel-soil system was simulated by a fully-coupled analytical model. The numerical results demonstrated that the building vibration levels decreases as the distance from the building to the railway line increases, which is induced by the attenuation of the waves due to geometrical spreading in the soil. The floating slab can significant reduces the building vibration levels starting from its cut-off frequency.

Keywords: inerter, base-isolated, optimal, tuned mass damper inerter

Abstract. *The recent earthquakes history shows that the conception of resistant, safe, and economical structures is daily challenges for structural engineers. Among the newest vibration control devices figures the inerter which is a device capable of developing a large fictive mass using rotational inertia. In this research work, a conventional passive tuned mass damper (TMD) is compared with an inerter based mass damper (TMDI) which consists of tuned mass damper attached to an inerter. The two devices are used to control the vibration of a base-isolator structure (BI) submitted to earthquake excitations. For this purpose, an eight (8) storey structure is equipped with a (TMDI) at the base floor compared with case TMDI in zeros inertance case TMD, the inerter is fixed to the (TMD) on one side and grounded on the second side. A set of dynamic parameters are optimized by exploring predefined bounds, the optimal parameters* ***(frequency tuning, damping tuning, inertance ratio, mass ratio)*** *are then used to confirm and perform a time history analysis is under different earthquake records. The obtained results demonstrated good performance and effectiveness of the structure equipped with a (TMDI) in terms of bearing displacement as well as top floor acceleration.*

1 INTRODUCTION

In recent years, seismic vibration control constituted a field of interest for a large number of researchers. The motivation behind such interest is the protection of lives and structures against earthquakes; this can be achieved by introducing passive, active, or semi-active control devices [1, 2].

In the same context, many researchers presented and investigated numerous devices which lead to acceptable results in terms of response reduction (e.g., base-isolated (BI), tuned liquid damper (TLD), magneto-rheological damper (MR), tuned viscous mass damper (TVMD), viscous mass damper (VMD), tuned inerter damper (TID), tuned mass damper (TMD)) [3, 4]. One of the widespread devices is the (TMD), a passive control device used to absorb and limit the vibration in a structure or a building [5]. It's attached to the main structure with mechanical elements small mass, viscous spring, and linear elastic dashpot to mitigate and decrease maximum displacement of main structure induced by numerous natural hazards [6]. As it is well known the (TMD) efficiency is mainly related to its mass. However, a large mass constitutes a constant challenge for the structural and architectural design of any building, hence a larger (TMD) mass involves bigger vertical loads and base shear but also a large space occupancy [2, 7].

In order to overcome these weaknesses or in other words disadvantages, a new mechanical device is known as "Inerter" has attracted the interest of researchers in several areas, this latter can be associated with (TMD) to obtain a larger mass [8, 9]. Furthermore, this tool has the possibility of developing a large fictive virtual mass proportional to the relative acceleration between its nodes [10]. The association of a (TMD) and an inerter is denoted tuned mass damper inerter (TMDI) [9]. The concept of mechanical inerter was introduced by Engineer Smith in 2002 at Cambridge University, it was firstly used in Formula One cars under the "J damper" name. Today, an inerter mechanism is capable to produce an equal and opposite inertia force at two ends, the force is proportional to the relative acceleration which can be analogous to a very large physical mass [8]. The factor of proportionality is known as inertance, the "mass amplification effect" can reach a magnitude from 1 to 350 times or higher the mass of a conventional (TMD) [11].

Undoubtedly, inertance plays a majority part of the apparent mass of (TMD) [12]. The inerter mechanism purposes divers' possibilities to be used in several domains (e.g., motors bike, turbine tower, train, mechanical vibration, vehicle cars, skyscraper, and automobile suspensions). Hence, several inerter types can be found (e.g., ball screw type, rack pinion gear flywheel type, hydraulic motor, fluid inerter type, electro-magnetic inerter) [13].

Along with (TMDs) base-isolation technology is widely used in order to secure buildings and prevent them from irreversible damages or collapse due to earthquake actions [14]. Nowadays, the extensive used of vertical building lead to the appearance of a large number of high rise buildings with multiple usages. As it is well known (BI) technique that contributes significantly to the reduction of both acceleration and inter-story drift response by shifting the frequency of the structure to the small acceleration branch in the response spectrum [15].

On the other hand, base-isolation involves large deformations and displacements due to smaller stiffness at the base of the structure [16].In order to overcome the large deformations issue is base-isolated buildings multiple solutions were proposed, a hybrid control strategy that combines (BI) technology and additional control systems are one of the recommended solutions. Yang [17] was one of the first researchers to propose such a solution, by combining base-isolation with (TMD) at the top of the building or above the base-isolated level. In this regard, researchers found that (TMD) can reduce maximum response if the input period is up-

per than the fundamental period of the base-isolated building [6, 7, 18]. However, most of the (TMD) has a frequency mistuning problem; if a mistuning occurs it can either reduce the performance or at times amplify the response of the main building, with this in the background, the author or the researcher De-Domenico focused on the possibility of enhancing the effects of (TMD) by transforming it into a (TMDI) via the inerter [12]. Therefore, the objective of his work is centered to evaluate the ground motion response of a base-isolated building equipped with tuned mass damper inerter (TMDI) which consists of a (TMD) mounted in series with viscous damper and elastic stiffness elements connected with an inerter. The latter is attached between the secondary mass of (TMD) and the ground, it worth noticing that a (TMD) is a particular condition of a (TMDI) when the inertance is set to be null [12]. The results obtained show a response reduction of the base-isolated system, especially the bearing displacement. Newly, a hybrid control strategy presented by De Domenico and Ricciardi demonstrated the efficiency of combining a BI and a (TMDI), it also shows that the (BI-TMDI) combination is more effective compared to a (BI-TMD) [12, 19-21].

In this work, a base-isolated building is equipped with a (TMDI). The second end of the inerter is grounded (fixed to the ground) or in other words, inerter with a single terminal exists. The system is submitted to a set of earthquake records with the aim of finding optimal parameters of (TMDI) and (TMD) such as frequency, damping, and inertance. Although the idea of using passive (TMDI) to control displacements in BI structures is not novel, this work aims to present optimal parameters without using optimization algorithms.

2 MATHEMATICAL MODEL

Figure 1(a) shows the model of an *n*-story base-isolated structure equipped with a TMD-Inerter on the ground floor. The masses of the building are concentrated at floor levels. Figure 1(b) illustrations the models of ideal inerter made by (rack, pinion, gear, and a flywheel) this is the inerter concept used in this paper. The location of TMD-Inerter is connected between ground and base-isolation. The hypothesis is made in such a way to disregard the impact of the rotational degrees of freedoms (*n*-DOF) in the models. The other key assumptions made for the structural system are the following: First, the inerter device must function sufficiently in any spatial direction and motion. Second, considering the only horizontal direction of earthquake applied. Third, the effects of soil-structure interaction is neglige. Finally, over the earthquake excitation, the building behavior remains linear elastic.

According to d'Alembert's principle, the general equation of motion model for the present hybrid system can be written as follows:

$$[M]\{\ddot{x}(t)\}+[C]\{\dot{x}(t)\}+[K]\{x(t)\}=-[M_{\partial}]\{\Im\}\{\ddot{x}_g\} \tag{1}$$

In equation (1); *[M]; [K]; [C];* are *[(n+1)×(n+1)];* mass the corresponding stiffness; and damping coefficient matrices of the system respectively. Further, $\ddot{x}(t),\dot{x}(t),x(t)$ are (n) dimensional acceleration; velocity; displacement vectors respectively, and the dots signifying the derivative with respect to time. $[M_{\partial}]$, $\{\Im\}$, $\{\ddot{x}_g\}$ are respectively the real mass matrix where $(\beta=0)$, the distribution unit vector with size *(n+1)*, earthquake ground acceleration motion vector.

The (TMDI) and (BI) components are denoted m_d; c_d; k_d; m_b; c_b; k_b, respectively. Clearly b denotes the apparent mass of inerter with two terminals, the latter integrated or mounted to (TMD) with a second terminal fixed to the grounded (inerter with only one terminal exist).

Equation (1); can be rearranged in transfer function (TF) method, more specifically "*State Space"* form, it will result in the following writing:

$$\begin{cases} \dot{\theta} = A.\theta + B.\psi \\ y = E.\theta + D.\psi \end{cases} \tag{2}$$

Where $[A],[B]$ are unknown or defines state or system matrix of order *(2n×2n)*, the input matrix is of the order *(2n×q)*; respectively, expressed as:

$$[A] = \begin{bmatrix} \Theta & \Psi \\ -M^{-1}.K & -M^{-1}.C \end{bmatrix} \; ; \; [B] = \begin{bmatrix} \Theta \\ -M^{-1}.M_{\partial} \end{bmatrix} \tag{3}$$

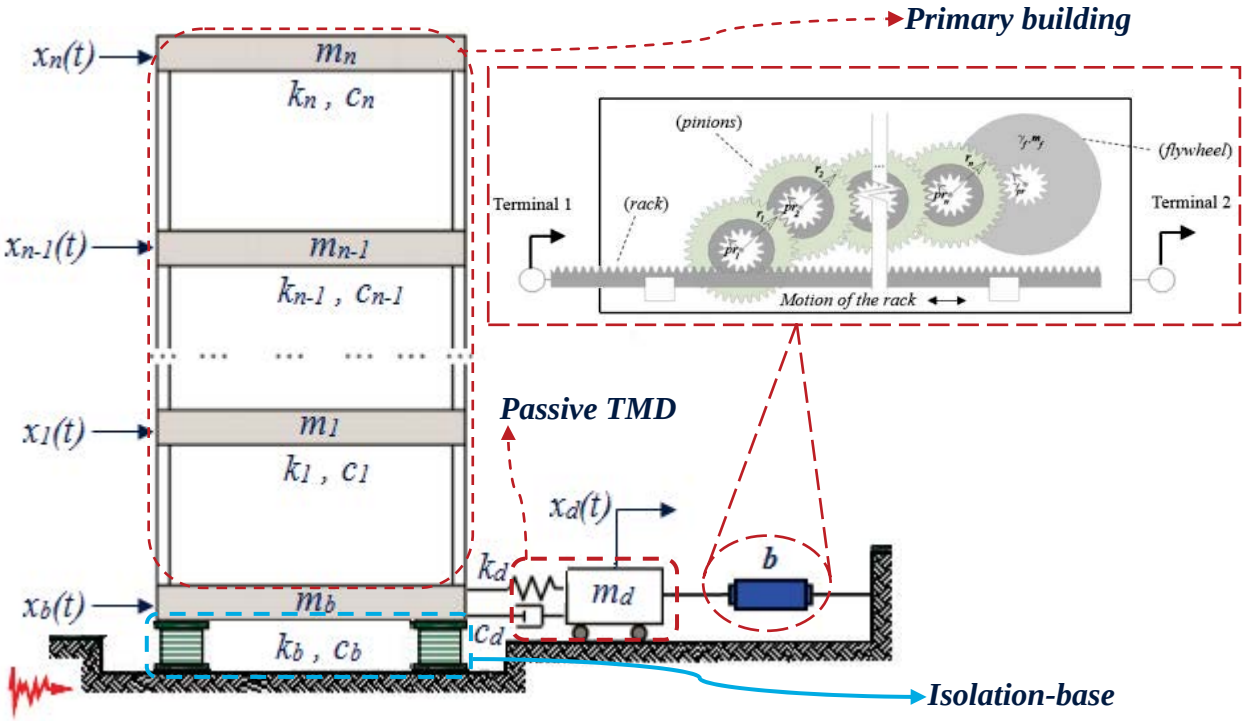

Figure 1. Simplified model of benchmark building integrating with (BI) and (TMDI) connected between (BI) and ground (i);(ii) Schematic representation of the two-terminal inerter device [12, 22].

For the building controlled with (TMDI), the structural matrices (mass, rigidity, and damping) of the system can be written as:

$$[M] = \begin{bmatrix} m_d + b & 0 & \cdots & & 0 \\ 0 & m_b & \cdots & & \vdots \\ \vdots & \vdots & m_1 & \cdots & \\ & & \vdots & \ddots & \\ \vdots & & & m_{n-1} & \vdots \\ 0 & \cdots & \cdots & 0 & m_n \end{bmatrix} \begin{Bmatrix} \ddot{x}_d(t) \\ \ddot{x}_b(t) \\ \ddot{x}_1(t) \\ \ddots \\ \ddots \\ \ddot{x}_{n-1}(t) \\ \ddot{x}_n(t) \end{Bmatrix} \tag{4}$$

$$[K]=\begin{bmatrix} K_d & -K_d & 0 & \cdots & 0 \\ -K_d & K_b+K_d+K_1 & -K_1 & 0 & \vdots \\ 0 & -K_1 & \ddots & \cdots & \\ 0 & 0 & & \vdots & \vdots \\ \vdots & \vdots & \vdots & K_{n-1}+K_n & -K_n \\ 0 & \cdots & 0 & -K_n & K_n \end{bmatrix} \begin{Bmatrix} x_d(t) \\ x_b(t) \\ x_1(t) \\ \ddots \\ \ddots \\ x_{n-1}(t) \\ x_n(t) \end{Bmatrix} \tag{5}$$

$$[C]=\begin{bmatrix} C_d & -C_d & 0 & \cdots & 0 \\ -C_d & C_b+C_d+C_1 & -C_1 & 0 & \vdots \\ 0 & -C_1 & \ddots & \cdots & \\ 0 & 0 & & \vdots & \vdots \\ \vdots & \vdots & \vdots & C_{n-1}+C_n & -C_n \\ 0 & \cdots & 0 & -C_n & C_n \end{bmatrix} \begin{Bmatrix} \dot{x}_d(t) \\ \dot{x}_b(t) \\ \dot{x}_1(t) \\ \ddots \\ \ddots \\ \dot{x}_{n-1}(t) \\ \dot{x}_n(t) \end{Bmatrix} \tag{6}$$

Therefore, the natural frequencies of the (BI) and (TMDI) respectively can be obtained using the following equation:

$$\omega_b=\sqrt{\frac{K_b}{m_b}} \;\; ; \;\; \omega_d=\sqrt{\frac{K_d}{\left(m_d+b\right)}} \tag{7}$$

And their damping ratio factors are evaluated by the following formulas:

$$\xi_b=\frac{C_b}{2.\mathrm{m}_b.\omega_b} \;\; ; \;\; \xi_d=\frac{C_d}{2.(\mathrm{m}_d+\mathrm{b}).\omega_d} \tag{8}$$

Moreover, the modal mass and the inertance ratio, which is expressed as:

$$\mu=\frac{m_d}{\sum_{j=1}^{j=n} m_j} \;\; ; \;\; \beta=\frac{b}{\sum_{j=1}^{j=n} m_j} \;\; ; \;\; and \;\; j=\left(1,2,..,n\right) \tag{9}$$

The mechanical layout of an ideal linear inerter device is a mechanism with two terminals, and both terminals of the inerter device should be connected, on one side to the moving attached mass (TMD) and on the other side to the structure, ideally the floor slab or to the ground.

The force of both ends is positively correlated with the relative acceleration and can be expressed by the following formula [3, 10]:

$$F_{Left}=F_{Right}=b\times\left(\ddot{u}_{Left}-\ddot{u}_{Right}\right) \tag{10}$$

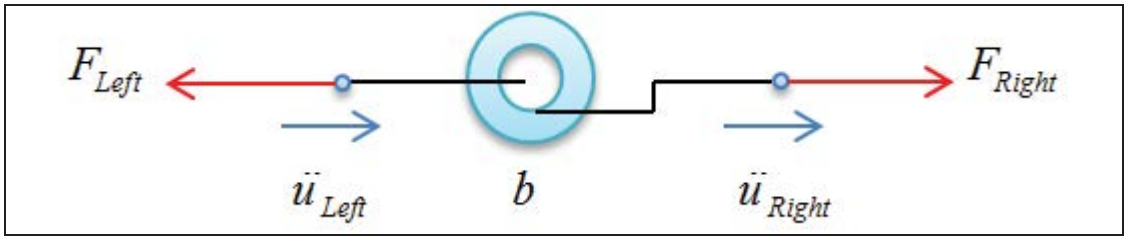

Figure 2. Schematic of ideal linear inerter device

As it can be seen in Figure 2, the constant of inertance (apparent mass) marked *b* can be expressed by the following relationship or formula below:

$$b = I_b \times \left(\frac{2 \times \pi}{L_b} \right)^2 \tag{11}$$

Where the moment of inertia of the flywheel is marked I_b; and the lead of the ball screw is marked L_b.

3 NUMERICAL STUDY

In order to develop and assess the performance of the hybrid strategy, an eight-story benchmark base-isolated building is chosen and equipped with TMD-Inerter, the building is submitted to several earthquakes ground motion, the responses are compared with a building equipped with a (TMDI)(β=0) , it means case (TMD). The mass, stiffness, damping, and frequency of the benchmark building are listed in Table 1 and Table 2 for BI parameters:

Storey	m_j *ton*	c_j *kN.s / m*	k_j *kN / m*	ω_j *rad / sec*	T_j sec	f_j *Hz*
1	345.6	490	3.4×10^5	5.24	1.19	0.83
2	345.6	467	3.26×10^5	14.0	0.45	2.23
3	345.6	410	2.85×10^5	22.55	0.28	3.58
4	345.6	386	2.69×10^5	30.22	0.21	4.81
5	345.6	348	2.43×10^5	36.89	0.17	5.87
6	345.6	298	2.07×10^5	43.06	0.14	6.85
7	345.6	243	1.69×10^5	49.54	0.13	7.89
8	345.6	196	1.37×10^5	55.96	0.11	8.91

Table 1. Benchmark building parameters [23].

	m_b *ton*	c_b *kN.s / m*	k_b *kN / m*
Base-isolator (BI)	450	26.17	18.050

Table 2. Base-isolator parameters [23].

3.1 Optimization and results

In order to find and investigate the performance of the optimal parameters, an optimization procedure is carried out on TMD-Inerter, in which the inerter's 2nd extremity is grounded. The optimization is achieved by the variance of four different parameters simultaneously. The range of the frequency ratio υ is bounded as [0.85, 1.12] and the damping ratio ξ range is set as [0.01, 0.2] while the inertance β is bounded as [0 , 1] where the mass ratio $\mu_{TMDI} = \beta - \mu_{TMD}$ is calculated in function of the continuously changing inertance factor. Figures 3-6, show the result in form of surf plots, in which it can be seen that the optimal tuning parameters lead to the minimization of the bearing displacement and top floor acceleration response under different earthquakes (El Centro, Northridge, Kocaeli, Imperial valley) respectively. The response reduction is clearly visible. This validates the fact that increasing the mass M_{tmdi} + b, could improve the base-isolation performance. Moreover, for a null inertence factor, where the system is equivalent to a conventional (TMD), the results are represented in Figure 5-6, it can be seen that the improvement of the response is directly related to the increase in the mass ratio. These findings show that the optimal parameters of the system allow increasing the linear stiffness of base-isolation. Hence, resulting in more effective reduction effect in terms of bearing displacement and top floor acceleration due to the increased of base-isolation restoring force. Therefore, the influence of the damping ratio and mass ratio and frequency ratio on the design parameters is significant and should be manipulated with an exceptional attention.

The results related to the optimization are listed in Table 3.

Remark: The bound use for the optimization parameters using later by [12].

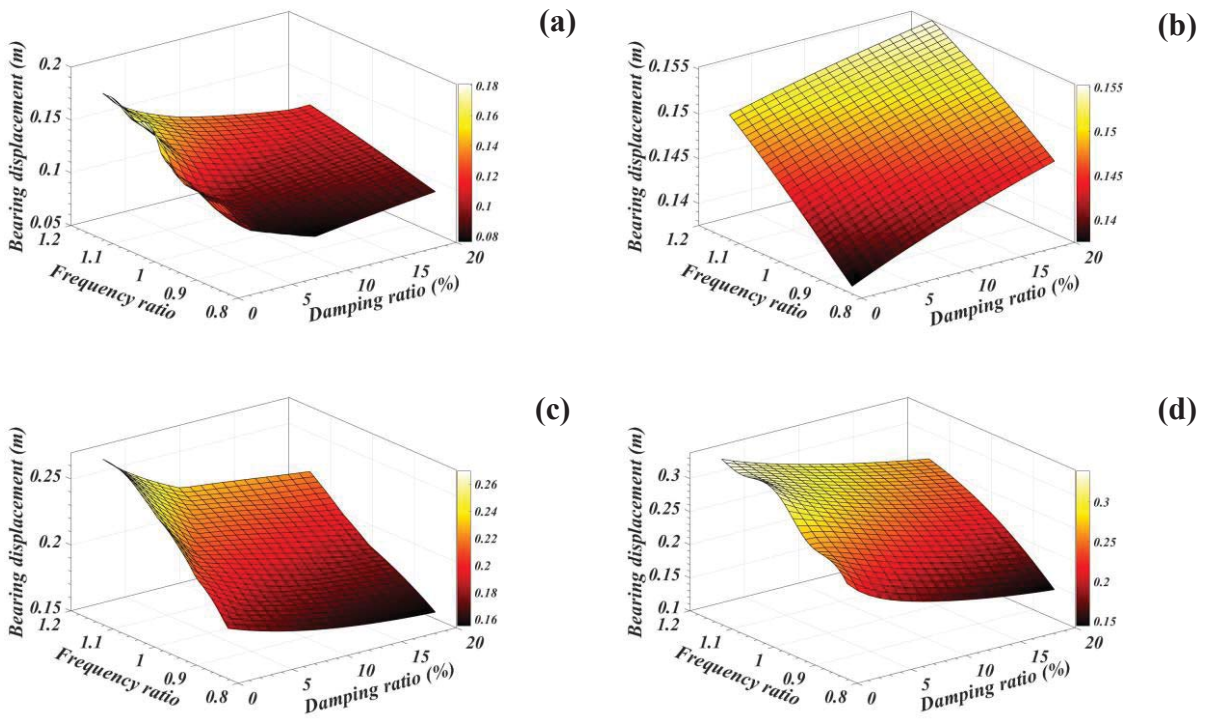

Figure 3. Bearing displacement of (BI-TMDI).(a) El Centro,(b) Northridge,(c) Kocaeli,(d) Imperial valley

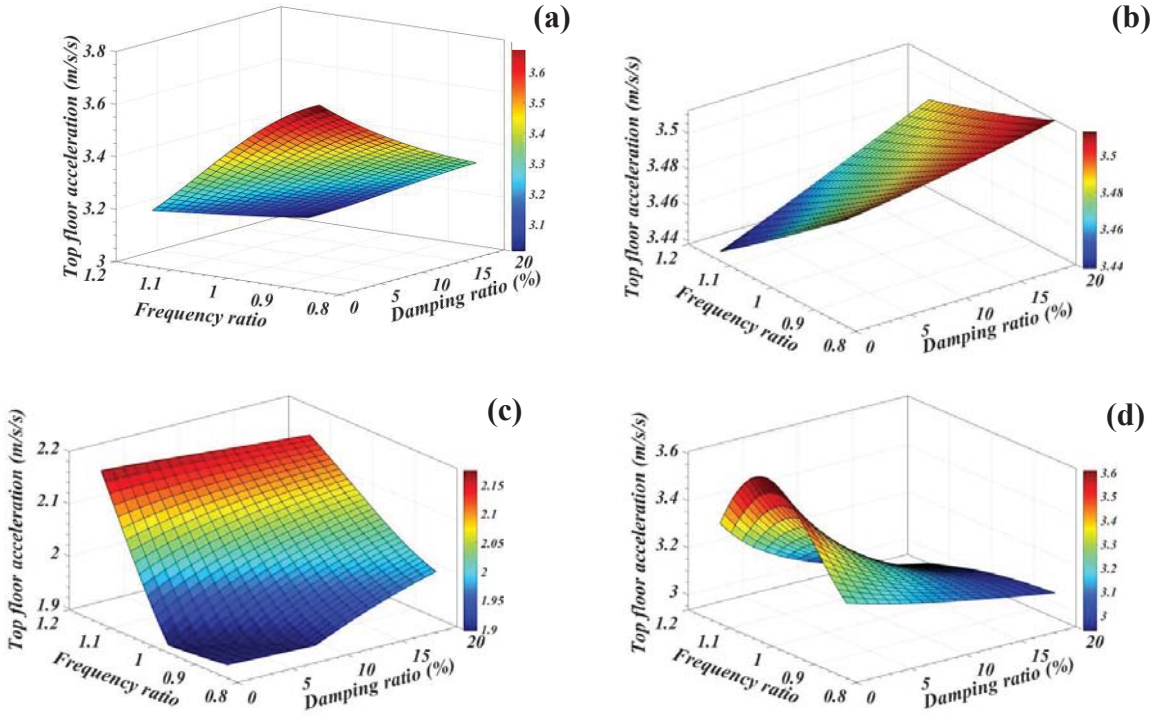

Figure 4. top floor acceleration of (BI-TMDI) .(a) El Centro,(b) Northridge,(c) Kocaeli,(d) Imperial valley

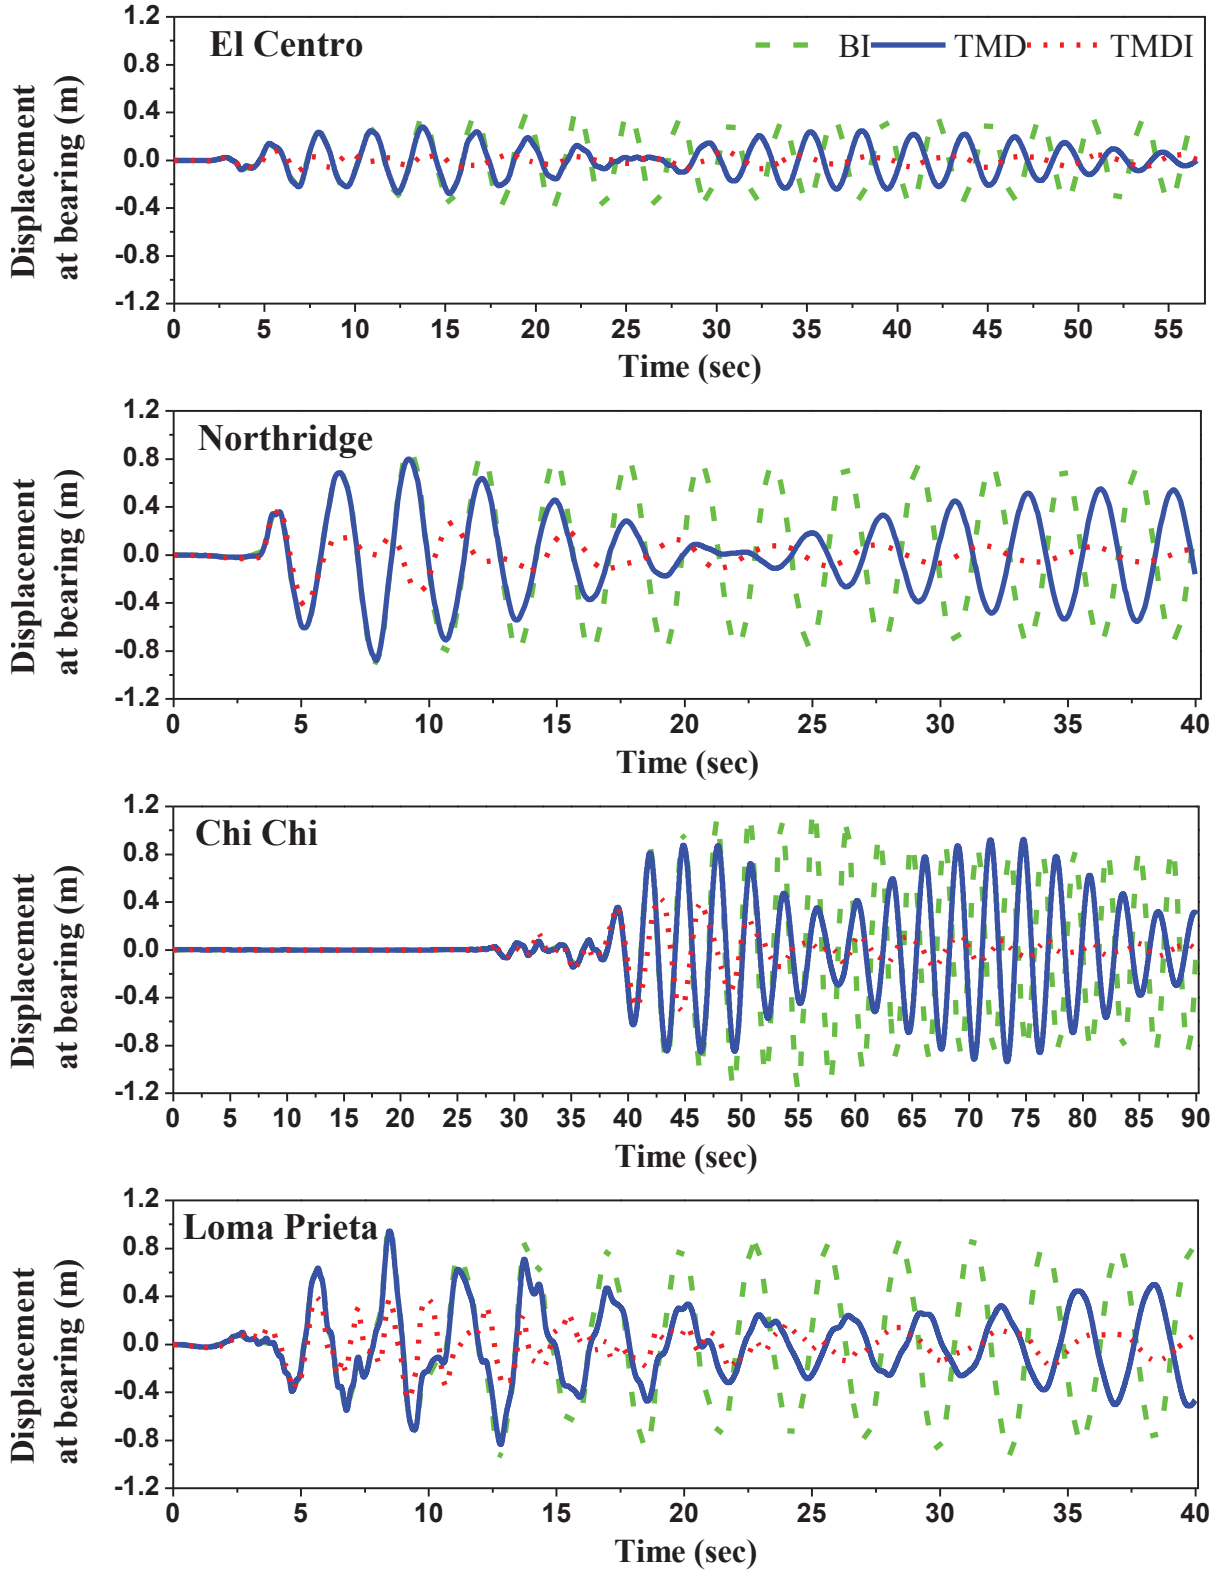

Figure 7. Time history of bearing displacement using a tuned mass damper inerter (TMDI) and a tuned mass damper (TMD).

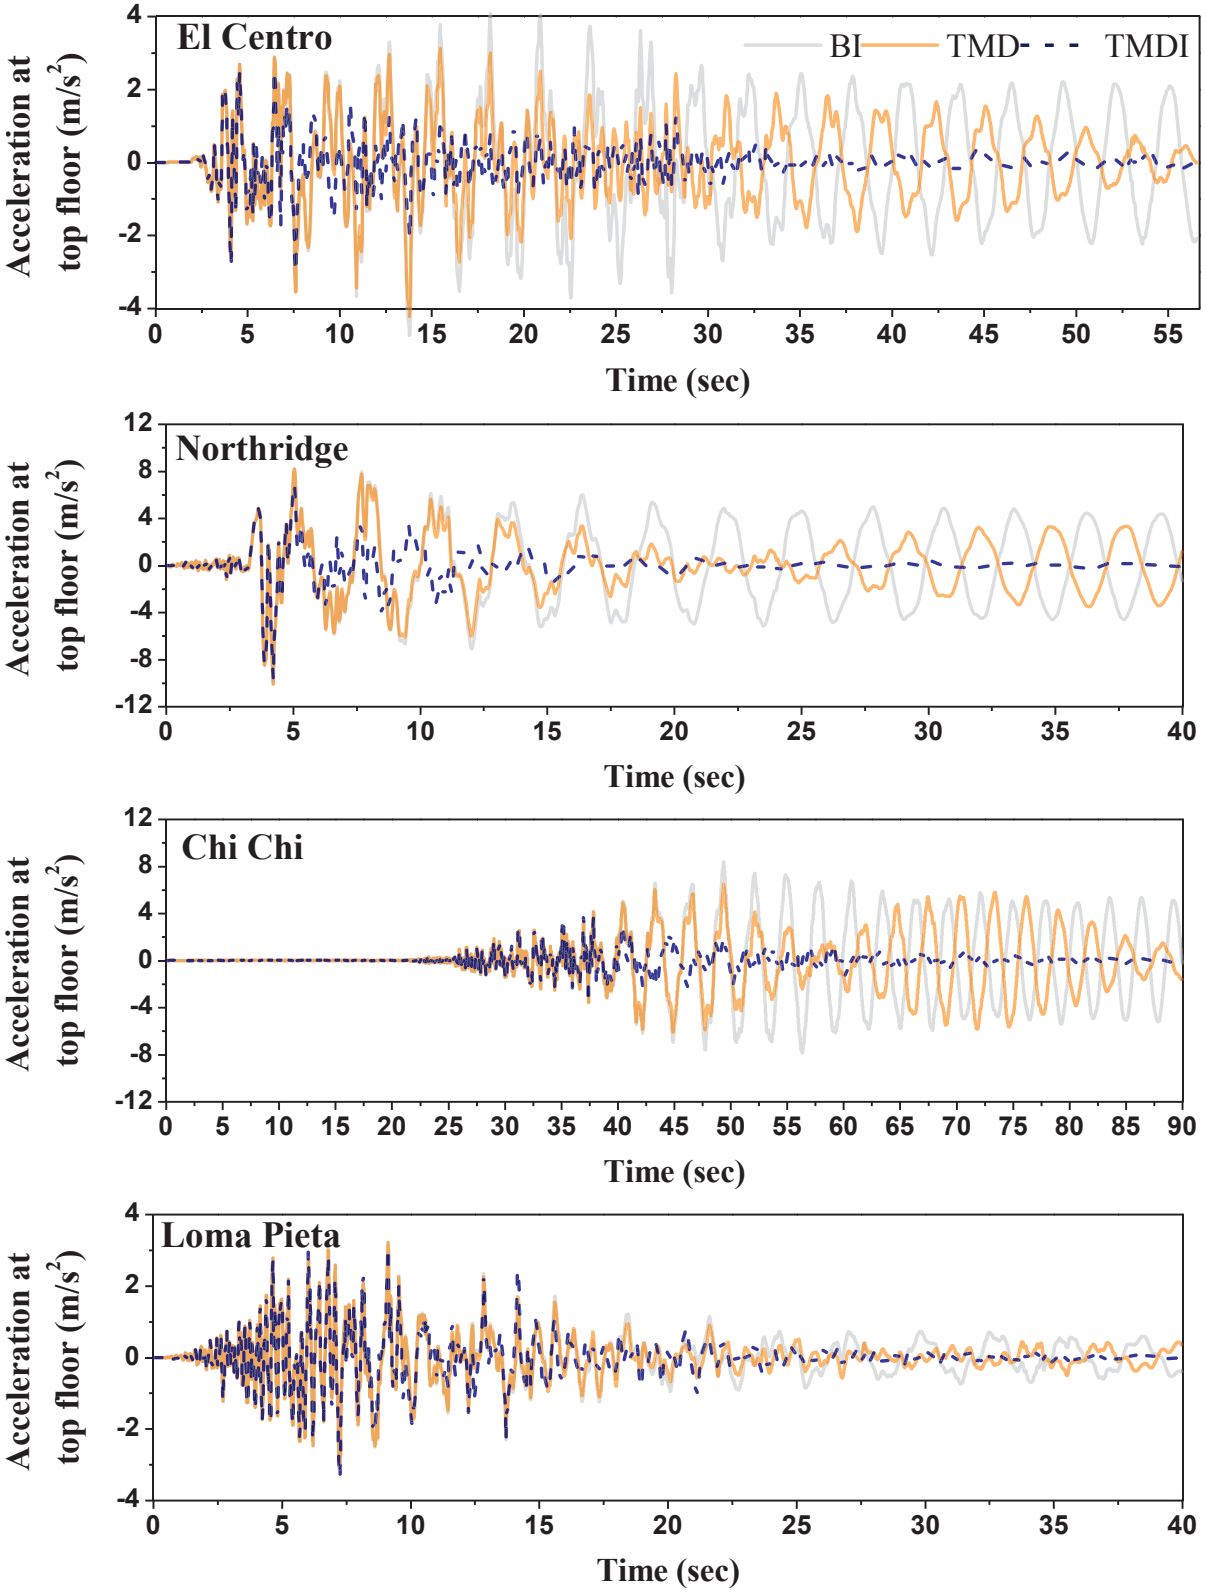

Figure 8. Time history of the top floor acceleration of the (eight-storey) base-isolated building, isolated with leading rubber bearing (LRB) and equipped with the single tuned mass damper inerter (TMDI), tuned mass damper (TMD).

Earthquake Name	Station Name	Years	PGA *(g)*	M_w	Distance. Epic *(km)*
El Centro	El Centro	1940	0.30	6.9	16.90
Northridge	San Marino	1994	0.84	6.69	40.32
Chi-Chi	HWA025	1999	0.33	7.62	90.78
Loma Prieta	Sunol-Forest fire station	1989	0.29	6.93	61.90
Kocaeli	Fatih	1999	0.16	7.51	93.86
Imperial valley	Brawley Airport	1979	0.25	5.01	25.84

Table 4.List of records earthquakes considered in this paper.

Time history analysis is conducted on the system using optimal parameters for further verification. The comparison is made under the input of the recorded accelerograms selected from the pacific earthquake engineering research center (peer ground motion database). Six natural seismic signals are investigated: El Centro, Northridge, Chi-Chi, Loma Prieta, Kocaeli, and Imperial Valley. Specifications of these earthquakes are listed in Table 4. Moreover, Table 3, contains the optimal parameters, such as inertance ratio β , frequency tuning f , and damping tuning ξ , for each TMDI and TMD device combined to a *BI* system. The corresponding response time histories of the BI reference building without and with control devices (both the total base displacement and roof acceleration response) are displayed in Figures 7 and 8, respectively. The figures are elaborated for different earthquakes. For comparison purposes, in each graph, the response of base-isolated building equipped with (TMDI) has been plotted along with the response of the BI structure equipped with a conventional (TMD) and the uncontrolled response of the base-isolated building (without any control device) which serves as a reference.

Figures 7 and 8, show that for the El Centro record, 31% and 78% response reduction in terms of bearing displacement is obtained using TMD and TMDI respectively, 11% and 37% response reduction in terms of top floor acceleration using TMD and TMDI respectively. For Northridge record, 5% reduction is obtained using TMD, and 55% reduction is obtained with TMDI in terms of bearing displacement, 1%, and 4% reduction in terms of top floor acceleration is obtained using TMD and TMDI, respectively. Chi-Chi record 19% and 56% response reduction in terms of bearing displacement, 22%, and 54% response reduction in terms of top floor acceleration under both TMD and TMDI, respectively. Loma Prieta record 4% and 52% response reduction in terms of bearing displacement using TMD and TMDI, respectively, a very small reduction in terms of top floor acceleration is obtained using both devices.

Moreover, the Chi-Chi earthquake made the utmost important amplification of the response in the median part of the ground motion, contrary to El Centro, Loma Prieta and Northridge earthquakes which produced the utmost important amplification of the response in the initial part of the ground motion. It is worth noticing that the displacement response of the additional mass such as TMD or TMDI should not surpass the displacement response of the uncontrolled base-isolated building.

4 CONCLUSIONS

The present paper studied the possibility of enhancing a base-isolated building dynamical performance. The building was equipped with tuned mass damper inerter (TMDI), optimal parameters of the (TMDI) were investigated and explored through a set of predefined bounds. The performance of the proposed system where compared to a conventional tuned mass damper (TMD), the main target of the hybrid strategy proposed in this work is to reduce the bearing displacement without increasing significantly the acceleration. With this in the background, the following main concluding remarks can be drawn:

- Numerical simulation shows that a recently control device known as tuned mass damper inerter TMDI is effective in controlling the lateral displacement (with a significant reduction of the average bearing displacement value of almost 60% compared to a TMD only which achieved a 15% reduction in average. In terms of top floor acceleration, a reduction average of 23% was obtained using TMDI while a 10% reduction average was obtained using a TMD.
- The results demonstrated that adding a grounded inerter leads to significant response reduction in terms of top floor acceleration and bearing displacement simultaneously.
- It has been demonstrated that the use of the inerter in along with a TMD to form a TMDI is a very practical control strategy.
- The use of the inerter integrated to a TMD results in a lightweight system, with superior capability and reliability compared to conventional TMD.
- A TMDI device designed with an optimal approach can effectively reduce the bearing displacement of a base-isolated building and as well as other response quantities such as top floor acceleration, compared to a conventional (TMD).
- The determination of a suitable apparent or physical mass $(M_{TMD}+b)$ should consider control performance, physical feasibility, and economic price.

Keywords: noise measurements, fundamental period, resonance, vulnerability

Abstract. *South and South-East of Spain are the regions with a higher seismic hazard in Spain Consequently, all the municipalities in Alicante province has to develop seismic emergency planning. Besides, the south of Alicante province and, in particular, the cities of Elche and Alicante are located in a sedimentary deposit, which can reach hundreds of meters, so site effects can be important. Additionally, most of the building stock belongs to periods without seismic normative, increasing, therefore, their vulnerability. Furthermore, following the damage caused by earthquakes in Spain, it has been observed that there are significant differences in the spatial distribution of damage from site to site in buildings with similar seismic behavior, located in a similar site. Hence, many authors have stated that the main factor responsible for the different damage distribution could be the building height. The seismic response of a building depends on its dynamic characteristics (fundamental period, T, damping ratio, ξ, and modal shape) and on the input ground motion. Among the existing methods to determine the T and ξ parameters, the best ones probably are to record weak earthquakes (or near explosions) or induced vibrations inside the building. However, both techniques need a very expensive and time-consuming effort when it is applied to a large number of buildings. A possible alternative is the measurement of ambient vibrations. In this work, ambient vibration measurements were performed at the geometrical center of the plan on the top floor of buildings with different height and year of construction in the municipality of Alicante and Elche (both in the Alicante province), assuming that this point coincides with the mass center of the floor. The preliminary results follow a linear relationship between the number of stories and the fundamental period. Finally, the results have been used to estimate the probability of resonance in several districts of both municipalities.*

1 INTRODUCTION

Spain has a moderate seismic hazard, compared with other European countries like Italy or Greece. However, South and South-East regions had been affected by damaging earthquakes and according to the updated seismic hazard map developed by [1], the expected peak ground acceleration (PGA) for an exceedance probability of 10% in 50 years is 0.24g (Granada province) and 0.23g (Alicante province). In this work, we have chosen two of the most important cities of Alicante province, in terms of population and number of buildings, that is, Elche and Alicante cities. Both cities are located above a sedimentary deposit with hundreds of meters deep, making it possible to feel the effects of small to moderate shallow earthquakes (5 to 10 km), which are very common in this area. According to the update of the seismic hazard maps [1], the PGA for exceedance probability of 10% in 50 years is 0.18g for Alicante and 0.20g for Elche.

The last damaging earthquake in Spain was the Lorca earthquake (May 11, 2011 with a moment magnitude of Mw = 5.2 and a focal depth of 4.6 km). Although the magnitude was not severe, the observed damage was very high. More than 300 buildings were demolished and many others repaired. Concretely in this city, [2] analyzed the dynamic behavior of the buildings before and after the Lorca earthquake. They concluded that the fundamental period of the buildings shows a permanent increase following a process of damage such as an earthquake. The fundamental period (T) is a parameter widely used to evaluate the seismic response of the buildings.

In contrast, the damping factor is not usually used as an indicator of damage in structures. The damping assessment is a complex problem due to all the variables involved. That fact is due to depending on many factors such as structure and soil characteristics [3].

Several studies have used the recorded ambient vibrations to obtain the seismic response of the building, e.g., [2, 4, 5, 6, 7, 8, 9, 10, 3, 11 and 12]. In essence, their results do not differ from other methods such as earthquake registration or forced vibration techniques.

Therefore, the main objective in the present work is to develop an empirical relationship between the fundamental period and the number of floors using the recorded ambient vibration on the top floor of the buildings in Alicante and Elche cities. Both cities represent the construction model of the Mediterranean coastal area. The obtained relationship will be used not only to establish the fundamental period of the current building stock but also to compare its evolution if damaging earthquakes would happen in the area.

2 DATA ACQUISITION AND ANALYSIS

Alicante and Elche have approximately 24,162 and 34,395 buildings respectively. The height of the buildings can be classified as low-rise (1 to 3 stories) with a 49 % for Alicante and 67 % for Elche; mid-rise (4 to 6 stories) with a 30 % for Alicante and 21 % for Elche and high-rise (>6 stories) with a 21 % for Alicante and 11 % for Elche. For this study, we have carried out a random selection of reinforced concrete buildings in both cities. Table 1 shows the selected buildings with information about the height, year of construction, and location.

The fundamental period of the buildings was estimated through ambient vibration measurements using a three-component digital seismometer Güralp 6TD. This is a broadband instrument with an on-board 24-bit digitizer and configurable output. The duration of the records was 10 minutes and the equipment was located on the top floor of the buildings (Figure 1). If some disturbance occurred during the recording time, the duration of the measurement was increased by 5 more minutes. [13] was used to compute the Fourier amplitude spectra and the fundamental period for each longitudinal direction. Finally, the building period was assigned as the average of both horizontal components.

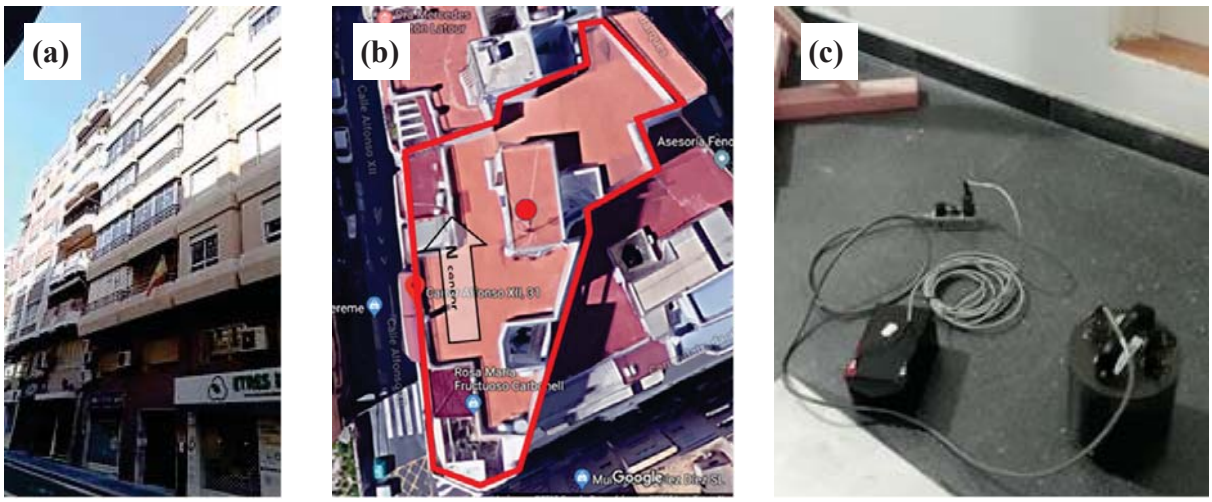

Figure 1: a) Main front of one of the studied buildings (no 19). b) Aerial view of the building with the location of the sensor and its orientation. c) Equipment arrangement during measurement inside the building.

Additionally, microzonification campaigns in urban areas of both cities were carried out using a 1 Hz Mark L-4C-3D seismographs connected to a Reftek digitizer. Regarding the number of H/V measurements, a total number of 123 and 90 measures were taken for Alicante and Elche, respectively. In both cases, the measurements were carried out leaving a separation of about 500 meters between them. In this case, attending to the expected resonant frequencies and the recommendations proposed in [14] the duration of the records was set up to 30 minutes.

3 FUNDAMENTAL PERIOD

To determine the fundamental period of the selected buildings of Alicante and Elche, the sensor was located in the available highest part of these buildings. In this way, the sensor records all the vibrations that pass through the building, assuming that the sensor is in the mass center of the floor [2].

The recorder noise can be produced by environmental factors (e.g. wind) or coming from different artificial sources such as traffic noise, elevators, presence of people, etc. The method is based on the fact that these sources of noise, excluding strong harmonic sources close to the instrument, contain energy with a broad spectrum and the building acts as a filter enhancing its dynamic properties [2].

Once the data were collected, the power spectral density of both horizontal components was determined for each building. An example is shown in Figure 2. As it can be observed, the steeper peak indicates the fundamental frequency of the building in that direction. However, erroneous peaks may appear as a result of the interaction with adjacent buildings or due to the building's own geometry, so the analysis has to be performed carefully.

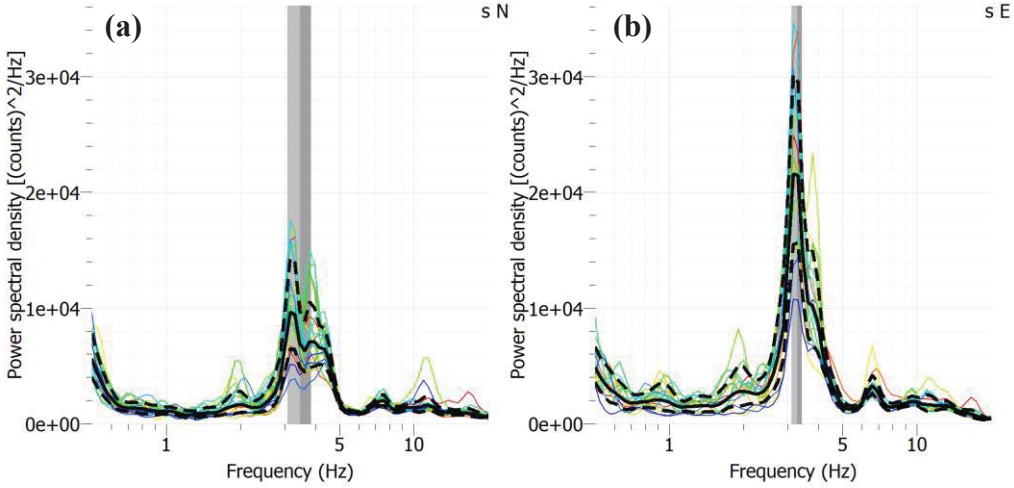

Figure 2: Power spectral density for North and East components of the building no 19.

The obtained results for the buildings of both cities show that the natural vibration period increases with the number of storeys (Table 2). In Table 2 it can be seen that the lowest value of the average fundamental period is 0.13 ± 0.06 sec for buildings with two floors and the highest value is 0.40 ± 0.14 sec for buildings with nine floors.

N (storeys)	T (sec)
2	0.13 ± 0.06
3	0.15 ± 0.02
4	0.16 ± 0.03
5	0.20 ± 0.03
6	0.23 ± 0.05
7	0.37 ± 0.01
8	0.36 ± 0.04
9	0.40 ± 0.14

Table 2: Average value of the fundamental periods obtained for buildings with different number of storeys.

Linear regression has been made using the commonly applied expression, T = a N, where T is the period and N is the number of storeys. The obtained relationship is as follow:

$$T = 0.045\ N \text{ with } \sigma = 0.035 \tag{3.1}$$

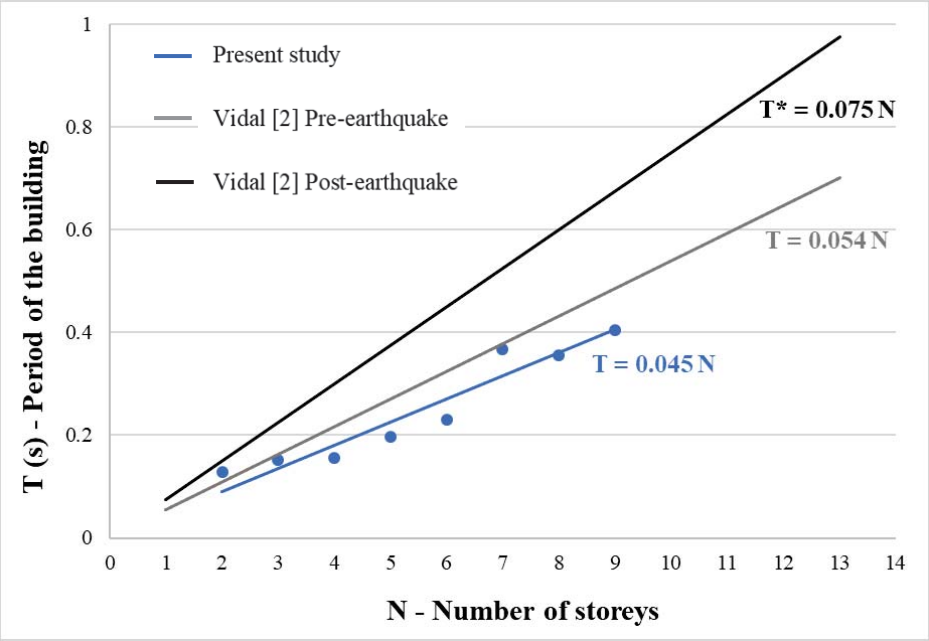

Figure 3: Relationship between the period of the building (T) and the number of storeys (N). Blue line represented the one obtained in this study while black a grey line represents the one obtained by [2] before (T) and after earthquake (T*).

Equation (3.1) has a correlation coefficient of $R^2 = 0.912$ and an average standard deviation of $\sigma = 0.035$. In Figure 3, the obtained relation is compared with the ones obtained by [2] in the Lorca city before and after the 2011 earthquake. The comparison shows that the obtained linear adjustment presents the lowest slope, providing a period of 0.39 sec for a 9 storeys building while [2] will assign 0.49 sec. As [2] used buildings with height up to 13 storeys, the difference can be due to a lack of data in our results so future studies will include buildings with higher height. If we assume that the slope increases for damaged buildings, our lower slope will also be indicative of a lower vulnerability of the reinforced-concrete buildings analyzed. The obtained results are also quite similar to other previous studies carried out in Europe using ambient vibrations, e.g., [4, 5 and 12].

4 RESONANCE PROBABILITY

The phenomenon of resonance occurs when the fundamental period of the buildings coincides with the predominant period of the soil. Resonance phenomenon results in an amplification of the movement of the structure, increasing the damage in the building. If the fundamental period of the building and the predominant period of the soil are different enough, the phenomenon of resonance will not exist.

In the present study, the predominant period of the soil was obtained using the H/V technique [15]. In Figure 4, an example is shown.

The probability of resonance (IR) of each of the buildings has been assigned using the ratio (in percentage) between the fundamental period of the building and the natural period of the soil. Thus, we have assumed the following classification: no resonance for IR <60%; slight resonance for IR between 60% and 75%; moderate for IR between 75% and 90% and full resonance for IR higher than 90%.

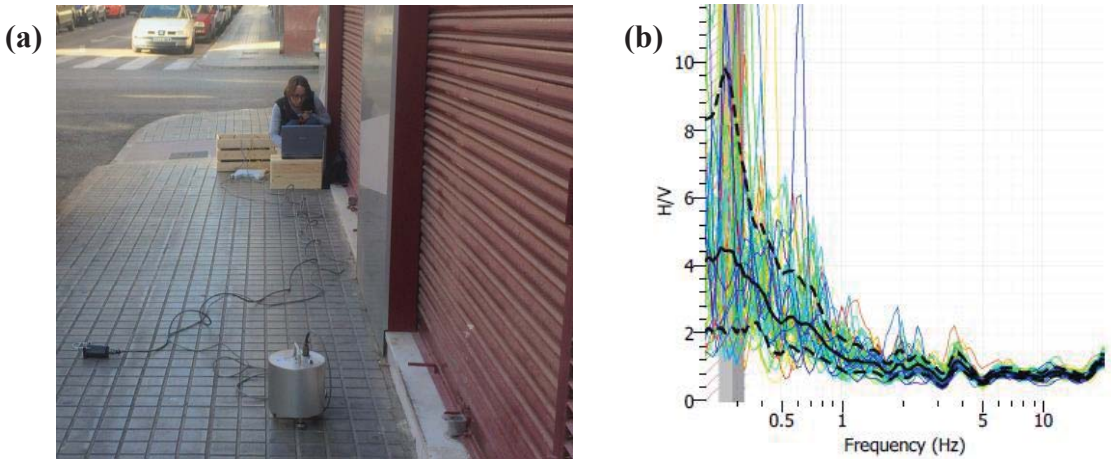

Figure 4: Example of the ambient noise measurements carried out in the vicinity of the building shown in Figure 1 (no 19). a) Field measurement and b) obtained H/V curve.

Table 3 shows the obtained fundamental period for the buildings and the predominant period of the soil as close as possible to the position of the building. In the right column is indicated the probability of resonance. Table 3 shows that, only one of the studied buildings is classified like moderate. The rest of the buildings do not show probability of resonance.

Building number	Storeys	T(s) Building	T(s) Soil	Resonance probability
no 1	2	0.088	3.690	no resonance

5 CONCLUSIONS

Ambient vibration measurements have been carried out in reinforced concrete buildings within the urban areas of Alicante and Elche in order to obtain the fundamental period and a relationship with the height of the building. From the obtained results, it can be concluded:

a) The obtained period-height relationship shows a similar behavior than the obtained by [2] in Lorca, but our slope is lower. This can be due to the lack of data in the regression or it may indicate a lower vulnerability of the reinforced-concrete buildings chosen for Alicante and Elche when compared with Lorca city.
b) Our period-height relationship has been used to propose a probability of soil-structure resonance and only one of the studied buildings has been assigned moderate resonance probability.

The next step in this research will be to continue the data acquisition to a higher number of buildings (also with higher heights), what will improve the estimated linear regression. Additionally, this will allow us to compute resonance probability maps for the whole cities using not only the fundamental period of the soil but also, considering the secondary peaks observed in the HV curves of some areas. These secondary peaks may appear due to the presence of more superficial contrasts and might have additional effects on certain buildings.

6 ACKNOWLEDGMENTS

The study has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 821046, the Ministerio de Economía, Industria y Competitividad through research project CGL2016-77688-R, the Generalitat Valenciana through the research project AICO/2016/098 with the collaboration and funding provided by Elche and Alicante municipalities.

Keywords: Structural dynamic displacement, Cable-stayed bridge, Field test, Geophone, Signal integration

Abstract. *Dynamic displacement is a highly valuable information for the evaluation of bridge safety and performance, providing data on the dynamic behaviour of the structure under service loads. However, its measure is often challenging and costly: traditional techniques require a fixed support and a direct connection (or a clear line-of-sight) with the target point that is rarely present in large-scale infrastructures, making their deployment in long-term monitoring often not feasible. In this study, an indirect measuring approach deploying an electro-dynamic velocity sensor (geophone) and digital filtering is adopted to measure human-induced dynamic displacements on a lively footbridge. These sensors have an excellent cost to performance ratio, do not require any powering and, overall, are easy to install and deploy for a long time. Furthermore, geophones measure velocities and consequently only "one integration step" is needed to obtain displacements. The field test was performed with the bridge partially open to pedestrian passages, the geophone was placed in different positions directly on the deck, and a reference measure of the vertical displacement was obtained from a laser-based system placed nearby. Appropriate digital filtering is then applied on the geophone data before the integration. The calibration of digital filters and the validation of the results was carried out comparing the reconstructed vertical displacements from geophone data and the directly measured vertical displacements from the state-of-art measuring device. Under the assumption of pure dynamic loading, some promising results were obtained, reaching a tenth of a millimetre accuracy for the integrated signals.*

1 INTRODUCTION

Structural dynamic displacement is a highly valuable information for the evaluation of structural safety and performance, providing data on the dynamic behaviour of the structure under service loads. Furthermore, contemporary pedestrian bridges are often slender structures, prone to human-induced vibrations [1], making the control of displacement of great interest.

However, measuring dynamic displacement is often challenging and costly: traditional techniques require reference fixed points that are rarely found in large-scale structures, making the deployment in long-term monitoring often not feasible. Particularly, traditional displacement transducers, e.g. LVDT, requires direct contact both with the target measurement point and with external fixed support. Laser-based or radar-based systems, such as Laser Doppler vibrometer or Ground-based Microwave Interferometer [2], respectively, can provide noncontact measures of dynamic displacements but they still require a line-of-sight to the target point.

In recent years, some promising applications of low-cost satellite-based systems for structural displacement measures, such as GPS [3] or GNSS [4], were carried out but the lack of accuracy often remains an issue.

Another interesting approach is based on indirect measurements with accelerometers or velocimeters. These sensors are small, relatively low-cost, and easy to install and deploy for long time. The main drawback of these technologies is the need for signal processing when performing double or single integration for displacement reconstruction. Indeed, if direct integration is performed, the presence of noise in the recorded data and the inaccurate measures in the low-frequency range brings to erroneous estimation of displacements [5]. For this purpose, various digital filters can be applied: Butterworth filter [6], Baseline Correction [7], finite impulse response filter (FIR filter) [8], or Spectral Subtraction [9] are some examples.

Among the technologies that record accelerations and velocities, geophones are of interest for their cost to performance ratio and the null power demand. Geophones are a well-established technology in the field of seismology, mainly used for measuring ground motion-induced velocities, showing remarkable results in estimating the dynamic displacements [5]. In addition, geophones are well-suited sensors for Operation Modal Analysis of civil engineering structures (see e.g. [10]), making their deployment in a monitoring system of twofold interest: (a) identifying the modal characteristics of the structure; (b) monitoring the maximum displacements induced by operational loads.

More recently, geophones were widely deployed to evaluate the deformations that occur to railway track foundations, during the passage of trains [11-12]. Bowness et al. [6] describe a technique to filter and integrate geophone signals in the context of railway track monitoring. Firstly, the signals are deconvoluted to consider the frequency-dependent sensitivity and the phase lag of the sensor. Indeed, these instruments have a limited linear frequency range, above its natural frequency, typically between 4 and 12 Hz, and when dealing with excitations that have a dominant frequency close to the natural frequency of the sensor, deconvolution is always needed. Secondly, a band-pass filter with a range of 0.3–15 Hz is applied: the high-pass removes the low-frequency drift while the low-pass removes noise at high frequencies. However, defining the cut-off frequency can be challenging, considering that the filter becomes unstable when approaching 0 Hz. Bowness et al. [6] define the lowest cut-off frequency equal to 0.2 Hz.

Notwithstanding, the promising applications of geophones in the monitoring of railway track deformations or recording of strong motion-induced displacements, very few studies are

present in the literature for the application of geophones to record structural dynamic displacements of bridges.

The present paper investigates the application of geophones in the measurement of dynamic displacement of pedestrian bridges. The procedure was exemplified on a cable-stayed pedestrian bridge: the human-induced vibrations are recorded in the same point with a geophone and a state-of-art technology for measuring dynamic displacement (i.e. a Laser Tracker). Therefore, to estimate the dynamic displacement from the geophone data, digital filtering was applied before signal integration. The validation of the results and the calibration of the digital filter was performed through the comparison between reconstructed (from geophone data) and directly measured (from the Laser Tracker) displacements. Particularly, the following steps were involved:

(i) performing a field test on the selected cable-stayed bridge, measuring the human-induced vibrations with multiple setups (subsequent measures in different points) deploying a geophone and a state-of-art measuring device;
(ii) performing the deconvolution of the geophone data with SEISMOWIN [13] software;
(iii) selecting and calibrating a digital filtering method (i.e. pass-band filter [6]) to minimise the difference between the measured and reconstructed dynamic displacements; and
(iv) consequently, developing a MATLAB-based algorithm to perform the filtering and the integration of geophone data for long-term monitoring purposes.

2 ADOPTED MEASURING DEVICES

Geophones are electro-dynamic velocity transducers that produce an output signal in voltage proportional to the recorded speed. The signal is generated by the relative movements of a coil suspended around a core magnet. Therefore, geophones are passive sensors and do not require any power supply. The main drawbacks of this technology are the limited frequency range and the limited excursion of the coil. In the low frequency range – below the resonant frequency of the sensors – the signal is attenuated, and a proper signal deconvolution must be performed. The limited excursion is given by the limited length of the suspended system.

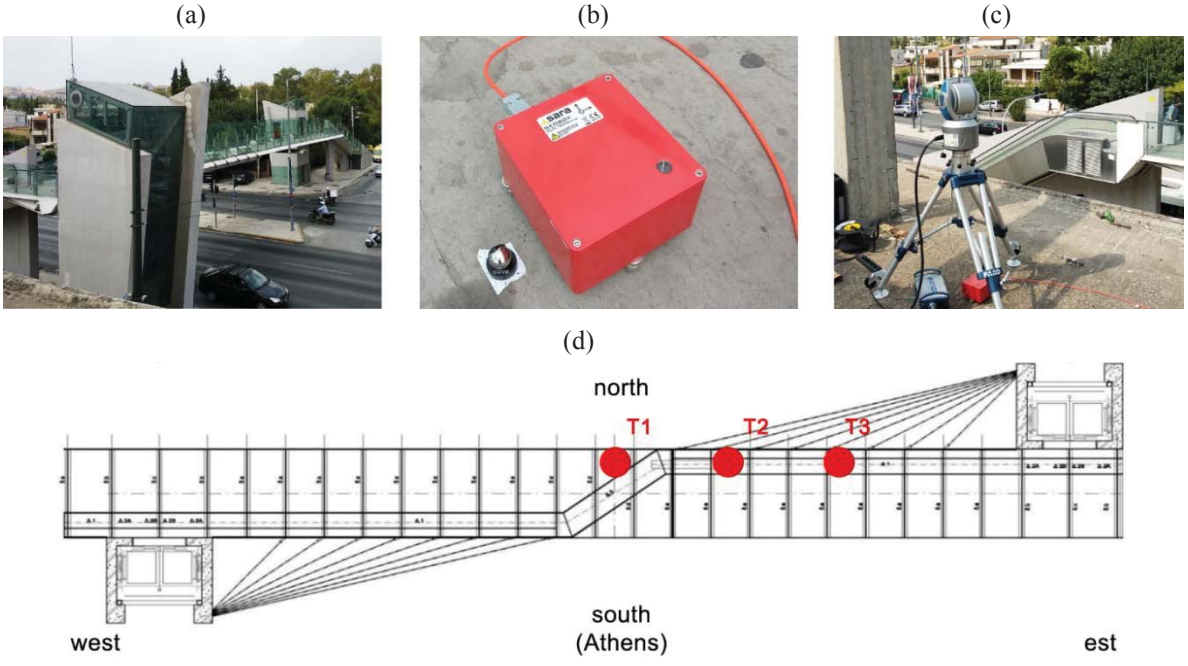

Figure 1: (a) Tested bridge; (b) Laser Tracker target and Geophone; (c) Laser Tracker; (d) Experimental setup.

The indirect measures of displacement were conducted with a high-sensitive seismometer (Fig. 1b), namely a SARA GEOBOX SS45 (nominal sensitivity 78 V/ms^{-1}; natural frequency 4.5 Hz). These specific geophones are of interest for the very good performance in the low-frequency range with a usable dynamic band – before an appropriate signal deconvolution – defined by the manufacturer of 0.2-400 Hz.

The direct measurements of displacements were conducted with a laser tracker, namely the FARO Vantage (Fig. 1c). The Vantage is a portable, three dimensional coordinate measuring instrument that determines the position of a special Spherically Mounted Retroreflector (SMR), through the extremely accurate measurement of a zenith angle, an azimuth angle and a radial distance from the instrument. It uses a phase shift Absolute Distance Meter (ADM), providing a Maximum Permissible Error (MPE) accuracy of ±16μm+0.8μm/m for the radial distance measurements, while its angular Maximum Permissible Error (MPE) accuracy is ±20μm+5μm/m. According to FARO, the typical performance of the sensor is half the MPE values. Vantage has a working range of 0m to 80m and it is capable of making static and dynamic measurements as well, since its maximum sampling frequency is 1 kHz.

3 BRIDGE DESCRIPTION AND TEST PROGRAMME

The test bridge (Fig. 1a), named "Bridge of dreams", is a cable stayed, composite bridge located in the North of Athens, Greece, crossing over the main road that leads to the Olympic Stadium Complex [14]. The bridge is suspended from two composite pylons using 16 fully-locked galvanized cables, anti-symmetrically distributed on each side of the structure. It has an overall length of 76.0 m, a free span of 31.5 m and is 4.0 m wide.

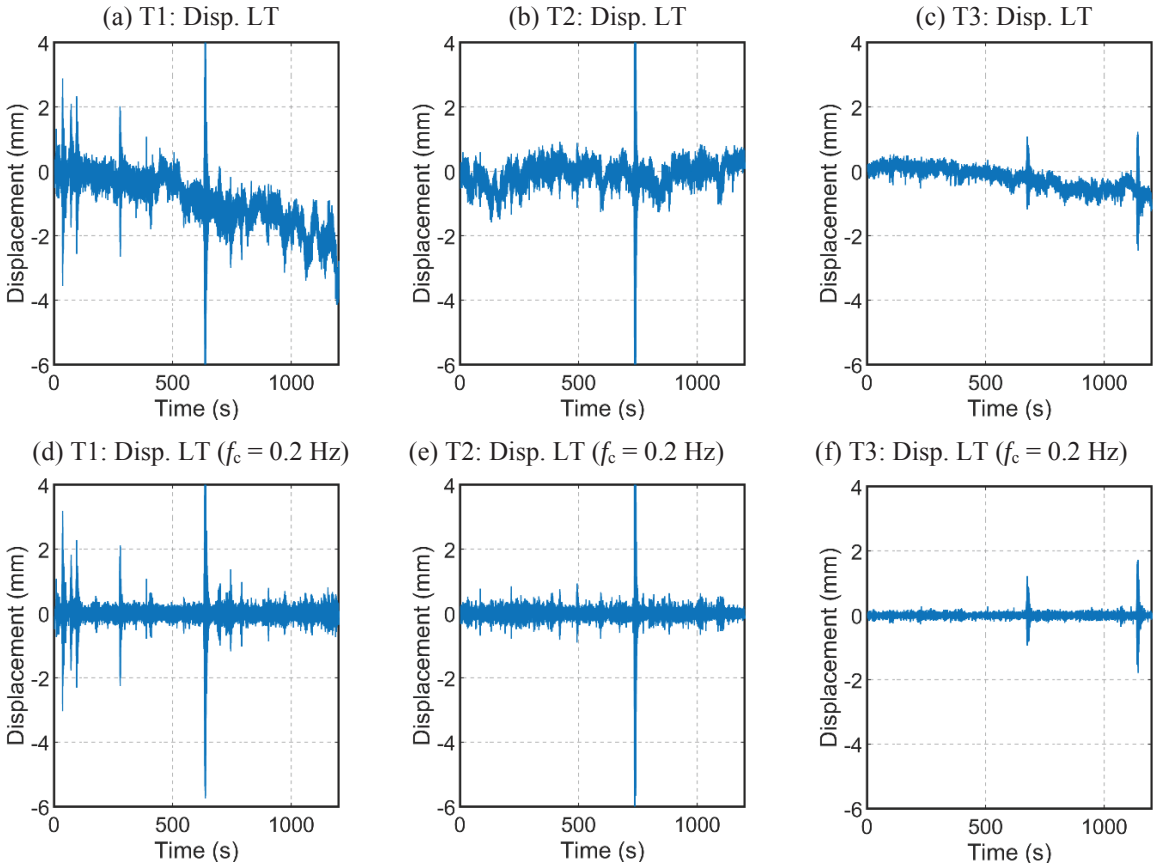

Figure 2: Laser tracker time-series of the 3 measured points: comparison between the non-filtered data (a-c) and the filtered data with a Bandpass Butterworth Filter with a lower cut-off frequency (f_c) of 0.2 Hz (d-f).

The field test was performed with the bridge partially open to pedestrian passages; the geophone was placed in different positions directly on the deck (Fig. 1d), and a reference measure of the vertical displacement was obtained from the laser tracker placed on the roof of a nearby building (Fig. 1c). Particularly the test involved the following steps: (i) positioning of the state-of-art measuring device on the top of a nearby building to obtain a clear line-of-sight to the target point (the small sphere in Fig. 1b); (ii) positioning of the geophone (the red box in Fig. 1b) and the target point in the selected position (Fig. 1d); (iii) recording of human-induced vibration with both devices for 1200 seconds with a sampling rate of 200 Hz.

4 SIGNAL PROCESSING AND DATA ANALYSIS

The calibration of digital filters and the validation of the results was carried out comparing the reconstructed vertical displacements from geophone data and the directly measured vertical displacements from the laser tracker (LT).

The recorded time-series of displacement from the LT are shown in Fig. 2. Figs. 2a-c illustrates the raw displacement data obtained just subtracting the initial recorded value. As mentioned earlier, the test was performed with the bridge partially open to pedestrian passages. During the test the number of people that were walking or staying (several benches are present on the bridge deck) changed continuously, creating an overall increase of quasi-static loads; this effect is particularly visible in the first recording (T1, Fig. 2a). To obtain a pure dynamic displacement, the effects of the quasi-static loads and the noise in the high frequency range were removed with a pass-band filter with cut-off frequencies of 0.2 Hz and 15 Hz (Figs. 2d-f).

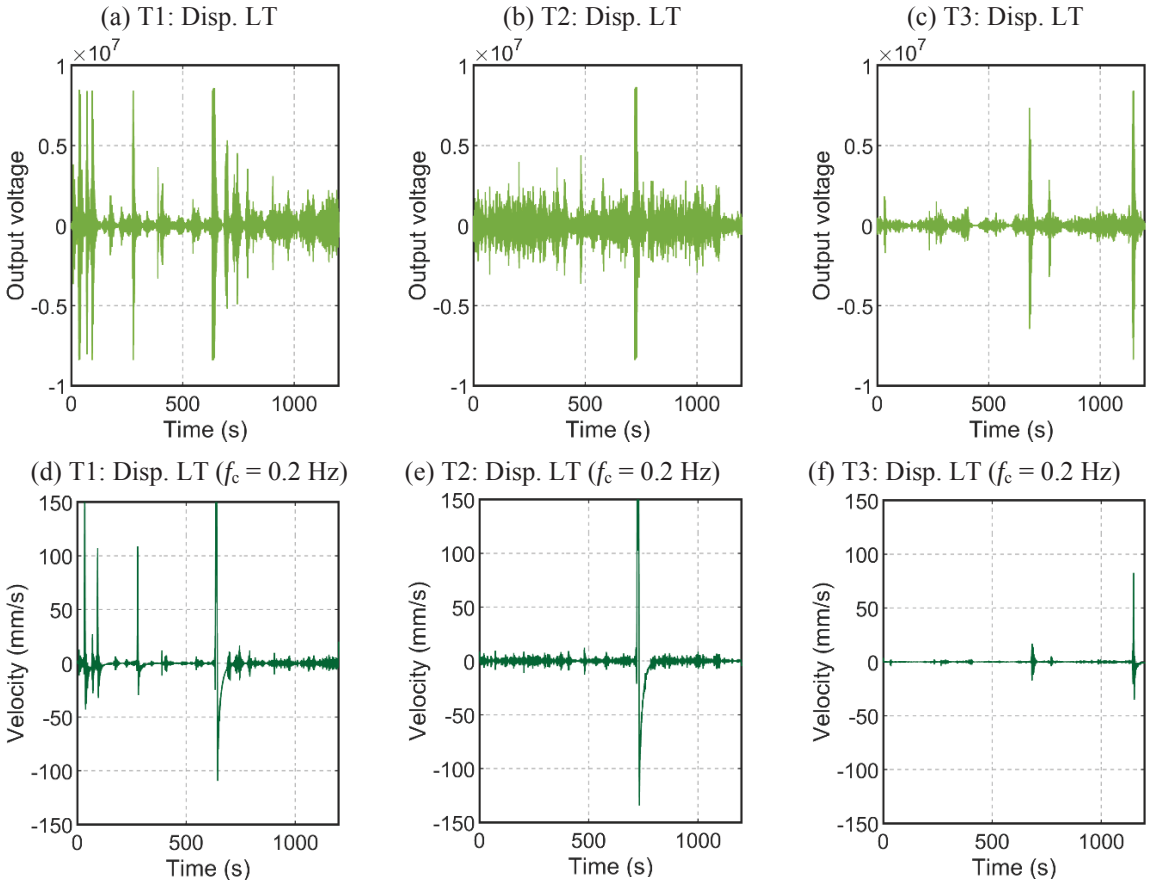

Figure 3: Geophone time-series from of the 3 measured points: comparison between the raw data (a-c) and the deconvoluted velocity data (d-f).

The recorded signals from the geophone are shown in Fig 3. Figs. 3a-c illustrates the raw output voltages: the sharp peaks, particularly visible in the first recording, are caused by high dynamic loads given by people running on the deck. In these instances, the signal reached the threshold given by limited excursion of the coil, resulting in a clipping of the recorded data. This is particularly visible in the deconvoluted velocity data (Figs. 3d-f): the clipped signals results in abnormal speed increases that must be removed or ignored.

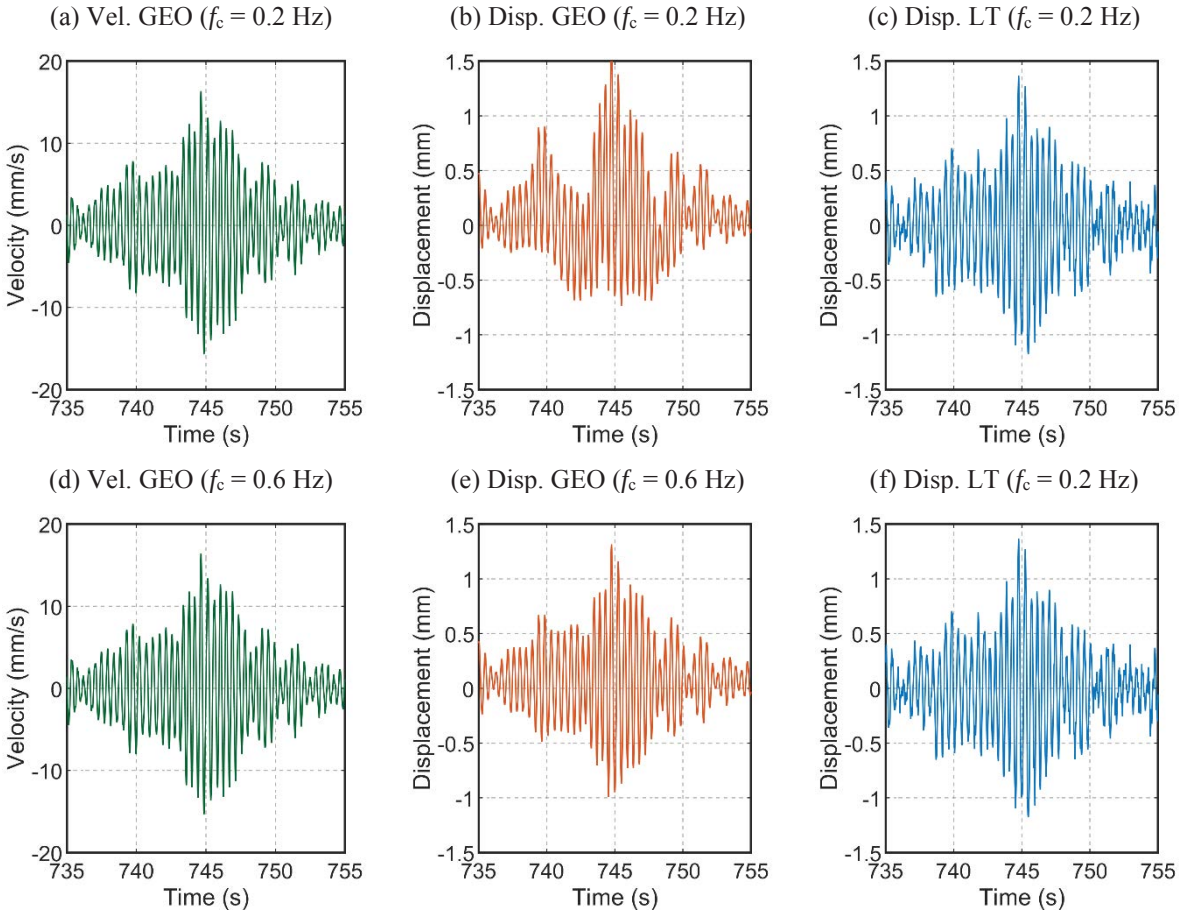

Figure 4: Time-series of 20 sec from T1: geophone velocities (a, d) and reconstructed displacements (b, e) with different cut-off frequency (f_c) and reference laser tracker displacements (c, f).

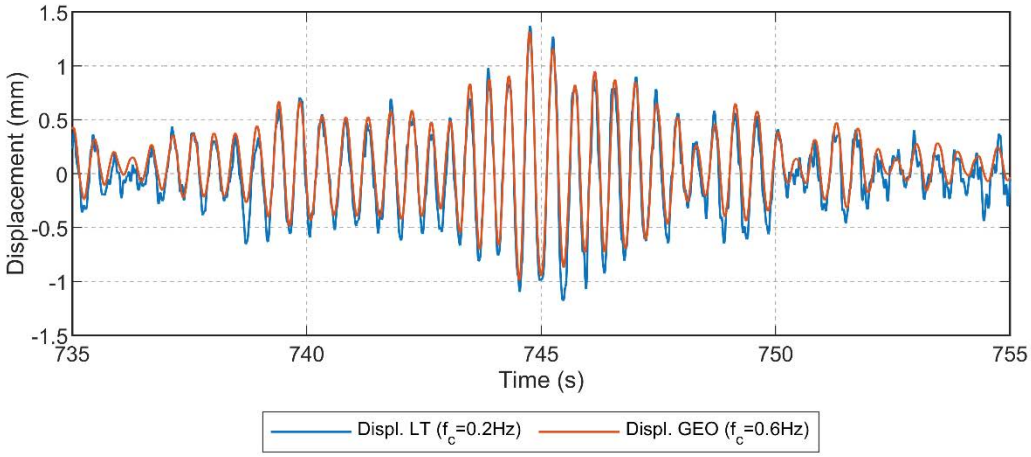

Figure 5: Time-series of 20 sec from T1: comparison between the reconstructed displacements from the geophone (f_c = 0.6 Hz) and the reference laser tracker displacements (f_c = 0.2 Hz).

Subsequently, a pass-band Butterworth filter was applied on the velocity data before the integration. The difference between the references and the reconstructed displacements were minimised with a manual tuning of the cut-off frequencies of the filter. To exemplify the calibration procedure, in Fig. 4 and Fig. 6 are shown few seconds of the time-series recorded at T1 and T3. Firstly, a lower cut-off frequency (f_c) of 0.2 Hz was adopted showing some distortion in the reconstructed displacements (Figs. 4b, 6b). The best match was obtained with f_c =0.6 Hz.

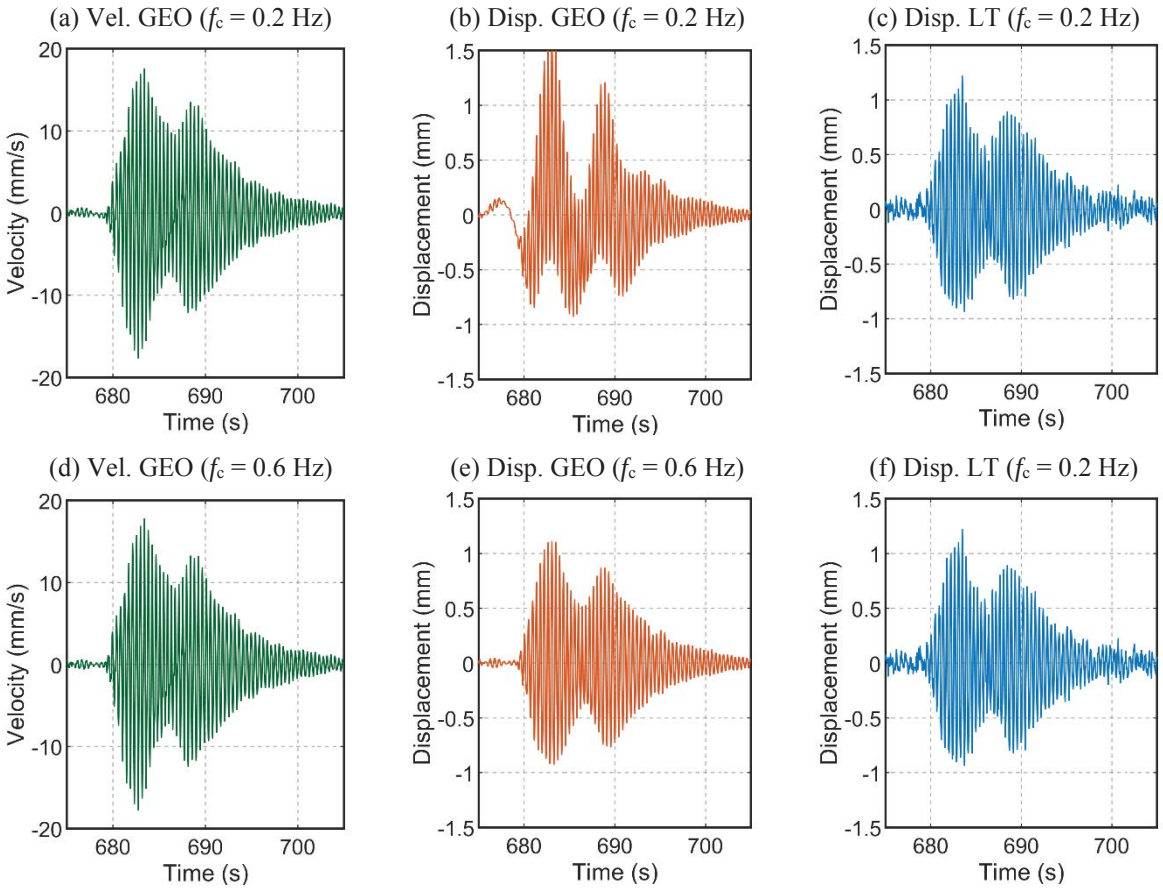

Figure 6: Time-series of 30 sec from T3: geophone velocities (a, d) and reconstructed displacements (b, e) with different cut-off frequency (f_c) and reference laser tracker displacements (c, f).

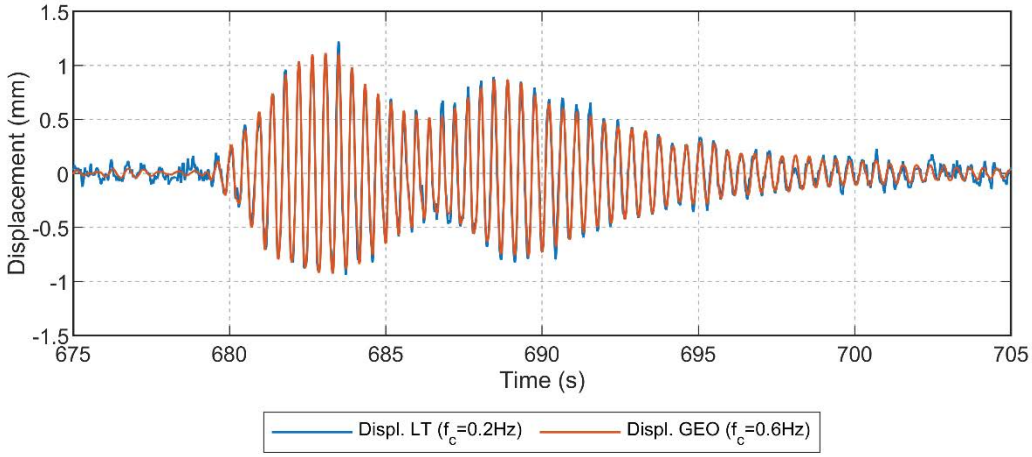

Figure 7: Time-series of 30 sec from T3: comparison between the reconstructed displacements from the geophone (f_c = 0.6 Hz) and the reference laser tracker displacement (f_c = 0.2 Hz).

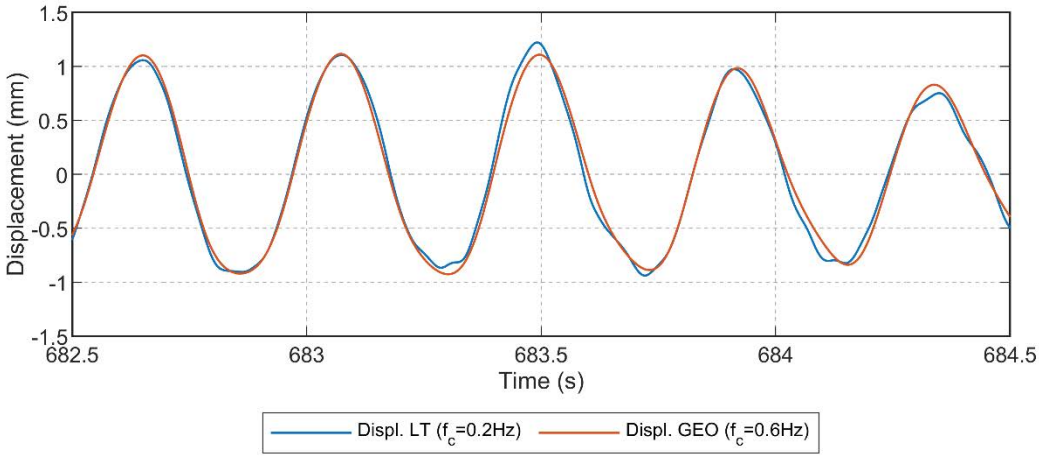

Figure 8: Focus on a time-series of 2 sec from T3: comparison between the reconstructed displacements from the geophone (f_c = 0.6 Hz) and the reference laser tracker displacement (f_c = 0.2 Hz).

Figs. 5 and 7 demonstrates the very good agreement between the reconstructed and the reference displacements.

5 CONCLUSIONS

Previous studies have demonstrated the successful application of digital signal processing on the velocity data recorded with geophones to reconstruct the displacements of railway track foundations and strong-motion induced displacements. In this study, an application of digital filtering for the reconstruction of human-induced displacements on a pedestrian cable stayed bridge is illustrated. The results from the investigated structure suggest the following conclusions:

1) Under the assumption of pure dynamic loading, it is possible to reconstruct the induced displacements from the geophone data by simply applying a Butterworth filter before the integration;
2) Approximately, a tenth of a millimetre accuracy was obtained for the integrated signals (Fig. 8);
3) The cut-off frequencies of the filter are connected to the dynamic characteristics of the investigated structure and to its operational loads;
4) Consequently, from a Structural Health Monitoring perspective, the filter calibration must be performed each time a long-term monitoring is installed;
5) Despite the generally very good accuracy in terms of reconstructed displacement, the sensor reached its measurement threshold several times, making impossible to reconstruct the maximum displacements experienced during the test. Further investigations are needed to reconstruct the clipped signals.

The promising results suggest the future application of the proposed signal processing strategy for the continuous monitoring of the dynamic displacement of bridges. In addition, more tests on structures with higher and lower stiffness have already been planned.

Keywords: Adjacent buildings, Earthquake, Vibration Control, SMA damper, Yield damper

Abstract. *Use of the supplemental damping systems (i.e. viscous or yield dampers), to mitigate the seismic hazard of adjacent building structures (two connected buildings), is proven to be a practical and very efficient approach. In the context of energy dissipation capacity and developing damper/ energy absorber, shape memory alloy (SMA) is well known for its high energy dissipation capacity (super-elasticity). In the present study, the superior seismic response control efficiency of SMA damper is explored over the yield damper. Response of two adjacent structures (steel building frames) connected with SMA damper and yield damper is evaluated through nonlinear dynamic time-history analysis, under a set of recorded near-fault ground motions. The robustness of the improved performances is studied under varying characteristics of damper strength, the building structure time period, as well as different scenarios of seismic loading. Finally, it is demonstrated that, the use of SMA damper significantly improves the floor displacement control efficiency over the yield damper and also provides considerable reduction in the peak absolute floor acceleration.*

1 INTRODUCTION

Construction of sustainable and resilient building structures is an important issue in structural engineering field. Specifically, modern cities are coming up with high rise buildings with very little clearance between them, putting them at risk of mutual pounding in case of an intense earthquake. Various researches are going on to prevent these poundings by connecting these buildings using active, passive or semi-active control devices [1–4]. The concept of vibration control using passive dampers is widely accepted and has frequently been implemented in the civil engineering structures due to its low maintenance costs, reliable performance in real time and low energy requirement. These passive devices respond to the relative responses of the connected buildings. These can be easily installed between the gaps of the buildings without the need for any additional space for its installation or working. These devices serve the dual benefits: (a) prevent the mutual pounding of the buildings and (b) dissipate a part of the seismic energy coming to the buildings.

Some of the popular passive control devices include linear and non-linear viscous dampers, MR damper, viscoelastic or Maxwell dampers, yield dampers, and friction dampers [5–10]. Application of viscous damper and/or viscoelastic damper in buildings does not reduce floor displacement significantly, whereas increases the floor acceleration. MR damper shows high control efficiency in case of semi-active devices. Use of hysteretic dampers such as metallic yield dampers and friction dampers provides good control efficiency but provides high level of residual displacement after a seismic event, therefore hindering immediate occupancy. Thus, researchers are actively involved to find some suitable passive energy dissipation devices for reducing building structural vibration. In this regard, use of advance and smart material gain attention from researcher community [11–13]. In recent years Shape Memory Alloy (SMA) is gaining significant popularity as damper material for passive vibration control device [14–18]. Two important characteristics of the flag-shaped hysteresis of SMA are (a) the hysteresis loop is fat enough to dissipate the input seismic energy and (b) the loop leaves no residual displacement on unloading. To reduce the response of building structure SMA spring is already used in mass damper [19,20] or as a supplement of conventional damper [15,18,21]. It has been shown in several previous studies [19,20] that, compare to the conventional viscous damping (as present in inverse pendulum dampers or mass dampers), hysteretic damping (as present in case of SMA or yield damper) provides much higher control efficiency, due to its higher energy dissipation capacity. Further, the primary application of mass damper or inverse pendulum dampers are mainly for reduction of displacement in single flexible structure, not in case of two connected building structurers. Thus in present study, SMA damper and yield dampers are considered to demonstrate the seismic response reduction control efficiency of adjacent and connected building structures.

In this paper, the focus is laid to demonstrate the superior control efficiency of SMA damper over yield damper in case of connected building structure system. Therefore, presently the performance of super-elastic shape memory alloy damper is assessed to reduce vibration of multistoried building frame under seismic excitation and compare with conventional metallic yield damper. Non-linear time-history analyses are performed to determine the control efficiency of the SMA damper and yield damper. An extensive parametric study is performed considering a wide range of damper parameters and building parameters, as well as under various scenarios of ground motions.

2 MODELLING OF DAMPERS

This section will provide a brief idea about the force-deformation hysteresis behaviour of the yield damper and super-elastic SMA damper.

2.1 Force deformation hysteresis of yield damper

Under cyclic loading, all types of metallic material dissipate energy through yielding and show stable bi-linear force deformation behaviour. Thus, the force deformation hysteresis loop of yield damper is modeled through the parametric Bouc-Wen model [17,22,23], as shown in Fig.1. According to this model, the nonlinear force deformation in a steel member is expressed as

$$F_s(x,Z) = \alpha_s k_s x + (1-\alpha_s) F_{ys} Z$$
$$\dot{Z} = \left(\frac{\delta}{q_s}\right)\dot{x} - \left[\left\{\left(\frac{\gamma}{q_s}\right)|\dot{x}||Z||Z|^{(\eta-1)}\right\} + \left\{\left(\frac{\beta}{q_s}\right)\dot{x}|Z|^{\eta}\right\}\right] \quad (1)$$

where, k_s is the initial elastic stiffness of the yield damper, α_s is the ratio of post to pre yield stiffness (i.e. rigidity ratio) of the yield damper, F_{ys} and q_s are the yield strength and yield displacement of the yield damper, x and $\dot{x}$ are the relative displacement and velocity of the yield damper, variable Z is a non-dimensional quantity, which represents the hysteretic behaviour of metallic material in the yield damper. Here, parameters δ, γ, β and η in Eq. (1) controls the shape and transition of the hysteresis loop.

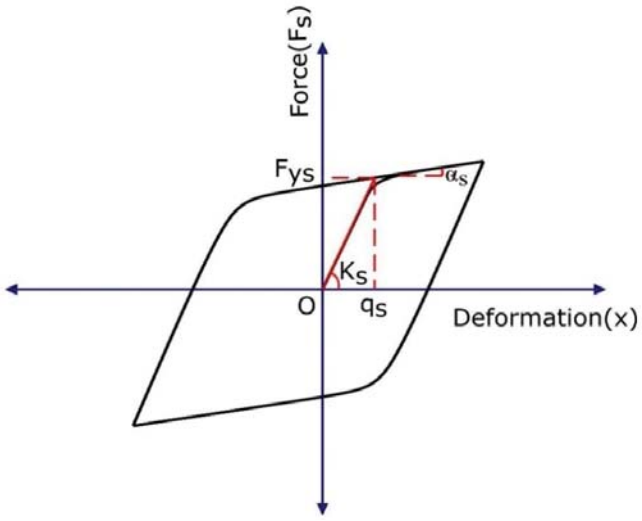

Figure-1: Bi-linear force-deformation hysteresis of yield damper

2.2 Force deformation hysteresis of SMA damper

Super-elasticity and the energy dissipation capability of SMA are primarily exploited in the vibration control applications. Fig. 2 shows that the force-deformation hysteresis of super-elastic SMA damper. The hysteresis behaviour of SMA has been characterized by different types of thermos-mechanical phenomenological models [16,23]. Out of several alternatives, the Graesser-Cozzarelli model [24] has been widely employed for studying the dynamic characteristic of SMA based system. The model is based on the parametric Bouc-Wen model [22]

with an added term incorporating the effect of super-elasticity. The one-dimensional form of this model is given as

$$\dot{F}_{sma}\left(\dot{x},F_B\right)=k_{sma}\left[\dot{x}-\left|\dot{x}\right|\left|\frac{F_{sma}-F_B}{F_{ysma}}\right|^{(\eta-1)}\left(\frac{F_{sma}-F_B}{F_{ysma}}\right)\right]$$
$$F_B=\alpha_{sma}k_{sma}\left[x-\left(\frac{F_{sma}}{k_{sma}}\right)+f_T\left|x\right|^{c'}erf\left(a'x\right)\right] \tag{2}$$

Here, F_{sma} is the restoring force, x and $\dot{x}$ are the relative displacement and velocity of the SMA damper, k_{sma} is the initial stiffness of SMA in austenite phase, F_{ysma} is the force triggering the forward-transformation from the austenite to martensite phase, α_{sma} is a constant determining the ratio of pre to post transformation stiffness, a' is a constant controlling the amount of recovery, the parameter η controls the sharpness of the loop, c' decides the slope of unloading path, F_B is one-dimensional back stress given by the Eq. (2), f_T is a constant to control the type and size of hysteresis

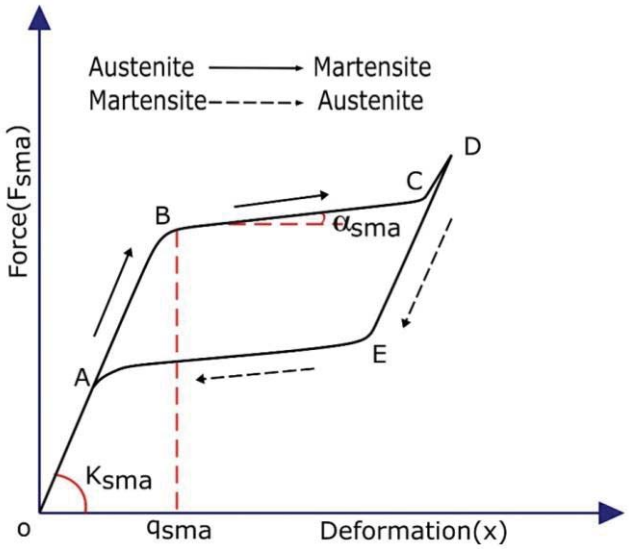

Figure-2: Force-deformation hysteresis of super-elastic shape memory alloy damper

3 SIMULATION DETAILS

This section provides the important details of the simulation process in terms of the equation of motion and ground motion information, as discuss below.

3.1 Nonlinear dynamic analysis

A two dimensional flexible and stiff building frame structure idealized as shear type building and connected by SMA damper or yield damper system has been considered here, as shown in Fig. 3 (a). The mechanical model of the SMA or yield damper system is shown in Fig. 3 (b), consist of super-elastic SMA spring or steel spring, respectively. Since, yield damper or SMA damper dissipate significant amount of input seismic energy via hysteresis loop, thus they will behave non-linearly, and both the building will behave linearly. With linear superstructure behaviour, the equation of motion can be written as

$$\begin{aligned}[M_1]\{\ddot{u}_1\}+[C_1]\{\dot{u}_1\}+[K_1]\{u_1\}+\{F_h\}&=-[M_1]\{r_1\}\ddot{u}_g\\ [M_2]\{\ddot{u}_2\}+[C_2]\{\dot{u}_2\}+[K_2]\{u_2\}-\{F_h\}&=-[M_2]\{r_2\}\ddot{u}_g\end{aligned} \tag{3}$$

Here, $[M_1]$, $[C_1]$ and $[K_1]$ are the mass, damping, and elastic stiffness matrices of flexible building of order $(n_1 \times n_1)$; $[M_2]$, $[C_2]$ and $[K_2]$ are the mass, damping, and elastic stiffness matrices of stiff building of order $(n_2 \times n_2)$, respectively. $\{u_i\} = \{u_{1i} \quad u_{2i} \quad u_{3i} \quad \cdots \quad u_{n_i i}\}^T$ is the lateral displacement vector (of order n_1 for flexible building and n_2 for stiff building) relative to the ground, where $i = 1$ for flexible building and $i = 2$ for stiff building. $\{r_i\}$ is the influence coefficient vector containing pseudo-elastic deformation of the stories under unit deformation of the ground, $\ddot{u}_g$ is the ground acceleration from the earthquake and $\{F_h\}$ is the hysteresis force of the yield or SMA damper.

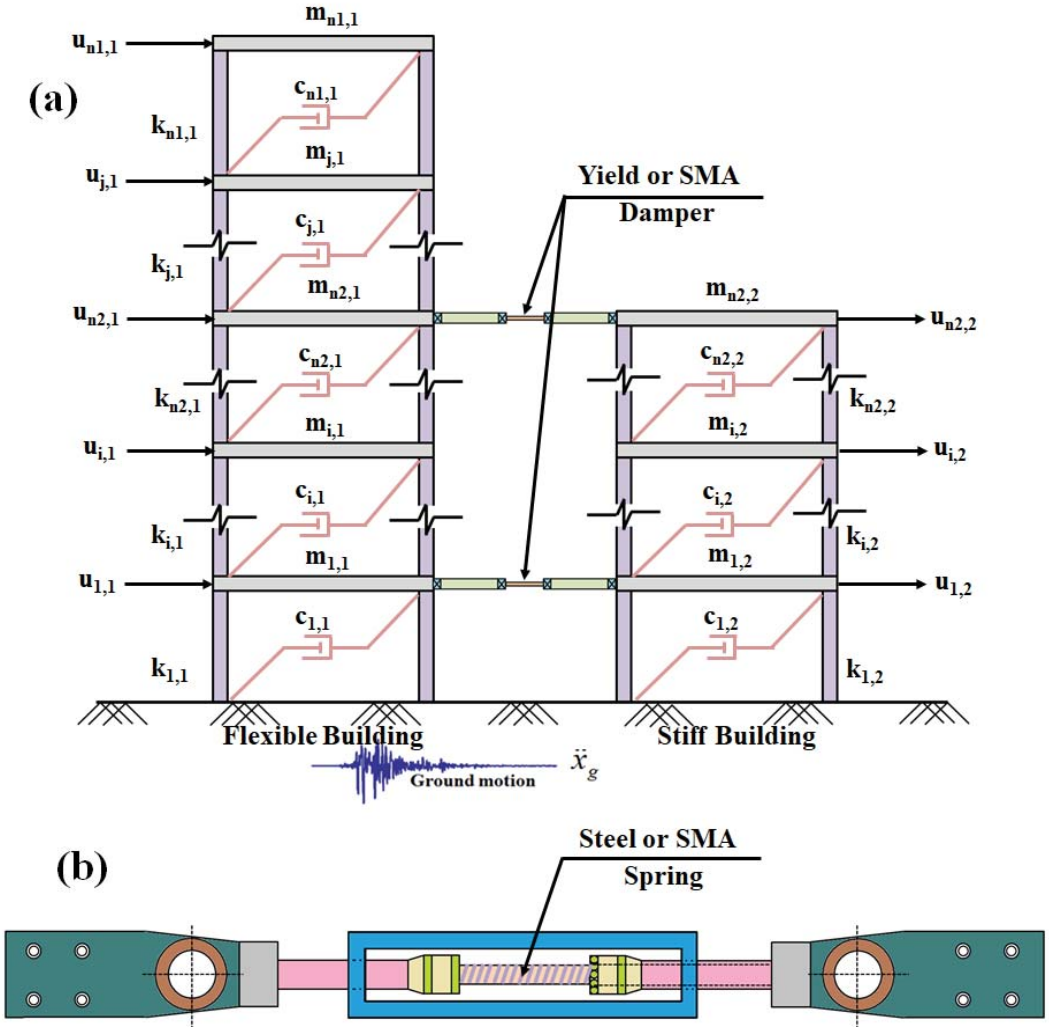

Figure-3: (a) Idealized model of the flexible and stiff building frame structures connected by the yield damper and super-elastic SMA damper. (b) Idealization mechanical model of yield damper and super-elastic SMA damper.

Hysteresis force $\{F_h\}$ is estimated using Eq. (1) for yield damper and Eq. (2) for SMA damper. In case of yield damper, yield strength is define as $F_{ys} = F_{0ys} W$ (here F_{0ys} is the normal-

ized yield strength) and for the super-elastic SMA damper, transformation strength is define as $F_{ysma} = F_{0sma} W$ (here F_{0sma} is the normalized transformation strength). Here, $W = (m_{i1} + m_{i2}) g/2$ is the average floor weight of flexible and stiff building. Numerical values of the different parameters of the build structure, yield damper and super-elastic SMA damper are provided in Table-1, based on the previous studies [17,23].

Table -1: Values of parameters adopted for buildings, yield damper, and SMA damper

Building Structure	*Yield damper*	*SMA damper*
Flexible building time period = 1.00 s Stiff building time period = 0.50 s Damping ratio = 2.00 %	Normalized yield strength $F_{0ys} = 0.100$ Hysteresis of yield damper $\alpha_s = 0.05,\ q_s = 0.025$ m $\delta = 1.0,\ \gamma = 0.5,\ \beta = 0.5$ $\eta = 0.5$	Normalized transition strength $F_{0sma} = 0.125$ Hysteresis of SMA damper $\alpha_{sma} = 0.10,\ q_{sma} = 0.035$ m $a' = 2500,\ c' = 0.001$ $f_T = 0.07,\ \eta = 3.0$

3.2 Ground motion selection

Response output of dynamic analysis of any structure strongly depends on the characteristic of the input excitation and thus ground motion selection is very important for assessment of the structural performance. A set of real earthquakes i.e. fault normal component of the ground motion with near fault characteristics (pulse type features) are adopted for the numerical study. Fig. 4 shows the spectral acceleration of the selected ground motions [25].

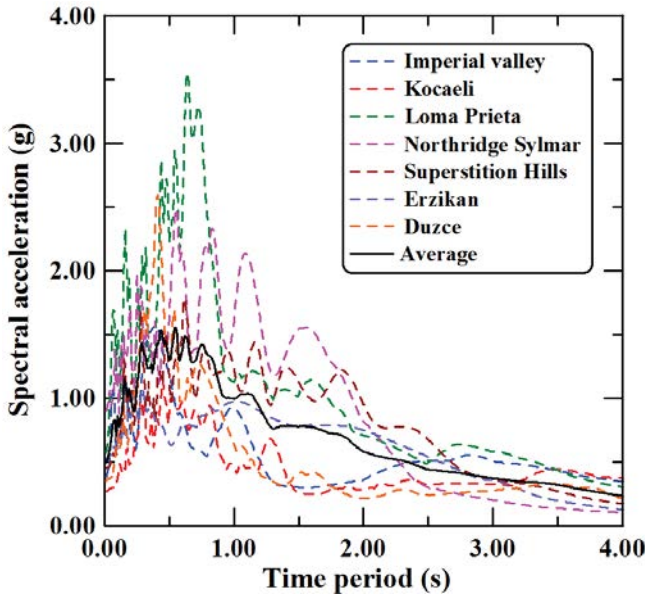

Figure-4: Spectral acceleration plot of selected ground motion

During the selection process of ground motion, consideration has been put to capture the wide range variations in PGAs and dominant frequency contents of the near fault type ground motion. Also, these ground motions are scaled accordingly, whenever needed for parametric study. Table-2 provides some salient characteristics of the adopted ground motions for the

present study. More detailed information about those ground motions are provided in a recent study by Gur et al [23,25,26].

4 RESULTS AND DISCUSSION

Performance of the controlled building structure is studied through the numerical simulation under a set of real, recorded near fault type ground motions as mentioned in the above section. Control efficiency of different types of control system i.e. yield damper, super-elastic SMA damper has been demonstrated through comparing the top floor acceleration and displacement of the flexible and stiff building structure.

4.1 Response analysis

To obtain the response of the isolated building under the earthquake excitation, step-by-step Newmark-beta (average acceleration technique) numerical integration method [27] is used with the time step $\Delta t = 0.0001$ seconds. Here, it is assumed that the damper system will dissipate input seismic excitation energy through its non-linear force deformation hysteresis loop and both the flexible and stiff buildings will remain in their linear-elastic regime. Thus, to obtain the correct solution at each time step, equation of motion of the building structures (both flexible building as well as stiff building) with the connected yield or SMA damper need to be solved iteratively. This iteration process continues until the error in any measured response quantities at the current time step becomes less than or equal to a tolerance limit δ_{tol}, and in the present study it has been considered as 10^{-5}. Different parameters for the numerical solution are adopted from Table-1.

A nonlinear time history analysis is first carried out to examine the responses of the linear steel building with and without passive yield and SMA dampers. In this case, the flexible and stiff building frames, yield damper, and SMA damper are simulated using Table-1 parameter. In this case of response analysis, a seven-story flexible building and a five-story stiff building

is considered. The Yarimca 060 (Koeri) record of the 1999 Kocaeli earthquake is selected as the input ground motion [23,25,26]. Time history responses are presented in Fig. 5. Figs. 5 (a) and 5(b) shows the variation of top floor acceleration of flexible and stiff buildings with respect to time, while Figs. 5(c) and 5(d) shows the variation of top displacement of flexible and stiff buildings with respect to time. It can be observed that, for both flexible and stiff building, yield damper increases top floor acceleration than the uncontrolled building structure. In terms of the floor displacement control efficiency, yield damper shows high level of reduction in the top floor displacement; however, SMA damper significantly improves this displacement control efficiency than yield damper. Such a noticeable improvement in the control efficiency of SMA damper can be explained from its energy dissipation capacity. It can be observed from Fig. 5 (e) that the hysteresis loop size (damper's strength) of SMA damper is more than yield damper, which causes more dissipation of seismic energy and thereby reduces the top floor displacement of the buildings.

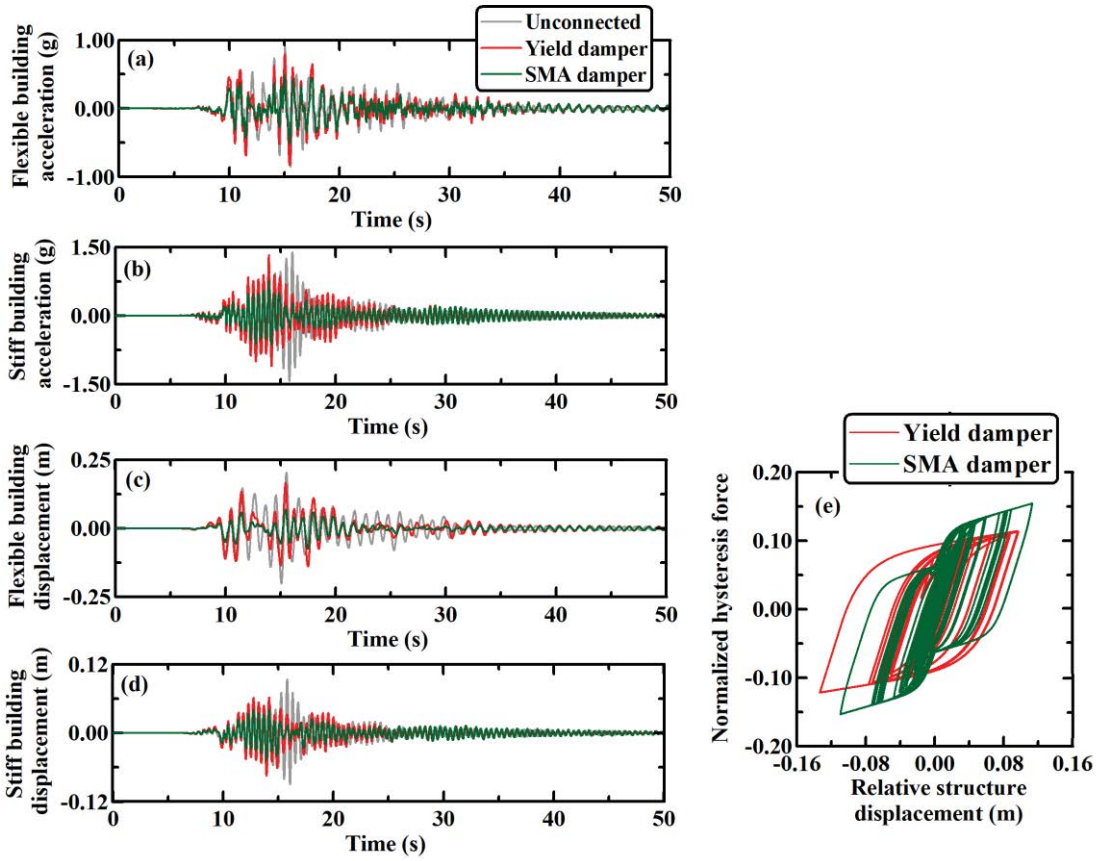

Figure-5: Time-history response of the top floor acceleration of (a) flexible building structure and (b) stiff building structure; top floor displacement of the (c) flexible building structure and (d) stiff building structure under Kocaeli (1999) earthquake. (e) Normalized force-deformation hysteresis loop of the yield damper and SMA damper.

As it can be observed in Fig. 5 (a) and (b) in contrast, super-elastic SMA damper shows reduction in top floor acceleration than unconnected buildings and as well as yield damper. This can be explained from the FFT plots of top floor acceleration of the flexible and stiff buildings, as shown in Fig. 6 (a) and (b), respectively. Fig. 6 (a) and (b) shows that, near to the fundamental frequency of the flexible and stiff buildings (i.e. 1.0 Hz and 0.5 Hz), FFT amplitude of top floor acceleration is much lower in case of SMA damper connected building structure than yield damper connected building structure or unconnected building structure.

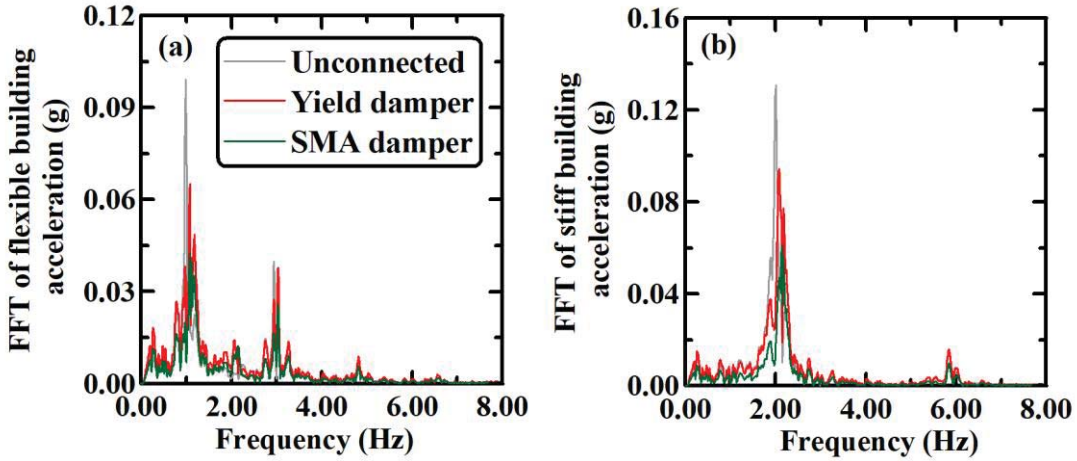

Figure-6: FFT of top floor acceleration (a) flexible building and (b) stiff building structures.

Table-3 provides the top floor absolute acceleration and top floor displacement, respectively, for flexible and stiff buildings without any dampers (only building), and buildings connected with yield or SMA dampers, under all the ground motion mentioned above in Table-2. Observing the values in Table-3 it is clear that, both the dampers reduces acceleration and displacement responses, however SMA dampers provides superior control efficiency than yield damper.

Table-3: Top floor responses of buildings under different earthquakes

4.2 Parametrical study

In this section, parametrical study is performed to demonstrate the superior control efficiency of SMA damper over yield damper. Here, peak acceleration and peak displacement of top floor are measured under all seven ground motions and the average response is reported herein.

As reported in previous studies [16, 17], normalized strength of yield or SMA damper is an important design parameter, and the optimal choice of this parameter will maximize the control efficiency. Fig 7 depicts the effect of normalized yield strength (for steel) or transformation strength (for SMA) of the dampers on the response parameters (i.e. peak top floor acceleration, peak top floor displacement for flexible and stiff building).

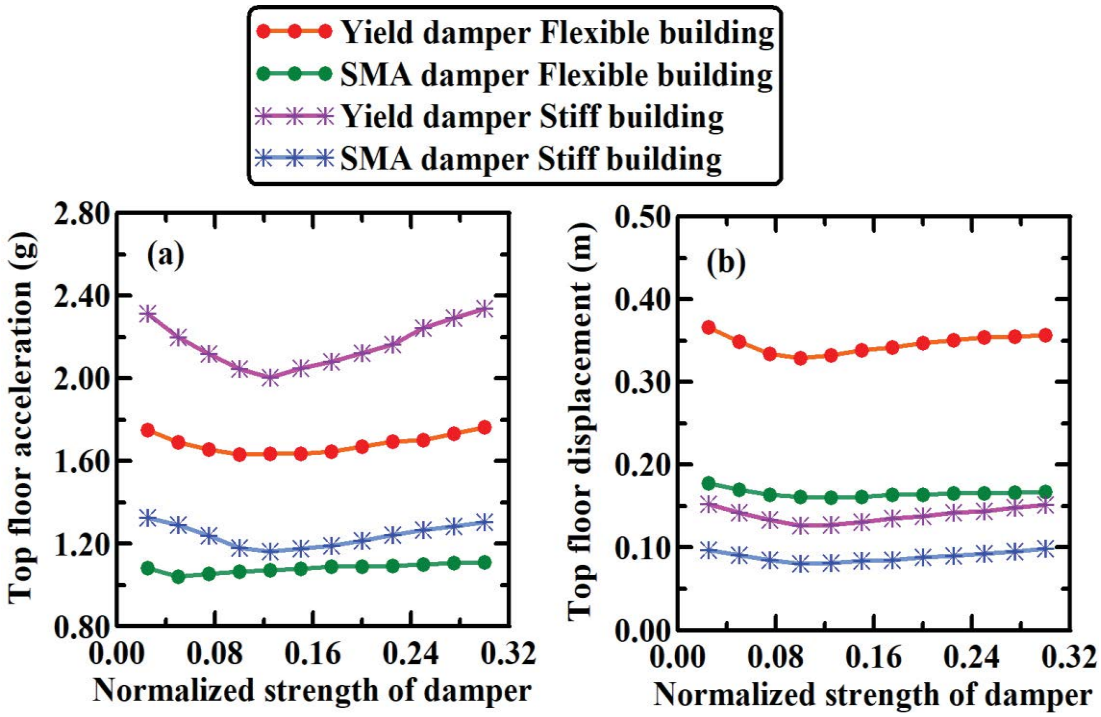

Figure-7: Variation of (a) peak top floor acceleration and (b) peak top floor displacement with respect to the normalized strength of yield damper and SMA damper, for flexible and stiff building.

Fig. 7 (a) and (b) shows variation of peak top floor acceleration and peak top floor displacement of the buildings connected by yield damper and SMA damper, where top floor acceleration and displacements were lesser in case SMA dampers connected building than yield damper. For all the values of normalized strength of damper, stiff building connected with yield damper system shows maximum top floor acceleration; whereas flexible building in SMA damper connected system shows the least (see Fig. 7 (a)). For top floor displacement, flexible building connected with yield damper system shows maximum top floor displacement for all the values of normalized strength of damper, whereas stiff building in SMA damper connected system shows the least (see Fig. 7 (b)). In case of flexible building structure, SMA damper reduces maximum 33.53 % top floor acceleration and 54.71 % top floor displacement. Similarly, for stiff building structure, SMA damper reduces 48.53 % top floor acceleration and 35.03 % top floor displacement.

Next, the effect of time period of flexible building structure on the response parameters are studied, and shown in Fig. 8. Variation of the top floor peak acceleration and peak displacement with respect to the time period of the flexible building are shown in Figs. 8 (a) and 8(b). As expected, for both the dampers (yield and SMA), with the increasing flexibility (i.e. time period) of the flexible structure, top floor peak absolute acceleration reduces. Fig. 8(a) shows that in comparison to the yield damper, SMA damper reduces top floor peak acceleration more in case of stiff building than the flexible building. Compare to the yield damper, SMA damper reduces top floor peak acceleration by 35.07 % for the flexible building structure, and 53.76 % for the stiff building structures. Opposite to the top floor peak acceleration, for both flexible and stiff buildings connected with yield damper and/or super-elastic SMA dampers, top floor peak displacement increases with the increasing time period of flexible structure (Fig. 8 (b)). Here, for the flexible building, SMA damper control efficiency is more than yield damper. In case of stiff building, displacement control efficiency for both SMA and yield damper are comparable. In terms of displacement control efficiency, SMA damper reduces top floor peak displacement up to 55.01 % for the flexible building, and 21.62 % for stiff building, when compare to the yield damper.

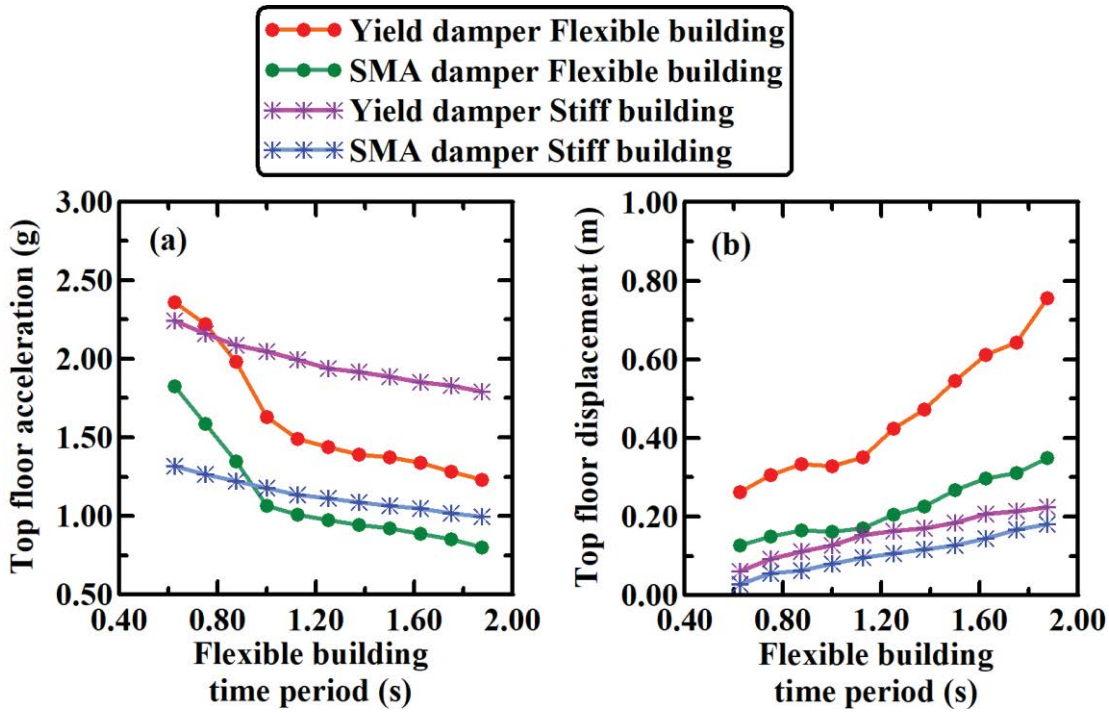

Figure-8: Variation of (a) peak top floor acceleration and (b) peak top floor displacement with respect to the flexible building time period, for flexible building and stiff building, connected with SMA damper and yield damper

Finally, the control efficiency of different type of damper has been studied under the varying peak ground acceleration (PGA); keeping frequency contents of the ground motions unaltered. This is achieved just by up-scaling individual ground motions by suitable factors i.e. multiplying the ordinates of the ground motion by some suitable factors. Variation of the different response quantities (i.e. top floor peak acceleration and displacement) under the varying PGAs are shown in Fig. 9. As expected, for both types of damper, the responses increase monotonically with increasing PGA. In any type of building structures (flexible or stiff), responses of SMA dampers connected building system are consistently lesser than the responses of yield dampers connected building system. At lower values of PGA, control efficiency of

SMA damper is almost comparable with yield damper. Whereas for higher values of PGA, SMA damper shows significant improvement in control efficiency than yield damper. Such aspect strengthens the fact that, the control efficiency of SMA damper over yield damper increases while subjected to a larger intensity of earthquakes. In terms of the floor acceleration control efficiency, SMA damper reduces top floor peak acceleration by 14.07 % for flexible building and 21.83 % for stiff building, when compare to the yield damper. Similarly, for floor displacement, SMA damper reduces top floor peak displacement by 35.67 % for flexible building and 19.45 % for stiff building, relative to the yield damper.

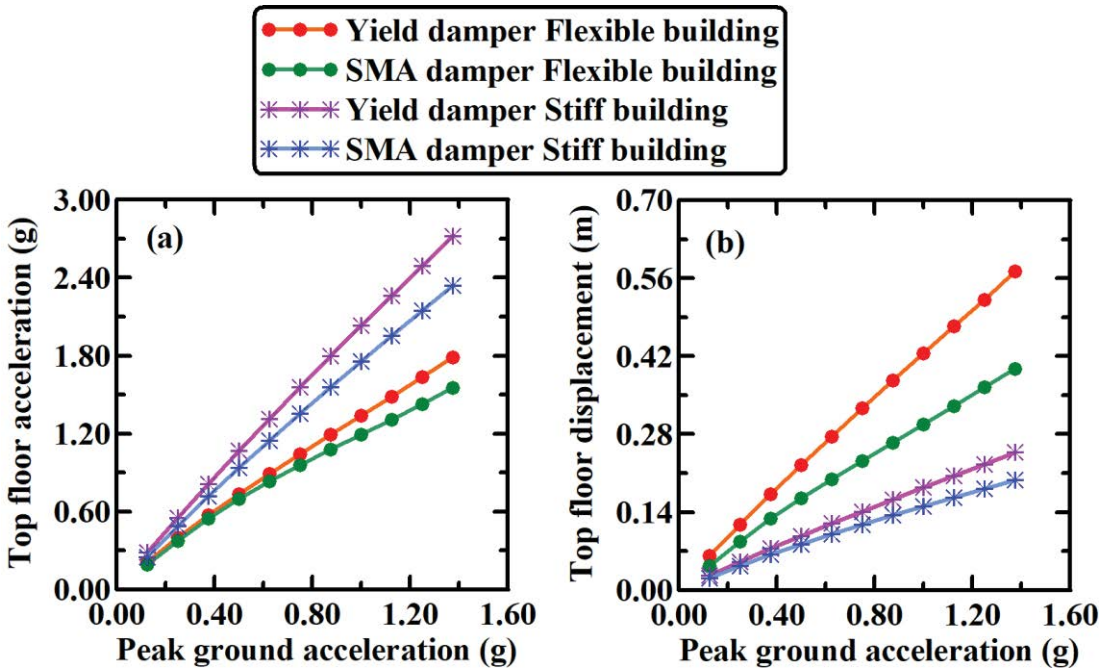

Figure-9: Variation of (a) peak top floor acceleration and (b) peak top floor displacement with respect to the peak ground acceleration for flexible building to stiff building, connected with SMA damper and yield damper

5 CONCLUSIONS

Performance of yield damper and SMA damper as passive control device in connected buildings are compared using non-linear dynamic response analysis under seven ground motions obtained from past earthquakes. Analyses results show that both the dampers help to reduce floor responses (peak acceleration and displacement) for connected buildings than unconnected buildings. Here, performance of both the dampers are evaluated under varying parameters like normalized strength of dampers, time period of buildings, peak ground acceleration. Response analysis shows that, SMA dampers significantly reduce the top floor responses (peak acceleration and displacement) when compare with the yield dampers. Finally, all the parametrical studies confirmed the superior control efficiency of SMA Damper over yield damper for connected buildings under the seismic excitation. Parametrical study results show that, compare to the yield damper, SMA damper reduces top floor peak absolute acceleration as high up to 35 % for flexible building and 55 % for stiff building. When displacement control efficiency is considered (in terms of the top floor peak displacement), compare to the yield damper, SMA damper provides 55 % more reduction for the flexible building, and 35 % more reduction for the stiff building.

Abstract. *Surface wave propagation can be investigated with the help of centrifuge and numerical modelling. An electromagnetic drop-projectile apparatus was used to generate surface waves in soil upon the impact of a spherical metal ball with a shallow foundation. A 3D LS-DYNA FE model was developed and first calibrated against the analytical solutions for the soil displacement at the ground surface due to the arrival of Rayleigh waves. The 3D model was then validated with the results of vertical acceleration obtained from geotechnical centrifuge test for homogeneous soil layer profile. The numerical results show that LS-DYNA can reliably be used as a numerical tool to simulate surface wave propagation. Following the validation, a parametric numerical study was performed to assess the impact of stiffness contrast in soil layers on surface wave propagation. In this parametric study, soil layer with relatively lower stiffness (shear wave velocity) was modelled below a stiffer upper layer. The attenuation of vertical acceleration of the surface waves at an increasing distance away from the source were investigated and compared between the results of geotechnical centrifuge test and numerical models. The results of parametric analysis tend to suggest that the presence of soft soil at shallow depth can amplify the amplitude of vertical accelerations within the stiffer upper layer. This effect however is likely to be localised near the source of vibration.*

1 INTRODUCTION

Inter-city high speed rail is one of the most efficient means of transportation systems and an attractive and viable alternative for promoting travel and commerce as compared to air or car-based land transport. Today, Spain and China have one of the largest high-speed rail networks in the world. After the success of High Speed 1 (HS1), Britain is now planning and moving ahead with the early stages of construction of its new high-speed railway line – High Speed 2 (HS2). The projected operational speed of trains on HS2 network will be 100 m/s with the proposed track alignment passing through cuttings and embankments with sub-surface conditions varying from soft alluvium and/or deep peat layers to stiff glacial till.

The increased operational speed of high-speed trains has also led to some notable case histories [1,2,3] of excessive ground-borne vibrations. Ground-borne vibrations are generated due to the wheel-axle pressure acting on the rails as shown in Figure 1. The vibrations due to geo-dynamic track-soil interaction tends to amplify as the train speed approaches critical velocity (Rayleigh wave velocity) of the subgrade supporting the tracks [4,5]. It is possible for modern-day high-speed trains to exceed this critical velocity if the soil below tracks consists of soft silty clays, peats and/or organics which typically have shear wave velocity in the range of 40-60 m/sec.

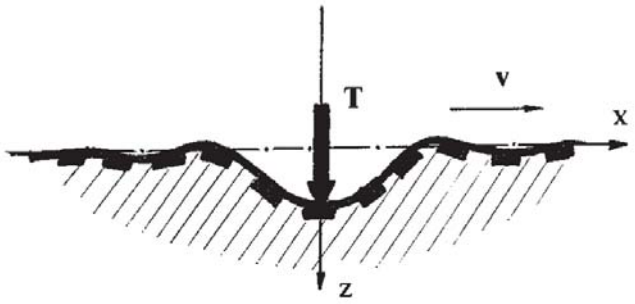

Figure 1: Wheel-axle pressure acting on rails [6]

Although the relevance of understanding propagation of surface waves (in the form of Rayleigh waves) is important to the high-speed rail industry, the phenomenon has not been that well understood experimentally. One of the earliest endeavors in studying surface wave propagation was with the means of full-scale tests [7] to understand efficacy of active and passive isolation systems as mitigation measures against excessive vibration. Since it is not always feasible to perform full-scale tests, some researchers have investigated the feasibility of centrifuge modelling to generate and measure surface vibrations in scaled-down models. A novel drop-ball apparatus [8] was developed to generate surface waves from a falling spherical metal ball under the effect of centrifugal acceleration. Piezoelectric accelerometers buried in the centrifuge package provided an estimate of geometric and material damping coefficients for surface waves. An enhancement was developed [9] to drop multiple balls to simulate a moving surface load and study the effect of geometry and material of wave barrier in attenuating the surface wave motion.

When the observations from full-scale or model-scale centrifuge tests are not available, numerical analysis in the form of BEM (Boundary Element Method), FEM (Finite Element Method), FDM (Finite Difference Model) and coupled FEM-BEM (2.5D) methods have been used for the propagation of surface waves generated due to high-speed trains. 2D and 2.5D BEMs were used [10,11] to assess the effect of geometry of structures such as wave barrier and stiffness contrast ratio between a structure (for example, wave barrier or embankment)

and in-situ soil on the propagation and attenuation of surface waves. Although, FEM/FDM are computationally expensive than BEM, several researchers [12-15] have used these methods for the flexibility of modelling 3D track-structure geometry, moving train loads and the ability to predict the effects of surface wave propagation along the length of track and in far-field (away from the track), which are generally obtained with some approximation in 2D (FEM/FDM/BEM) and 2.5D BEM-FEM coupled models.

In this paper, we discuss the development of drop-ball centrifuge test to generate surface waves in a medium of homogeneous, dry sand. A 3D FE numerical model is proposed which is calibrated with analytical solution of particle displacement at soil surface due to arrival of Rayleigh waves and afterwards, calibrated with the results from centrifuge test. A parametric study is performed with the FE model to demonstrate the possible effect of soil stiffness contrast in a layered soil profile on surface wave propagation.

2 PHYSICAL MODELLING OF GROUND-BORNE VIBRATIONS

In centrifuge modelling, the stress state of soil at a certain depth in the prototype can be replicated under the centrifugal acceleration of N*g. Scaling laws used to correlate stress, strain and other behaviour in a prototype and scaled-down centrifuge model are presented in Table 1 [14].

Parameter	Dimensions	Model/Prototype
Length	L	1/N
Velocity	LT^{-1}	1
Acceleration	LT^{-2}	N
Mass	M	$1/N^3$
Time (dynamic)	T	1/N
Frequency	T^{-1}	N

Table 1: Scaling laws for centrifuge modelling

Centrifuge tests were performed on the 10 m beam centrifuge at the Schofield Center (UK). The results from centrifuge experiment reported in this paper correspond to centrifugal acceleration 40 (N) times the gravitational acceleration. Only a brief discussion of the centrifuge model is presented below; the details of drop-ball system and preliminary centrifuge test results are discussed in another paper [17].

2.1 Centrifuge model for calibration of numerical model

The centrifuge model was prepared by pouring Hostun HN31 silica sand from an automatic sand pourer in an 850 mm (internal) diameter model container, to a height of approximately 232 mm. The material parameters of Hostun HN31 silica sand are presented in Table 2. An average relative density of about 50% was achieved for the homogeneous sand bed.

Parameter	Value
Density of solid particle (kg/m^3)	2650
Minimum Void Ratio	0.555
Maximum Void Ratio	1.01
d_{50} (mm)	0.334

Table 2: Material parameters of Hostun HN31 silica sand [16]

Time-lag in the arrival of shear waves generated by Air Hammer [15] placed near the bottom of model container and recorded by piezoelectric accelerometers at different elevations in the sand bed were used to derive in-situ shear wave velocity profile. Surface waves were generated by dropping spherical metal ball onto a circular metal foundation placed at the top of soil surface [17] as shown in Figure 2.Vertical accelerations in the soil were recorded by MEMS-type accelerometers buried at shallow depth and at an increasing radial distance away from the metal foundation.

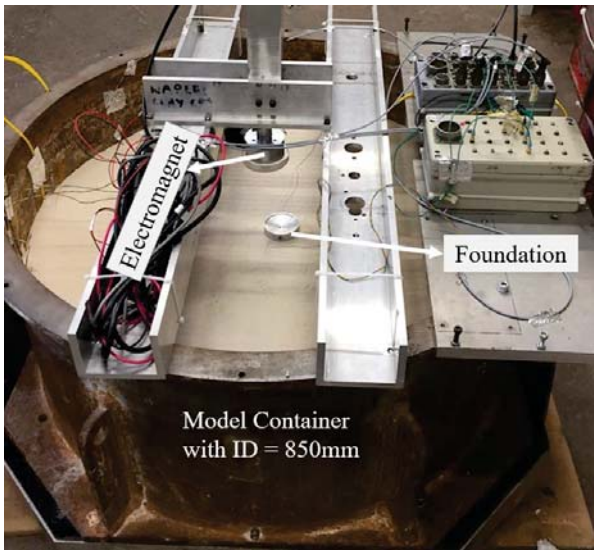

Figure 2: Centrifuge Model with Drop-Ball Apparatus (homogeneous soil layer)

3 NUMERICAL MODELLING OF GROUND-BORNE VIBRATIONS

Numerical analysis for surface wave propagation is performed with LS-DYNA (http://www.lstc.com/) using Explicit Solver. The explicit solution technique is based on integration of constant accelerations over a time increment. It is important that an FE model is appropriately discretised in space and time domains to avoid numerical dispersion and errors due to mesh size and analysis time step.

An FE mesh with coarse element size acts like a low-pass filter which can filter high-frequency waveforms unable to propagate over large element size. Spatial discretisation (mesh element size) of FE mesh is based on the highest frequency of propagating surface wave (f_{max}) and Rayleigh wave velocity (V_R) of the medium. The minimum mesh element size (d_{min}) can be chosen as one-tenth of the minimum wavelength propagating through the medium [18]. The minimum time-step for integration of accelerations in the explicit solution scheme is then derived as the ratio of minimum mesh element size (d_{min}) and Rayleigh wave velocity (V_R) [19].

3.1 Validation with analytical solution

A 3D LS-DYNA FE model (Figure 3) was developed to simulate Lamb's problem [20] where the surface waves are generated by a point impulse load acting on a semi-infinite elastic medium. This step serves as a benchmark exercise before the application of LS-DYNA FE for simulating surface wave propagation observed in centrifuge test. The time-dependent impulse load has the form[21]:

$$F(t) = F_b \frac{t}{(t^2 + \tau_p^2)} \quad (1)$$

The peak amplitude of the pulse and pulse width it modulated with parameters F_b and τ_P with their respective amplitudes taken as 2.0×10^{-6} and 6.0×10^{-4}. Taking advantage of the symmetry of the problem, only a quarter-geometry is modelled in FE analysis with an edge length of 1m along each cartesian axes. The soil parameters adopted for this analysis correspond to shear wave velocity (V_s) of 60 m/sec [19] modelled with *MAT_ELASTIC in LS-DYNA. Since only finite dimensions of soil domain are modelled, special boundary elements were placed around the bounded domain to absorb outgoing waves and minimise their reflection back into the model domain. Absorbing boundaries along the outer planes of geometry were modelled with perfectly matched layers (PML) using *MAT_PML_ELASTIC in LS-DYNA [22]. The perfectly matched layers were modelled with the same elastic properties as that of the soil domain with 8 elements through the depth. For geometry planes along the axis of symmetry, the nodes were constrained against translation in the normal direction and the nodes of PML elements were fully fixed against translation using *BOUNDARY_SPC.

Using the guidelines presented above, a 3D mesh with uniform element size of 10 mm was adopted for analysis resulting in approximately 1.26 million solid elements. The time-step used for analysis was taken as 1.36×10^{-5} sec. The solid elements were modelled with *SECTION_SOLID with fully integrated selectively reduced formulation (Elform = 2). To dampen any spurious oscillations in the elastic medium, a nominal damping of 0.1% was defined using *DAMPING_FREQUENCY between a frequency range of 20 Hz to 0.5 kHz. The impulse load (Equation 1) was defined using *DEFINE_CURVE and applied to a node along the axis of symmetry using *LOAD_NODE in the vertical direction. The total analysis run time was adopted as 0.03 sec and was analysed with double-precision LS-DYNA R11 explicit solver.

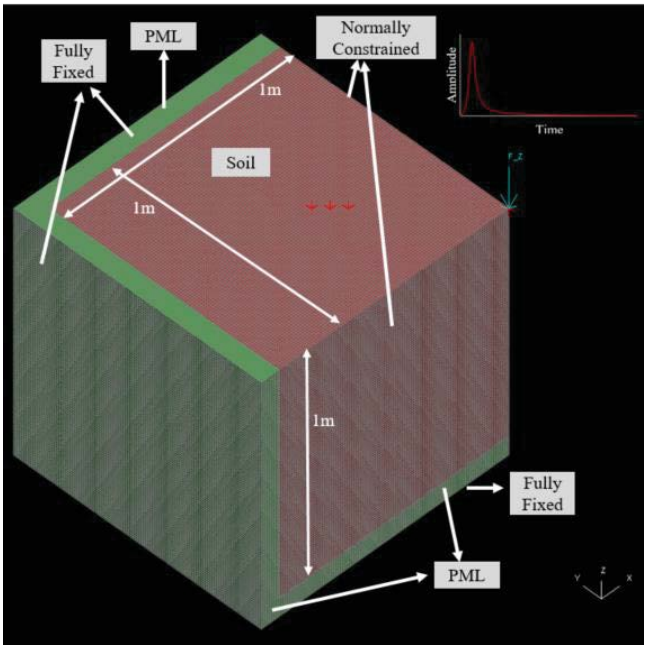

Figure 3: 3D LS-DYNA model for validation with Lamb's problem

Vertical displacement time histories of nodes at pre-defined locations on surface were obtained from the numerical analysis and compared with the analytical solution [21]. As shown in Figure 4, the numerical solution captures the arrival of P-waves and S-waves before the arrival of Rayleigh waves which causes peak particle displacement [7,22]. The Rayleigh wave velocity (V_R) calculated from the numerical solution as the time-lag (dt = 0.001031 sec) be-

tween the arrival of peak particle displacement at two node locations (distance = 0.49 m; distance = 0.55 m) is 54.9 m/sec, which matches reasonably with the theoretical value of 56.7 m/sec [19]. This step shows a good agreement between theoretical solutions and numerical analysis with LS-DYNA for Rayleigh wave propagation.

Figure 4: (a) Deformed Shape of FE mesh (magnified by 5.0×10^5) showing wave propagation at $t = 0.16$ *sec*, (b) Comparison of vertical displacement time-histories between theoretical and LS-DYNA analysis

3.2 Validation with centrifuge test

After validating LS-DYNA with analytical solutions for Rayleigh wave propagation, the FE model was modified to represent the physical dimensions of centrifuge test in Section 2.1. The modified 3D quarter-model has lateral dimensions equal to the internal radius of the model container (425 mm) and a model height of 232 mm (Figure 5).

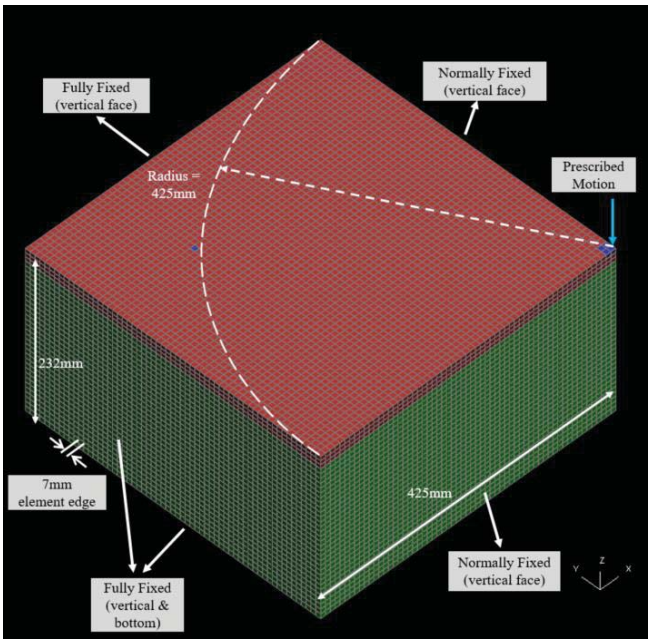

Figure 5: 3D LS-DYNA model for validation with centrifuge test

The model container in centrifuge test was cylindrical, the 3D FE model was modelled with a parallelepiped mesh domain to maintain a uniform and regular shape of 3D solid element with straight edges. Although, this approximation resulted in model domain with its diagonal length greater than radius of centrifuge model container (425 mm), it was unlikely to influence the acceleration calculated in soil close to the source of vibration in the FE model.

The soil was modelled as a linear elastic material with a uniform shear wave velocity of 120 m/sec [17] taken at the depth of MEMS-accelerometers in soil. The model boundaries (*BOUNDARY_SPC) were also updated to represent the fixed condition at the interface of soil-model container, thereby allowing for reflection of outgoing waves back into the model domain. The vertical acceleration measured at the circular foundation (source) in centrifuge test was directly applied in the FE model with *BOUDNARY_PRESCRIBED_MOTION. All the results presented hereafter refer at model scale unless stated otherwise.

The vertical acceleration measured at the metal foundation from the centrifuge test for a drop height of 100 mm and its corresponding FFT is presented in Figure 6. Based on the maximum cutoff frequency at the source of about 1500 Hz, a minimum mesh size of 8 mm was obtained. This cutoff frequency is significantly higher than what can typically propagate through soil (typically in the range of 10-25 Hz at 1g). Nevertheless, the mesh element size was further reduced to 7 mm purely from the perspective of placing FE nodes at the locations of MEMS-accelerometers placed in soil in the centrifuge test.

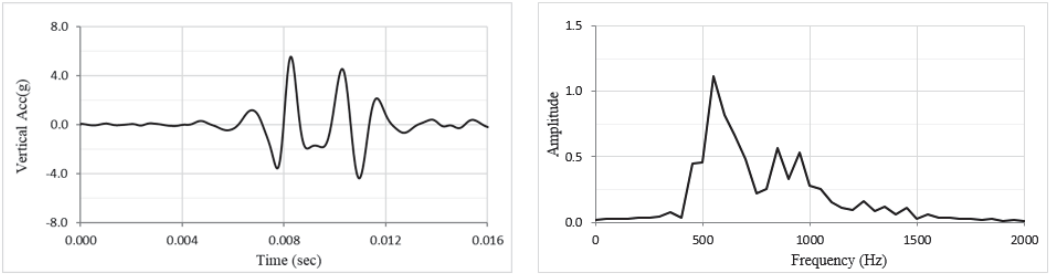

Figure 6: (a) Vertical acceleration measured at foundation disk (source), (b) FFT spectrum

The vertical accelerations (model-scale) at a depth of 18 mm from surface and at 60 mm and 90 mm lateral distance with from the source were compared (Figure 7) between the results obtained from centrifuge tests and from the 3D FE model. The preliminary results suggest that the arrival of the first peak in the acceleration pulse match reasonably well with the experimental measurements.

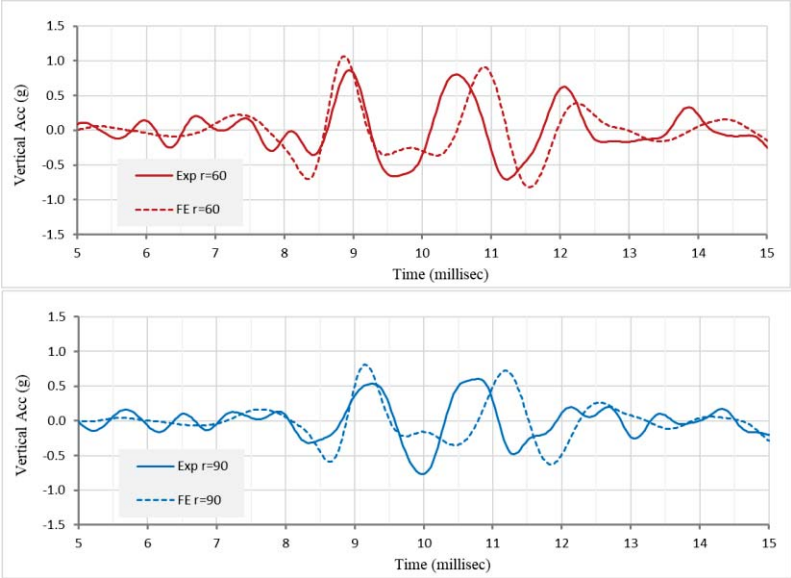

Figure 7: Comparison of vertical acceleration between centrifuge test and numerical model

3.2.1. Parametric study – soil stiffness

Amplification of the surface wave vibrations have generally been reported for sites where soft soil conditions were present below the stiff track-structure. Remediation measures such as piled embankments with piles ending in a competent stratum or ground improvement with dry deep mixing method to a certain depth below the track-structure [1, 3] were applied to reduce the amplification of vibrations. The 3D FE model previously calibrated with the results of centrifuge test was updated for non-uniform soil stiffness as shown in Figure 8. It was assumed that the stiff upper layer has a prototype thickness of 0.72 m (or, 18 mm at model scale). A uniform shear wave velocity of 60 m/sec was assumed for the soft soil layer which is similar to the values reported in literature [1, 17, 24].

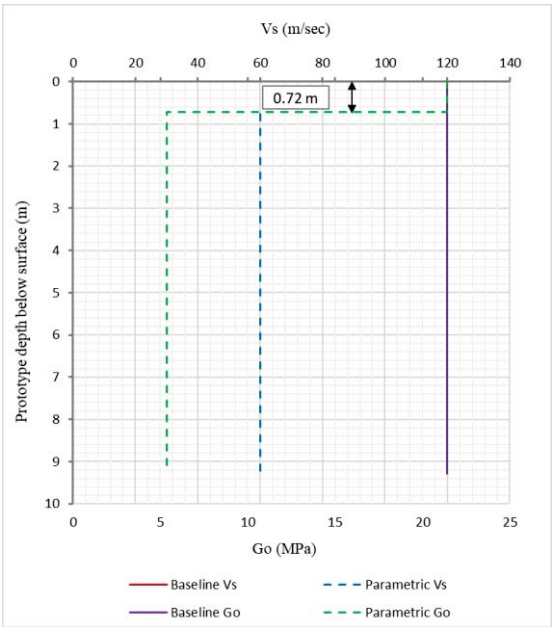

Figure 8: Comparison of shear wave velocity (and equivalent small-strain stiffness (G_o)) profile assumed for baseline and parametric FE analyses

In order to numerically assess the effect of having soft soil conditions at a shallow depth, the FE model was re-run with vertical acceleration at source (Figure 6) and with 'stiff soil over soft soil' shear wave velocity profile (Figure 8). Vertical acceleration time histories (Figure 9) at 60 mm and 90 mm (lateral distance) from the source were compared with the ones obtained with uniform shear wave velocity profile. In Figure 10, the peak amplitude of first arrival of vertical accelerations (prototype level) were plotted at an increasing distance (resultant of lateral distance from source and depth below soil surface) from the source for centrifuge test and numerical analysis with uniform and layered soil (stiffness) profiles. The preliminary results tend to suggest that a presence of soft soil layer at a shallow depth from the source of vibration can potentially amplify the vibration.

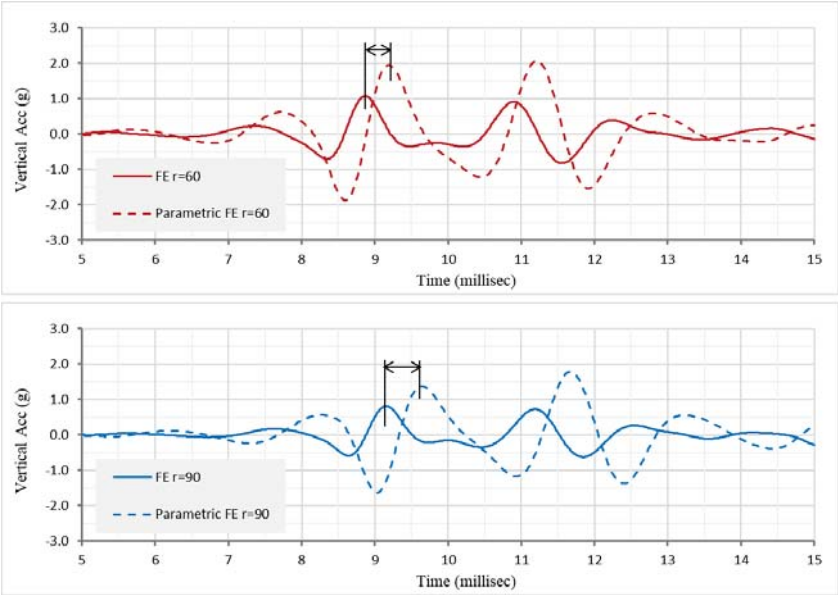

Figure 9: Comparison of vertical acceleration from numerical model for Uniform and Layered soil profile (Stiff soil over soft soil)

4 CONCLUSIONS

This paper forms part of an ongoing research into the generation and propagation of surface waves with the help of a series of centrifuge tests. In this paper, finite element analysis was used as tool to simulate ground-borne vibrations generated by a stationary point impulse load. Following conclusions are drawn from the preliminary results presented in this paper:

- Reliability of LS-DYNA as a numerical tool for modelling surface wave propagation was presented by validating the numerical response with analytical solutions. Infinite domain was represented in a finite domain model by modelling solid elements along outer boundaries with Perfectly Matched Layers (PML).
- Another 3D FE model was developed without the absorbing boundaries to simulate the physical conditions of the centrifuge model container. This model was validated with the results from centrifuge test.
- Parametric FE study was performed to investigate the potential effect of soft soil at a shallow depth from the source of vibration.
- The results from numerical analysis tend to suggest that the presence of soft soil at shallow depth can amplify the amplitude of vibrations in the stiff upper layer as compared to a homogenous soil layer with uniform soil stiffness.
- The attenuation of vertical accelerations at an increasing distance from source suggest that the effect of soft soil on the surface wave propagation tend to decay rapidly and could be a localised phenomenon. At sufficiently far away distance from the source, the attenuated accelerations levels are similar regardless of soil stiffness profile.
- It is likely that closer to the point of impact, plastic strains develop in soil which would lead to faster attenuation and lower amplitude of vertical acceleration in the centrifuge test results as compared to the numerical predictions obtained with an assumption of soil behaving as a linear elastic material. At a far away distance from the source, this behaviour would diminish and soil behaviour could be assumed as linear elastic.

5 ACKNOWLEDGEMNTS

The authors would like to thank colleagues and technical staff at the Schofield Center for their insightful opinions, time and support.

The first author would also like to acknowledge the Mott MacDonald Research Fund in supporting research at Cambridge University and Dr. Barnali Ghosh, Tony O'Brien and Imran Farooq for their guidance.

Keywords: Gap monitoring, ultrasonics, ferronickel, furnace.

Abstract. *Cerro Matoso SA (CMSA) is one of the world's major producers of ferronickel. As one of the companies leaders of this sector, CMSA is continuously changing and improving all its processes to ensure the business sustainability, one of these improvements is the refurbishment of one of its electric furnaces. This procedure will replace the current furnace sidewalls of one of its electric furnaces in order to process material of new compositions by applying new refractory brick lining. This procedure will require the shut down of the furnace which will generate a contraction of the bricks mainly in the hearth of the furnace. During the furnace startup, the behavior of the hearth will tend to recover its position in such a way that it will expand, for this reason it is planned to left a gap between the skew the hearth lining. Such gap is allowed for bricks to expand properly, however,it is important to highlight that this gap must be closed since the molten material can be filtered through such spaces causing catastrophic damage. Therefore, the need arises to establish a process for monitoring the growth of the hearth of the furnace. In this work, the ultrasound method was used for gap monitoring by detecting pressure exerted by the expansion of the bricks on the metallic shell. Measurements were made without pressure, with 300 and 600 psi to demonstrate the problem of closing the expansion gap. Results show that the developed methodology can detect when the gap is closed by using ultrasonic inspection and the use of two gap monitoring indicators.*

1 INTRODUCTION

To implement new technologies that allow Cerro Matoso SA (CMSA) to enhance its operational efficiency, a series of activities have been proposed that seek to optimize fundamental aspects in the production chain of ferronickel. As a smelting industry, CMSA is interested in monitoring the state of the refractory walls of its furnaces in search of more informed decision making in order to increase the furnace efficiency and prolonged campaign life. Due to the continuous operation, the refractory walls of the furnace show deterioration through its use, this is caused mainly by mechanical, thermal stress cracks and chemical attack resulting in loss of heat transfer capability, shrinkage and change of thermal conductivity of the refractories [6]. Due to the nature of smelting furnaces, it is nearly impossible to drill into the lining while the furnace is in operation and directly evaluate the refractory thickness and condition [5].Because of this limitation the industry demand non-destructive testing (NDT) methods for furnace refractory walls during operation. Some of the NDT techniques commercially available that have been used to measure the refractory wall thickness in furnaces are: Radioactive Tracers, Infrared (IR) Thermography, Electromagnetic (EM) / Microwave Techniques, Ultrasonic, Acousto Ultrasonic-Echo (AU-E), among others [6]. In the industry, there exists Furnace Integrity Monitoring System (FIMS) which are based on the utilization of Acoustic Emission (AE) signal detection, however, these systems are not available for refractory gap monitoring. Three case studies of FIMS using ultrasound sensors to monitor furnaces are described in the work of Sadri et al., in 2018 [7] . In all three cases, the Acousto Ultrasonic-Echo (AU-E) measurements in combination with other data such as thermocouple readings and surveying information, resulted in the extension of furnace campaign life by improving the accuracy and reliability of thermal furnace models. An acoustic emission-based furnace integrity monitoring system was developed by Gebsky and Sadri in 2012 [2], in this system, the capability of detecting emissions related to the fracture development in the furnace wall, movement of the refractory and electrode arcing is satisfactory accomplished. An Integrated Furnace Control system for shielded arc smelting of the 75 MW Cerro Matoso Line 2 Furnace is described in [4], it is aimed to detect the gap between the bricks of the furnace hearth when it shrinks and then expands. As a contribution to the need for a gap monitoring system, this work presents a furnace refractory gap monitoring methodology that uses data from the ultrasonic pulse echo technique and the current indicators for the detection of the presence of a gap in the refractory bricks. The remainder of this paper is organized as follows. The second section presents a theoretical background that briefly describes the most relevant concepts of the measurement technique used in the proposed methodology. Section 3 is devoted to present the gap measurement methodology and section 4 describes the data acquisition process. Then, section 5 shows the experimental results and their corresponding discussion. Finally, the last section outlines the main conclusions.

2 THEORETICAL BACKGROUND

In this section, some concepts about the methods used in the gap monitoring methodology are summarized, we recommend reviewing the bibliography for deepen understanding of the methods.

2.1 Ultrasonic inspection

Ultrasound is a non-destructive inspection technique that is used to measure different characteristics in materials. These include, for example, the measurement of thickness as an element of quality in manufacturing processes or as an element of continuous monitoring in processes

where changes in the structure can be a critical element to consider.

2.2 Signal to noise ratio SNR or S/N

Signal to noise ratio is a measure that allows comparing the level of the desired signal to the level of the background noise [3]. In general terms, it allows to know how well is the signal captured in relation to the noise in the acquisition.

2.3 Fast Fourier Transform (FFT)

Fourier Analysis is a kind of analysis very common in the analysis of signals, it allows to convert a signal from its original domain to another domain, for example to change from the time or space to the frequency domain. FFT is a kind of algorithm to apply Fourier Analysis and allows to compute the discrete Fourier transform of a sequence by decomposing a sequence into components of different frequencies.

3 GAP MONITORING METHODOLOGY

Gap Monitoring methodology considers the following elements, first, data acquisition, second, data pre-processing, third, index calculation and evaluation. For gap monitoring indicators, two measurements are considered as illustrated in figure 1 and figure 2 which results in two possible methodologies. The first approach considers the use of the signal to noise ratio (SNR) and the second approach calculates the FFT to extract the dc component.

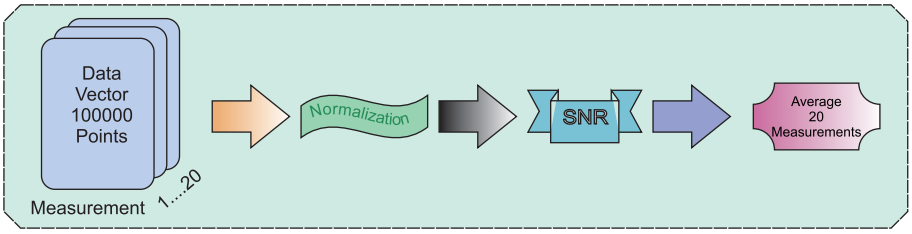

Figure 1: Methodology I - Signal to noise ratio

In both methodologies, pre-processing and normalization are considered in order to avoid data acquisition biases such as noise, coupling of the sensors, and others [1]. Measures from the experiment are averaged to facilitate comparisons and avoid biases before the application of the indicators and the final gap detection [8].

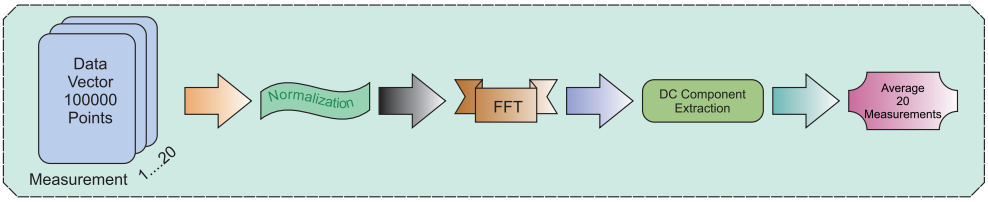

Figure 2: Methodology II - DC component extraction

4 EXPERIMENTAL SETUP

Since it is impossible to create a gap when the furnace is in operation, CMSA built a model to evaluate the methodology as in Figure 3. This model is in scale 1:1 and represents a small

section of the skew. As it is possible to observe there is an expansion paper between bricks and shell.
The experiment was designed so that samples were taken at different points of the external wall (iron shell), these samples were taken when the refractory bricks in the internal part had a gap (without pressure), then with 300 psi and finally, 600 psi. This pressure was applied to the skew by a hydraulic jack to emulate the pressure applied by the bricks to the shield once the gap is closed. For this experiment, three indicators of the acquired signal were proposed to observe measurement magnitude changes with respect to the applied pressure, the first magnitude is the signal to noise ratio, the second is to the power spectrum, and finally, the third is extracting the DC level of the acquired signal. The results indicated that there are two evaluations that could be taken into account to detect the pressure in the inner wall and these are, the calculation of signal to noise ratio and the extraction of the DC component. Both cases can differentiate when pressure is applied to the shield by the inner wall and hence determine the existence of a gap.

Figure 3: Experimental setup for gap evaluation

5 EXPERIMENTAL RESULTS

Excitation of the structure was performed by the use of pulses at a frequency of 55-kilohertz and 1000 volts of amplitude as it is shown in figure 4. The signal in the figure includes an attenuation 1:100. This excitation signal was applied by a commercial source with reference Humboldt C369NH/AH/0009. The receiving signal from the structure is captured by the ultrasonic sensor and it is digitized by using a tiepie HS04 oscilloscope. In each acquisition, clock and excitation signal are considered to determine the echo from the structure.

In this work, signals from six positions in the external shield are considered to evaluate the methodology, these positions are labeled as A3, A4, A5, A6, A7 and A8. The sensor location was defined at the same height as the first bricks that are in contact with the gap. For each position, 200 measurements were obtained, averaged, and compared with the others results to avoid the influence of noise.

5.1 Signal to noise ratio

Figure 5 shows the average results for each load condition (0, 300 and 600 psi) when the methodology applied was the signal to noise ratio.

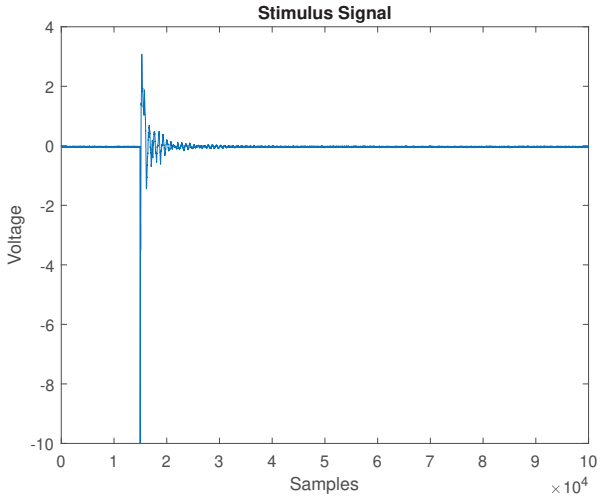

Figure 4: Stimulus Signal

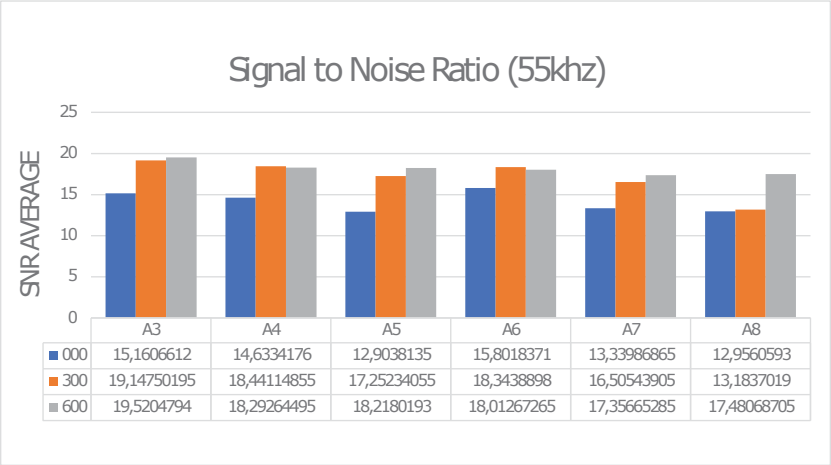

Figure 5: SNR Levels

In all cases, it is possible to evidence the influence of an existence of a gap in the signal to noise ratio, Figure 5 also shows that there are changes in the SNR in each pressure condition that were evaluated.

5.2 DC Levels

In the second analysis, spectral decomposition is used. The methodology includes the use of the FFT and the extraction of the first value to determine the presence of a gap in the configuration. Results of this process were averaged using 20 DC components, figures 6 and 7 shows the frequency decomposition for two points at the three different pressures.

As can it be seen in figure 8, the DC level of the measured signal decreases when pressure is applied by the intern wall. In the same way, as in the methodology with SNR, there are different values for each pressure condition.

(a) Position A8 - 0 psi (b) Position A8 - 300 psi (c) Position A8 - 600 psi

Figure 7: FFT Signals - position A8

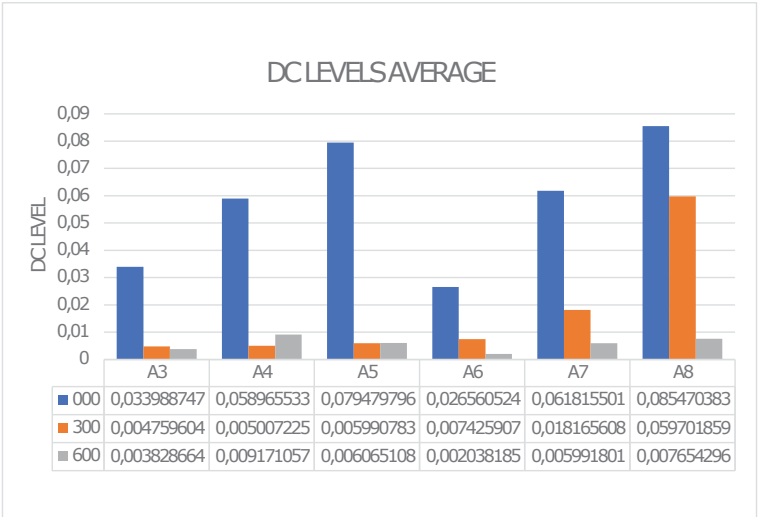

Figure 8: DC Levels

6 CONCLUSIONS

Results showed that two indicators could be taken into account for gap monitoring in a furnace with refractory bricks, these are, signal to noise ratio and the extraction of the DC components. These indicators present a difference when a gap exists and allow also to determine differences when there is a pressure from the skew to the external shield. This is an important result because by simple visual inspection it is not possible to determine variations in the wall because most of the signal is attenuated by the external shield which results in the presence of noise in the signal. For the results, the normalization of the measurements is an essential task since it prevents different factors in the signal acquisition (like sensor pressure, actuator pressure, coupling gel, surface imperfections, and others) to affect the data used by these methodologies.

The experiments were performed on a test-bed that does not consider the temperature. However, a task in the future is verifying the methodology's immunity to the temperature changes. It is expected that temperature can affect the measurements, however from previous experiences with this kind of signals, these changes are evidenced as an offset to all the measurements which can be removed by compensation techniques.

Although each methodology provide interesting results, one option that could be studied is to fuse both indicators in a single methodology to increase the reliability of the procedure for online monitoring applications.

Keywords: structural dynamics, random vibration, seismic analysis, stress assessment

Abstract. *Linear random vibration analysis aims to the probabilistic characterization of response functions; classical procedures are targeted to the time histories of output kinematic variables, such as displacement, velocity and acceleration, and to parameters which are linearly related to them, such as internal forces, deformations, stress components ecc. Much less attention has been devoted, by researcher and developers, to the case of response variables which are non-linearly dependent of the lagrangian coordinates or their derivatives; the most typical among these is the Von Mises equivalent stress, whose square value is quadratic in the components of the stress tensor, and thus in the lagrangian coordinates. The topic is of relevance especially for the structural safety of industrial equipment and systems, which is usually based on local stress integrity assessment.*

In the paper an innovative analytical procedure to deal with the probabilistic characterization of the VM stress is proposed as an extension of the classical approach adopted for linear output parameters. To this aim the matrix of the quadratic form delivering is decomposed into the sum of suitable factors; each of them deserves the same treatment as for linear parameters.

The various features related to the numerical implementation of the procedure for stationary or non-stationary (evolutionary) random excitation are discussed, with reference to both the application via direct frequency domain treatment and to the modal superposition approach; an example is finally shown and commented.

1 INTRODUCTION

Linear random vibration analysis is a powerful tool for the probabilistic characterization of the response of linearized systems to dynamic perturbative forces, both for the case of environmental interactions and for excitations of anthropic nature.

Aim of the analysis is usually the assessment of both the functionality under serviceability loads and the structural integrity under exceptional loads. The first is naturally checked in the linear range, in which no damage occurs. For the second, which should imply inelastic behavior and/or large deformations, elastic methods are nevertheless accepted in many situations. A typical example is represented by the integrity assessment of equipment components in industrial plants, which can be performed (see ASME B31.30) by means of elastic methods against complex damage phenomena, such as ratcheting, ….

Linear random vibration analysis aims to the probabilistic characterization of response functions; classical procedures are targeted to the time histories of output kinematic variables, such as displacement, velocity and acceleration, and to parameters which are linearly related to them, such as internal forces, deformations, stress components ecc. Much less attention has been devoted to the case of response variables which are non-linearly dependent of the lagrangian coordinates or their derivatives; the most typical among these is the Von Mises equivalent stress, whose square value is quadratic in the components of the stress tensor, and thus in the lagrangian coordinates. The topic is crucial for the structural safety of industrial equipment and systems, which is usually based on local stress integrity assessment.

The extreme-value distribution of the Von Mises (VM in the following) stress is addressed in [1] by estimating, through the Rice formula, the outcrossing rate of an ellipsoid by the stress component vector process; the derivation is performed for stationary gaussian random processes. In the same context, in [2] the estimation of the RMS value of the VM stress is pursued; classical approaches are here exploited such as modal analysis and frequency domain integration.

In this paper the approach proposed in [2] is cast into the more general framework of non-stationary (evolutionary) random processes. For the stationary case an innovative analytical procedure to deal with the probabilistic characterization of the VM stress is proposed as an extension of the classical approach adopted for linear output parameters. To this aim the matrix of the quadratic form delivering the equivalent stress is decomposed into the sum of suitable factors; each of them deserves the same treatment as for linear parameters. The various features related to the numerical implementation of the procedure for stationary or non-stationary (evolutionary) random excitation are discussed, with reference to both the application via direct frequency domain treatment and to the modal superposition approach; an example is finally shown and commented.

2 STRESS RESPONSE TO RANDOM DYNAMIC EXCITATION

The response of a linear *n* dof system is considered, governed by the following equations of motion

$$\mathbf{m}\ddot{\mathbf{q}}(t) + \mathbf{c}\dot{\mathbf{q}}(t) + \mathbf{k}\mathbf{q}(t) = \mathbf{F}\mathbf{g}(t) \tag{1}$$

where **m**, **c** and **k** are respectively the mass, damping and stiffness matrices, **F** is a matrix of load amplitude coefficients and **g***(t)* is the vector listing the functions that define the time variation of the loads.

Assuming non-stationary (evolutionary) random excitation, the time histories of the loads can be expressed (see Priestley [3]) according to the Fourier-Stieljes integral formulation

$$\mathbf{g}(t) = \int_{-\infty}^{\infty} \mathbf{\Psi}(t, f) \exp(i2\pi ft) d\mathbf{G}(f) \tag{2}$$

where $\mathbf{\Psi}(t, f)$ is a diagonal matrix listing deterministic, slowly varying envelope functions. $d\mathbf{G}(f)$ is an orthogonal process related to a zero-mean stationary process, having a Spectral Power Density (SPD) $\mathbf{S}_g(f)$, through the relation

$$E\left[d\mathbf{G}(f_1) d\mathbf{G}^*(f_2) \right] = \delta(f_1 - f_2) \mathbf{S}_g(f_1) \tag{3}$$

In such setting, the response of the system can be expressed, by integrating in the frequency domain, through the following expression

$$\mathbf{q}(t) = \int_{-\infty}^{\infty} \mathbf{\Gamma}(t, f) \exp(i2\pi ft) d\mathbf{G}(f) \tag{4}$$

The $\mathbf{\Gamma}(t, f)$ function appearing in (4) is in turn obtained via the time convolution

$$\mathbf{\Gamma}(t, f) = \int_{-\infty}^{\infty} \mathbf{h}(u) \mathbf{F} \mathbf{\Psi}(t-u, f) \exp(-2\pi fu) du \tag{5}$$

where $\mathbf{h}(u)$ is the matrix of the unit impulse response functions of the system.

If we now express a generic stress component as a linear combination of the configuration vector components we can write:

$$\sigma_{jk}(t) = \mathbf{z}^T \mathbf{q}(t) = \mathbf{z}^T \int_{-\infty}^{\infty} \mathbf{\Gamma}(t, f) \exp(i2\pi ft) d\mathbf{G}(f) \tag{6}$$

so that

$$\sigma_{jk}^2(t) = \mathbf{q}^T(t) \mathbf{z} \mathbf{z}^T \mathbf{q}(t) = \mathbf{z}^T \mathbf{q}(t) \mathbf{q}^T(t) \mathbf{z} \tag{7}$$

Note that, if modal analysis is performed, by expressing the configuration vector as a linear combination $\mathbf{q}(t) = \mathbf{\Phi} \mathbf{y}(t)$ of the system eigenvectors, we get the following

$$\sigma_{jk}^2(t) = \mathbf{q}^T(t) \mathbf{z} \mathbf{z}^T \mathbf{q}(t) = \mathbf{y}^T(t) \mathbf{u} \mathbf{u}^T \mathbf{y}(t) \tag{8}$$

where $\mathbf{u} = \mathbf{\Phi} \mathbf{z}$ and $\mathbf{y}(t)$ is the vector of modal coordinates.

If direct analysis is performed, i.e. without modal expansion, the mean square value of the stress component can thus be expressed, from (7), as

$$E\left[\sigma_{jk}^2(t) \right] = \mathbf{z}^T E\left[\mathbf{q}(t) \mathbf{q}^T(t) \right] \mathbf{z} = \mathbf{z}^T \mathbf{\mu}_q \mathbf{z} \tag{9}$$

i.e. as a function of the covariance matrix $\mathbf{\mu}_q$; taking expressions (3) to (5) into account the latter can be in turn obtained from the following derivation

$$\begin{aligned}
\mathbf{\mu}_q &= E\left[\mathbf{q}(f_1) \mathbf{q}^T(f_2) \right] = \\
&= \left[\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathbf{\Gamma}(t, f_1) E\left[d\mathbf{G}(f_1) d\mathbf{G}^*(f_2) \right] \mathbf{\Gamma}^*(t, f_2) \exp\left(i2\pi \left(f_1 - f_2 \right) t \right) \right] = \\
&= \left[\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathbf{\Gamma}(t, f_1) \mathbf{S}_g(f_1) \mathbf{\Gamma}^*(t, f_2) \delta(f_1 - f_2) \exp\left(i2\pi \left(f_1 - f_2 \right) t \right) df_1 df_2 \right] = \\
&= \int_{-\infty}^{\infty} \mathbf{\Gamma}(t, f) \mathbf{S}_g(f) \mathbf{\Gamma}^*(t, f) df
\end{aligned} \tag{10}$$

A time-varying (evolutionary) SPD is consistently defined as:

$$S_{\sigma_{jk}}(f,t) = \mathbf{z}^T \boldsymbol{\Gamma}(t,f)\mathbf{S}_g(f)\boldsymbol{\Gamma}^*(t,f)\mathbf{z} = \mathbf{z}^T \mathbf{S}_q(f,t)\mathbf{z} \tag{11}$$

For a stationary excitation we get the following:

$$\boldsymbol{\Psi}(f,t) = \mathbf{I} \quad ; \quad \boldsymbol{\Gamma}(f,t) = \mathbf{H}(f)\mathbf{F} \quad ; \quad S_{\sigma_{jk}}(f) = \mathbf{z}^T \mathbf{H}(f)\mathbf{F}\mathbf{S}_g(f)\mathbf{F}^T\mathbf{H}^*(f)\mathbf{z} \tag{12}$$

in which $\mathbf{H}(f)$ is the usual matrix of Frequency Response Functions, i.e. the inverse of the Mechanical Impedance matrix $\mathbf{E}(f)$, so that

$$\mathbf{H}(f) = \mathbf{E}^{-1}(f) = \left[-(2\pi f)^2 \mathbf{m} + (i2\pi f)\mathbf{c} + \mathbf{k} \right]^{-1} \tag{13}$$

3 THE ESTIMATION OF THE VON MISES EQUIVALENT STRESS

Starting from the stress tensor components the equivalent Von Mises stress can be expressed by the following quadratic form

$$\sigma_{VM}^2(t) = \boldsymbol{\sigma}^T(t)\mathbf{A}\boldsymbol{\sigma}(t) \tag{14}$$

where **A** is a 6*x*6 symmetric positive definite matrix, whose entries are given in the Appendix. By expressing the stress components as linear functions of the configuration we get

$$\sigma_{VM}^2(t) = \boldsymbol{\sigma}^T(t)\mathbf{A}\boldsymbol{\sigma}(t) = \mathbf{q}^T(t)\mathbf{Z}\mathbf{A}\mathbf{Z}^T\mathbf{q}(t) = \mathbf{q}^T(t)\mathbf{B}\mathbf{q}(t) \tag{15}$$

in which ***Z*** is a matrix of dimension $6xn_c$, being n_c the number of lagrangian coordinates affecting the computation of the stress tensor $\boldsymbol{\sigma}$.

Expressions (15), (4) and (5) formally solve the problem of the Von Mises stress evaluation. When the evaluation of the expected value of the squared VM stress is addressed, however, it can be easily verified that an approach similar to equations (8)-(10) is problematic. To overcome these problems, the matrix **B**, symmetric and positive definite, can be decomposed in terms of its eigenvectors, i.e.

$$\mathbf{B}\bar{\mathbf{R}} = \bar{\mathbf{R}}\boldsymbol{\Lambda} \quad \rightarrow \quad \mathbf{B} = \bar{\mathbf{R}}\boldsymbol{\Lambda}^{1/2}\boldsymbol{\Lambda}^{1/2}\bar{\mathbf{R}}^T = \mathbf{R}\mathbf{R}^T \tag{16}$$

$$\sigma_{VM}^2(t) = \mathbf{q}^T(t)\mathbf{R}\mathbf{R}^T\mathbf{y}(t) = \mathbf{q}^T(t)\left(\sum_{i=1}^{M} \mathbf{r}_i\mathbf{r}_i^T \right)\mathbf{q}(t) = \sum_{i=1}^{M} \mathbf{r}_i^T\mathbf{q}(t)\mathbf{q}^T(t)\mathbf{r}_i \tag{17}$$

It is worth noting that, having applied the eigenvector transformation, we have obtained in (17) an expression which is simply the sum of *M* terms having exactly the same form as obtained in (8) for the linear response parameter (generic stress component); one the expectation operator is applied, it can be now interchanged with the summation, leading to an expression which is the sum of terms sharing the same form as in (9), i.e.

$$E\left[\sigma_{VM}^2(t)\right] = E\left[\sum_{i=1}^{M} \mathbf{r}_i^T\mathbf{q}(t)\mathbf{q}^T(t)\mathbf{r}_i \right] = \sum_{i=1}^{m} \mathbf{r}_i^T E\left[\mathbf{q}(t)\mathbf{q}^T\right]\mathbf{r}_i = \sum_{i=1}^{m} \mathbf{r}_i^T\boldsymbol{\mu}_q\mathbf{r}_i \tag{18}$$

The efficiency of the proposed procedure deserves further comments when applied within the context of the modal superposition approach. In such setting, by expressing the configuration vector as a linear combination $\mathbf{q}(t) = \boldsymbol{\Phi}\mathbf{y}(t)$ of the system eigenvectors, we get the following alternative formulation

$$\begin{aligned} \sigma_{VM}^2(t) &= \boldsymbol{\sigma}^T(t)\mathbf{A}\boldsymbol{\sigma}(t) = \mathbf{q}^T(t)\mathbf{Z}\mathbf{A}\mathbf{Z}^T\mathbf{q}(t) = \mathbf{y}^T(t)\boldsymbol{\Phi}^T\mathbf{Z}\mathbf{A}\mathbf{Z}^T\boldsymbol{\Phi}\mathbf{y}(t) \\ &= \mathbf{y}^T(t)\boldsymbol{\beta}^T\mathbf{A}\boldsymbol{\beta}\mathbf{y}(t) = \mathbf{y}^T(t)\mathbf{D}\mathbf{y}(t) \end{aligned} \tag{19}$$

It can be observed, on practical grounds, that each row of the (*n*,6) $\mathbf{\Phi}^T\mathbf{Z}$ matrix lists the components of the stress tensor occurring when the corresponding modal shape is imposed to the system; these are often available through commercial software, so that the final matrix **D** can be assumed as available also for large and complex structural models.

Again, the eigenvalue decomposition of the matrix **D**, which is symmetric and positive definite, can be considered, leading to the following factorization:

$$\mathbf{D}\overline{\mathbf{S}} = \overline{\mathbf{S}}\mathbf{\Lambda} \quad \rightarrow \quad \mathbf{D} = \overline{\mathbf{S}}\mathbf{\Lambda}^{1/2}\mathbf{\Lambda}^{1/2}\overline{\mathbf{S}}^T = \mathbf{S}\mathbf{S}^T \tag{20}$$

Since **D**, from its definition (19), has maximum rank equal to six, the squared VM stress can be now expressed as a quadratic form in the normal coordinates given as the combination of six terms having the same form as in equation (8), i.e.

$$\begin{aligned}\sigma_{VM}^2(t) = \mathbf{y}^T(t)\mathbf{S}\mathbf{S}^T\mathbf{y}(t) = \mathbf{y}^T(t)\left(\sum_{i=1}^{M}\mathbf{s}_i\mathbf{s}_i^T\right)\mathbf{y}(t) = \sum_{i=1}^{M}\mathbf{y}^T(t)\mathbf{s}_i\mathbf{s}_i^T\mathbf{y}(t) = \\ = \sum_{i=1}^{M}\mathbf{s}_i^T\mathbf{y}(t)\mathbf{y}^T(t)\mathbf{s}_i\end{aligned} \tag{21}$$

The computation of (19) requires availability of the (*p*,*M*) matrix **S** (with $M \le 6$), which can be clearly much less expensive than the direct storage of **D,** the latter being implicit in the method proposed in [2].

The variance of the VM stress can thus be expressed in terms of the covariances $\sigma_{y_j y_k}$ among normal-mode response functions, i.e.

$$E\left[\sigma_{VM}^2(t)\right] = \sum_{i=1}^{M}\mathbf{s}_i^T E\left[\mathbf{y}(t)\mathbf{y}^T(t)\right]\mathbf{s}_i = \sum_{i=1}^{M}\sum_{j=1}^{p}\sum_{k=1}^{p} s_{i,j}\sigma_{y_j y_k} s_{i,k} \tag{22}$$

In the stationary case $\sigma_{y_j y_k}$ can be, in turn, expressed via the following frequency integral

$$\sigma_{y_j y_k} = \int_{-\infty}^{+\infty} S_{y_j y_k}(f)\,df = \mathbf{\varphi}_j^T\mathbf{F}\int_{-\infty}^{+\infty}\bar{H}_j(f)\bar{H}_k(f)\mathbf{S}_g(f)df\;\mathbf{F}^T\mathbf{\varphi}_k \tag{23}$$

In the integral (21) the modal Frequency Response Functions (FRFs) appear, defined as:

$$\bar{H}_j(f) = \frac{1}{\left(2\pi f_j\right)^2 M_j}\frac{1}{1-\dfrac{f^2}{f_j^2}+i2\xi_j\dfrac{f}{f_j}} = \frac{1}{\left(2\pi f_j\right)^2 M_j}\tilde{H}_j(f) \tag{24}$$

In (22) f_j, M_j and ξ_j are respectively the modal frequency, mass and damping ratio.

In the case of perfect correlation of input forces, typical of one-component seismic excitation, the input spectral matrix becomes a scalar SPD; in addition, in can be noted that:

$$\mathbf{\varphi}_j^T\mathbf{F} = -\mathbf{\varphi}_j^T\mathbf{m}\mathbf{r} = -\Gamma_j M_j \tag{25}$$

where **r** is a vector having non zero (unit) components along coordinates expressing displacement components parallel to the seismic input and Γ_j is the usual modal participation factor. Upon substitution of (24,25) into (23) we obtain the following:

$$\sigma_{y_j y_k} = \int_{-\infty}^{+\infty} S_{y_j y_k}(f)\,df = \frac{\Gamma_j\Gamma_k}{16\pi^4 f_j^2 f_k^2}\int_{-\infty}^{+\infty}\tilde{H}_j(f)\tilde{H}_k(f)S_{\ddot{u}}(f)df \tag{26}$$

in which the SPD of the free-field ground acceleration is now introduced in the integral.

It is worth noting that all the quantities appearing in equation (26) can be easily computed (the integral) or obtained by standard structural analysis software, as the participation factors and modal frequencies. Given that the matrix **D** can be obtained as well from the standard code, and its eigenvalues easily computed, the evaluation of the mean square VM stress is easily at hand.

Finally, the most general case in which 3D seismic excitation is applied in addition to static loading can be addressed upon simple superposition of effects, by stating:

$$\sigma_{VM}^2(t) = \left\{\boldsymbol{\sigma}^{(x)T}(t) + \boldsymbol{\sigma}^{(y)T}(t) + \boldsymbol{\sigma}^{(z)T}(t) + \boldsymbol{\sigma}^{(st)T}\right\} \mathbf{A} \left\{\boldsymbol{\sigma}^{(x)}(t) + \boldsymbol{\sigma}^{(y)}(t) + \boldsymbol{\sigma}^{(z)}(t) + \boldsymbol{\sigma}^{(st)}\right\} \tag{27}$$

By expressing the stress vector in terms of the normal response, applying again the eigenvalue decomposition to the matrix **D**, considering that the normal coordinates are zero-mean processes and taking the average of (27) it can be derived that the SRSS rule can be adopted for combining the static effect and the effect of the three components of excitation, provided that the latter are uncorrelated.

3 CASE STUDY

The preceding criteria have been applied, as a first test, to a problem obtained upon drastic simplification of a real life case; this was an equipment component located in a seismically isolated industrial building. Isolation was acting only in the horizontal plane; accordingly, the vertical excitation applied to the component is by far the most significant.

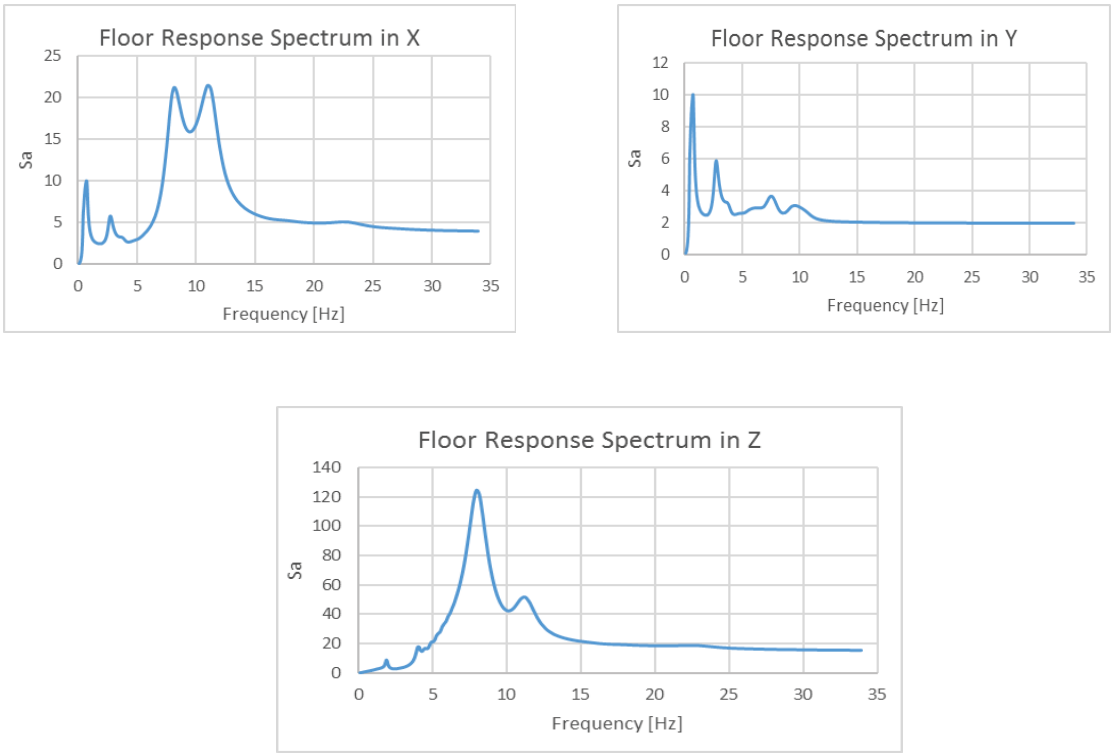

Figure1. Floor response spectrum in X, Y (horizontal) and Z (vertical) direction.

Figures 1 and 2 show the floor response spectra (FRS) applied to the system and a triplet of spectrum-compatible accelerograms obtained from the FRS; seven triplets were generated for the subsequent comparisons. In Table 1 the natural frequencies of the first ten normal modes of the model are given, spanning a range which is quite typical for a broad class of equipment components.

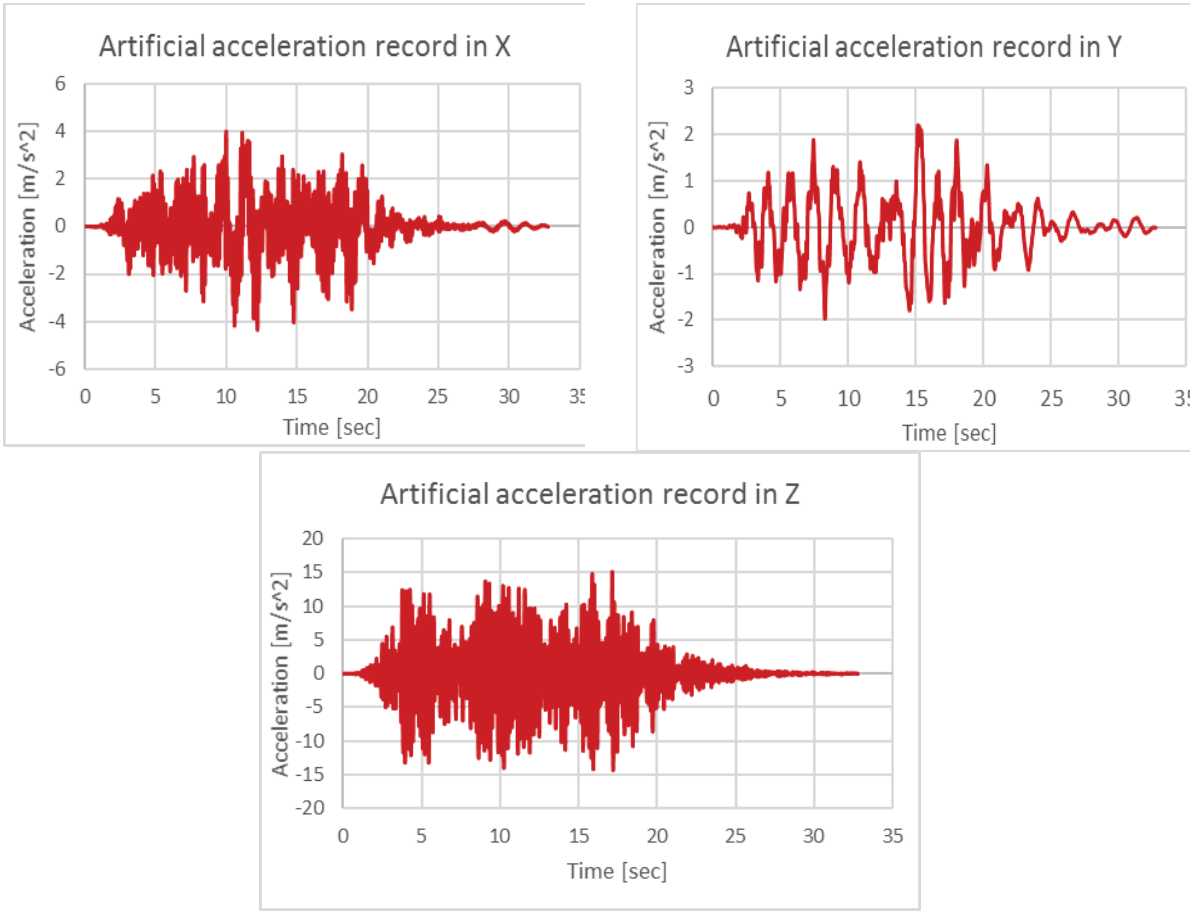

Figure 2. Artificial acceleration records in X, Y (horizontal) and Z (vertical) direction.

11.728	11.755	40.698	61.899	85.527
127.03	171.51	202.23	207.04	284.71

Table 1: Natural frequencies [Hz] of the example model.

The subsequent figure 3 shows the Finite Element mesh and the point where the stress assessment was performed. In these points the mean square Von Mises stress has been evaluated according to the following procedures:

- application of formulas (22) and (23),
- step-by-step time domain analysis, performed for the seven FRS compatible triplets of accelerograms; the mean square VM stress is obtained by simply averaging the values obtained in the seven cases,
- application of the ANSYS procedure based on [2].

In the following tables the result of the comparison is shown, suggesting the following general comments;

- the proposed method outcomes are generally in excellent agreement with the ones of the ANSYS procedure,
- both random vibration based procedures deliver slightly larger results when compared to step-by-step analysis, this being justified by the stationarity assumption.

4 CONCLUSIONS

A numerical procedure has been proposed in the paper for estimating the RMS value of the Von Mises equivalent stress within a random vibration analysis. The procedure is based on a transformation allowing the VM stress, which is a quadratic form in the coordinates, to be represented as the sum of linear output quantities; on this basis standard procedures targeted to the latter parameters can be exploited.

Some tests performed on a simple FE system are shown, in which the results obtained by means of the procedure are satisfactorily compared to the ones obtained by the method available in the software ANSYS and to the ones computed by a time-domain step-by-step procedure. The results here shown open the way to applications performed via more common design approaches, such as the response spectrum method.

Keywords: Seismic intensity parameters, Hilbert-Huang Transform (HHT), Hilbert Spectrum (HS), Park and Ang damage index, Multivariate statistics.

Abstract. *In this study, new proposed seismic intensity parameters based on Hilbert-Huang Transform (HHT) analysis are presented and associated with the seismic damage potential. The HHT is a procedure utilized to gain a better insight into complex seismic signals. Its use to the process of a seismic excitation leads to the evaluation of Hilbert Spectrum (HS). From the investigation of Hilbert Spectrum, derived from velocity-time histories, new frequency-related parameters are evaluated. A first application of the suggested new parameters reveals the interrelation between them and the structural damage of two reinforced concrete frame structures. The results are compared with the corresponding ones obtained from conventional seismic parameters with well-known seismic structural damage interrelation. Park-Ang global structural damage index ($DI_{PA,global}$) is used to describe the postseismic structural damage. Thus, a set of recorded seismic accelerograms from all over the word is applied on a seven-story reinforced concrete frame structure, and the values of $DI_{PA,global}$ index are evaluated through nonlinear dynamic analyses and considered subsequently as numerical reference values. Two statistical methods, namely correlation analysis, and multiple linear regression analysis, are applied to the set of conventional parameters and the set of new parameters separately to confirm their interrelation with the caused structural damage. The numerical results validate the significant ability of the proposed HHT-based new seismic intensity parameters to approximate the postseismic structural damage, which presented to be equal to this attained from the established parameters.*

1 INTRODUCTION

In earthquake engineering, a quick and accurate estimation of seismic hazard in both existing and planned structures remains a significant task for study. Knowing the level of the seismic hazard is indispensable for the determination of the planning process before, during, and after a severe seismic excitation. In general, the seismic intensity is a metric of the effect or the power of seismic damage potential. Thus, in the earthquake engineering and engineering seismology scientific literature, several seismic intensity parameters are presented and interrelated with the structural damage [1-9].

These parameters are evaluated by signal processing techniques meaningful mainly for stationary data and interrelated with the structural damage quantified by different damage indices. However, the seismic signals as the most signals in nature are nonlinear and non-stationary. In the last years a new, signal processing method, namely Hilbert-Huang Transform (HHT) analysis, has been developed [10-14] for that kind of signals. The HHT analysis is based on the local characteristic time scale of the data and, thus, considered as the most appropriate method for the processing of non-stationary and nonlinear signals like seismic accelerograms. In this research, the Hilbert Spectra derived from several worldwide natural earthquake records are investigated, and new seismic intensity parameters based on their features are proposed.

Subsequently, one first application of the proposed HHT-based seismic intensity parameters is presented and their interrelationship with the seismic structural damage, expressed by Park and Ang overall structural damage index [15, 16], is emerged. For the verification of this interdependence, two statistical methods, the correlation analysis, and the multiple linear regression analysis are utilized. The results are compared with the corresponding ones that occurred by several seismic parameters, already established in the scientific literature by their interrelation with the structural damage. The first statistical procedure reveals the interrelation between the new proposed seismic parameters and the structural damage. Whereas the second one proves that these parameters are able to accomplish the development of a rapid technique for the investigation of the seismic vulnerability of existing buildings.

2 HILBERT-HUANG TRANSFORM (HHT)

The HHT is a time-frequency analysis technique that offers higher frequency resolution and more accurate timing of transient and non-stationary signal events than other more common techniques for the analysis of nonlinear signals (e.g., Fourier transform, wavelet analysis) which assume that signals are stationary within the time window of observation. In contrary to the last analysis techniques, HHT is associated with adaptive bases that describe the most signals in nature [17-19].

The HHT presented first by Huang et al. [10] and can be separated into two parts: the empirical mode decomposition (EMD) and the Hilbert spectral analysis (HSA).

2.1 Empirical Mode Decomposition (EMD)

The EMD decomposes any complex signal data into non-sinusoidal oscillatory modes, and each of them represents an intrinsic mode function (IMF). The following conditions define the IMF:

1. In the whole signal, the number of extrema and zero-crossings must be either equal or differ at most by one, and

2. at any point, the mean value of the envelope defined by the local maxima and the envelope defined by the local minima must be zero.

The following procedure is performed, taking into account the above definition. For the seismic signal $X(t)$ in the study, all the local maxima are identified and connected by a cubic spline

to create the upper envelope $u_{max}(t)$ of the signal. An identical procedure is performed for the local minima and the lower envelope $u_{min}(t)$ of the signal is created. The two envelopes must enclose the whole signal between them. The mean value of the two envelopes assigned as m_1 is provided in Eq. (1).

$$m_1(t) = \frac{(u_{max}(t) - u_{min}(t))}{2} \tag{1}$$

Moreover, the difference between the seismic signal and the $m_1(t)$ is the first component

$$h_1(t) = X(t) - m_1(t) \tag{2}$$

By going on the procession, the signal is considered to be the first component $h_1(t)$ and then

$$h_{11}(t) = h_1(t) - m_{11}(t) \tag{3}$$

where $m_{11}(t)$ is the new mean of the two envelopes of $h_1(t)$. This process is repeated for k times and $h_{1k}(t)$ is provided by

$$h_{1k}(t) = h_{1(k-1)}(t) - m_{1k}(t) \tag{4}$$

The $h_{1k}(t) = c_1(t)$ consists of the first IMF of the signal in the study, and it should contain the shortest period of it. After that, the residue $r_1(t)$ is derived by subtracting the first IMF from the initial signal

$$r_1(t) = X(t) - c_1(t) \tag{5}$$

The residue $r_1(t)$ contains components of longer periods and then is considered as new signal. The new data are submitted to the same iteration mentioned above process until all the functions $r_j(t)$ are obtained

$$r_j(t) = r_{(j-1)}(t) - c_j(t),\ j = 2, 3, \dots, n \tag{6}$$

The sifting procedure stops when one of the two following criteria comes true:

1. The value of the component $c_n(t)$, or the value of the residue r_n(t), is less than a predetermined one.

2. The residue r_n(t) is a monotonic function with only one extreme or a constant, and therefore, no further IMFs can be extracted from it.

Finally, the initial seismic signal $X(t)$ is resulting from the summation of all IMFs and the residue r_n(t) as presented in Eq. (7).

$$X(t) = \sum_{J=1}^{n} c_j\,(t) + r_n\,(t) \tag{7}$$

2.2 Hilbert Spectral Analysis (HSA)

During HSA the Hilbert transform is applied to each intrinsic mode function (IMF), $c_j(t)$,

$$y_j(t) = \frac{1}{\pi}\ P \int_{-\infty}^{\infty} \frac{c_j(\tau)}{t-\tau}\ d\tau \tag{8}$$

where P denotes the Cauchy principal value of the integral. The IMF $c_j(t)$ and the Hilbert transform $y_j(t)$ form an analytical signal $z_j(t)$

$$z_j(t) = c_j(t) + iy_j(t) = a_j(t)e^{i\theta j(t)} \tag{9}$$

where $a_j(t)$ is the radius of the rotation of the analytical signal and $\theta_j(t)$ is the instantaneous phase function and are defined as

$$a_j(t) = \sqrt{c_j^2(t) + y_j^2(t)} \tag{10}$$

$$\theta_j(t) = arctan[\frac{y_{j(t)}}{c_j(t)}] \tag{11}$$

The instantaneous angular velocity of the rotation ω_j(t) is computed from the derivative of the phase function, and ω_j(t), the instantaneous frequency can be calculated as presented in Eq. (12).

$$\omega_j(t) = \frac{d\theta_j(t)}{dt} = 2\pi \cdot f_j(t) \rightarrow f_j(t) = \frac{\omega_j(t)}{2\pi} = \frac{d\theta_j(t)}{dt} \tag{12}$$

By using the above equations, the IMF components are designated as

$$c_j(t) = Re(a_j(t)e^{i\theta j(t)}) = a_j(t)cos\theta_j(t) \tag{13}$$

where Re() is the real part of the analytical signal $z_j(t)$. Therefore, the initial signal can be written as:

$$X(t) = Re\left[\sum_{j=1}^{n} a_j(t)cos(\int 2\pi \cdot f_j(t)dt\right] \tag{14}$$

The residue term r_n(t) of the initial signal X(t) in Eq. (7), has been left out in Eq. (14) because it is either a monotonic or a constant function. From the Eq. (14) is revealed that the amplitude and frequency are functions of time and can be presented in a three-dimensional plot forming the time-frequency distribution of the amplitude. This time-frequency representation of the amplitude is called the Hilbert Amplitude Spectrum, or simply Hilbert Spectrum (HS) (see Figure 1). Subsequently, the quantities of instantaneous amplitude and frequency refer to the three-dimensional Hilbert Spectrum and not to j-th intrinsic mode function (IMF) separately.

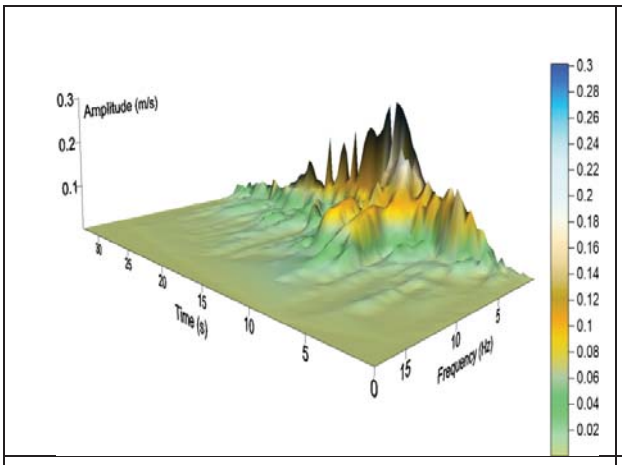

Figure 1. Hilbert Spectrum of seismic excitation.

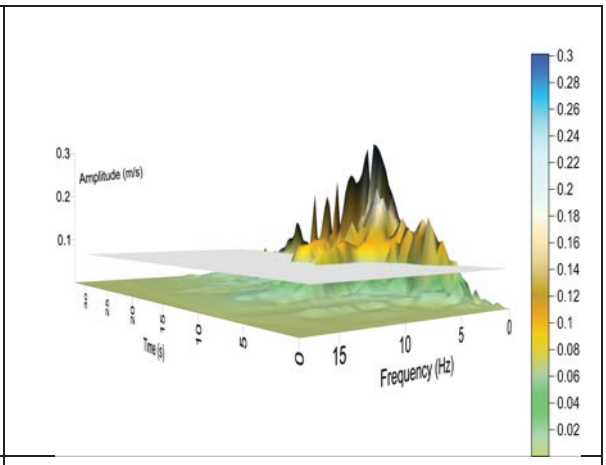

Figure 2. A layer crosses the amplitude-axis of Hilbert Spectrum vertically at $A_{(mean,HHT)}$.

3 NEW PROPOSED HHT-BASED SEISMIC INTENSITY PARAMETERS

In this study, HHA is applied to several seismic excitations, and the Hilbert Spectrum of the velocity-time history of every excitation is obtained. From the analysis and the processing of these Hilbert Spectra, new proposed seismic intensity parameters are resulting.

In particular, as aforementioned, every Hilbert spectrum, which presents the distribution of time-frequency-amplitude, leads to a time-frequency-energy (square of the amplitude) description of a signal. From the illustrated Hilbert spectrum plot, the volume of the confined space is

evaluated. The numerical value of the volume, limited from every produced Hilbert spectrum of seismic velocity, consists of an essential seismic feature because it reveals the amount of the released energy during the seismic excitation of the considered record. For this research, the specific volume is considered as a new seismic parameter, which is denoted as $V_{(HHT)}$ and is defined in Eq. (15),

$$V_{(HHT)} = \int_0^{f_{max}} \int_0^{t_{max}} a(f,t) \cdot df \cdot dt \tag{15}$$

where f_{max} is the maximum instantaneous frequency, t_{max} the total duration of the seismic signal, and $\alpha(f,t)$ denotes the instantaneous amplitude.

The area of the general surface $S_{(HHT)}$ provided by the Hilbert Spectrum, which is a function of two variables, HS(f,t) is defined in Eq. (16).

$$S_{(HHT)} = \int_0^{f_{max}} \int_0^{t_{max}} \sqrt{1 + \left(\frac{da(f,t)}{df}\right)^2 + \left(\frac{da(f,t)}{dt}\right)^2} \cdot df \cdot dt \tag{16}$$

The maximum, the mean value, and their difference of instantaneous amplitude $\alpha(f,t)$ that are obtained from the analytical signal are presented in Eq (17)-(19).

$$A_{(max,HHT)} = max(\alpha(f,t)) \tag{17}$$

$$A_{(mean,HHT)} = mean\big(\alpha(f,t)\big) \tag{18}$$

$$A_{(dif,HHT)} = A_{(max,HHT)} - A_{(mean,HHT)} \tag{19}$$

Moreover, the corresponding values of volume and area above the parallel to the time-frequency layer that intersects the amplitude-axis of Hilbert Spectrum at the value of $A_{(mean,HHT)}$ (see Figure 2), denoted as $V_{(Pos,HHT)}$ and $S_{(Pos,HHT)}$, are presented respectively in Eq. (20) and Eq. (21).

$$V_{(Pos,HHT)} = \int_0^{f_{max}} \int_0^{t_{max}} a(f,t) \cdot df \cdot dt \;\; , a \geq a_{mean} \tag{20}$$

$$S_{(Pos,HHT)} = \int_0^{f_{max}} \int_0^{t_{max}} \sqrt{1 + \left(\frac{da(f,t)}{df}\right)^2 + \left(\frac{da(f,t)}{dt}\right)^2} \cdot df \cdot dt \;\; , a \geq a_{mean} \tag{21}$$

In the end, the following quantities that come of the combination of the above parameters are evaluated, as described in Eq. (22)-(25).

$$VA_{(max,HHT)} = V_{(HHT)} \cdot A_{(max,HHT)} \tag{22}$$

$$VA_{(mean,HHT)} = V_{(HHT)} \cdot A_{(mean,HHT)} \tag{23}$$

$$VA_{(dif,HHT)} = V_{(HHT)} \cdot \big(A_{(max,HHT)} - A_{(mean,HHT)}\big) \tag{24}$$

$$A_{(Pos,HHT)} = \frac{V_{(Pos,HHT)}}{S_{(Pos,HHT)}} \tag{25}$$

The volume $V_{(HHT)}$ obtained from the Hilbert spectrum is increased while it is multiplied by the maximum and mean amplitude and their difference. The quantities, $VA_{(max,HHT)}$, $VA_{(mean,HHT)}$, $VA_{(dif,HHT)}$, are three new quantities that are representative of every seismic record since every one of them includes two or three characteristic features of each record. In the case where the difference between the mean and maximum amplitude is minimal, the quantity $VA_{(dif,HHT)}$ is statistically equivalent to one of the other two quantities.

Finally, the volume $V_{(Pos,HHT)}$ is divided by the $S_{(Pos,HHT)}$, and new parameter $A_{Pos,HHT}$ is obtained, which can be considered as the mean amplitude of the positive volume (volume above the $A_{(mean,HHT)}$-layer) of the Hilbert spectrum.

4 CONVENTIONAL SEISMIC INTENSITY PARAMETERS

Besides the HHT-based seismic parameters, several well-known and extensively surveyed parameters are also used in this study to validate the significance of the results referring to the estimated structural vulnerability by the new parameters. These already established seismic parameters are presented in Table 1.

Description	Symbol	Reference
Peak Ground Acceleration	PGA	(Meskouris, 2000) [20]

5 SEISMIC DAMAGE INDICES

Damage indices (DIs) are quantities that perform the damage status of a structure with a single numerical value that can be efficiently utilized in calculations for the vulnerability assessment of a structure and their correlation with the single-value of a seismic intensity parameter. In this study, the overall structural damage index of Park and Ang ($DI_{global,PA}$) is employed [15, 16].

Park and Ang damage index is an index defined as the ratio between the initial and the reduced resistance capacity of a structure during a seismic excitation evaluated by nonlinear dynamic analysis. The classification of the structural damage status, according to $DI_{PA,global}$ values are presented in the table below.

Structural damage index	Structural damage level			
	Low	Medium	Great	Total
$DI_{PA,global}$	≤ 0.3	$0.3 < DI_{PA,global} \leq 0.6$	$0.6 < DI_{PA,global} \leq 0.8$	$DI_{PA,global} > 0.80$

Table 2. Structural damage level (DL) classification according to $DI_{PA,global}$.

The structural damage located in the "Great" (G) level is non-repairable, and damage level characterized as "Total" (T) signifies the partial or complete collapse of the structure. Thus, it is essential to be known if the caused damage of an earthquake is located in the "Low" (L) or "Medium" (M) level which means that the structure is repairable or if the damage is characterized as "Great" or "Total" which means that the structure is not repairable.

6 SEISMIC EXCITATIONS

A total number of 80 natural seismic excitations derived from ground strong motions all over the world (Table 3) are employed, and the association of their destructive power with the caused damage on the constructions is achieved using the aforementioned seismic index [2-4]. The utilized earthquakes generate for statistical reasons, a broad spectrum of damage (Low, Medium, Great, and Total) as presented in Table 2. Table 4 and Table 5 provide the categorization per PGA range and Richter magnitude scale for the used excitations, respectively. Subsequently, all the seismic parameters described above are evaluated for every utilized seismic excitation, and the results are correlated with the structural damage.

Country	Number of seismic excitations
Albania	1

7 REINFORCED CONCRETE FRAME STRUCTURES

All the utilized accelerograms are applied to a seven-story reinforced concrete frame structure with a total height of 22 m. The examined structure is designed in agreement with the rules of the recent Eurocodes for structural concrete and aseismic structures, EC2 (2000) [34] and EC8 (2004) [35], and shown in Figure 3, where the dimensions are provided in meter and centimeter, respectively. The cross-section of the beams are T-shapes with 30 cm width, 20 cm plate thickness, 60 cm total beam height. The effective plate width is 1.15 m at the end-bays and 1.80 m at the middle-bay. The distance between frames in the three-dimensional structure has been chosen to be 6 m. The building has been considered as an "importance class II", "ductility class Medium," and "subsoil of type B".

Additionally, to the dead weight and the seismic loading, snow, wind, and live loads have been taken into account. The fundamental period of the frame is 0.95 s. After the design procedure of the reinforced concrete frame structure, a nonlinear dynamic analysis has been occurred using the software computer program IDARC2D [36] for the evaluation of the structural seismic response for every seismic excitation utilized in the present study. The hysteretic behavior of beams and columns has been specified at both ends of each one using a three-parameter Park model.

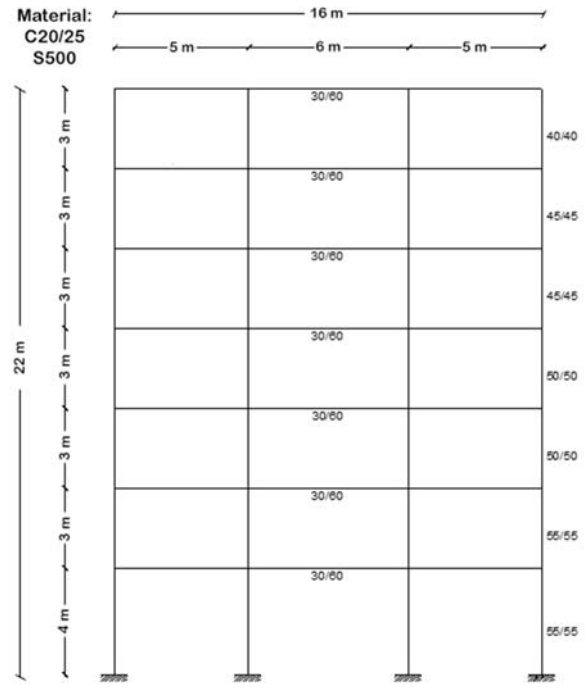

Figure 3a: Seven-story reinforced concrete frame.

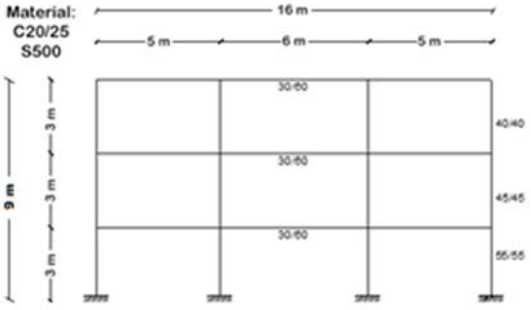

Figure 3b: Three-story reinforced concrete frame.

This model incorporates stiffness degradation, strength deterioration, non-symmetric response, slip-lock, and a trilinear monotonic envelope. The parameter values, which specify the above degrading parameters, have been chosen from experimental results of cyclic force-deformation characteristics of typical components of studied structure [16, 37]. Thus, the nominal parameters for stiffness degradation and strength deterioration have been chosen. In contrast, no pinching has been taken into account. From the derived response parameters of the nonlinear dynamic analysis, this study is concentrated on the overall structural damage index of Park and Ang ($DI_{PA,global}$). Figures 4a and 4b present the $DI_{PA,global}$ index per number of employed excitations, for each examined reinforced concrete frame.

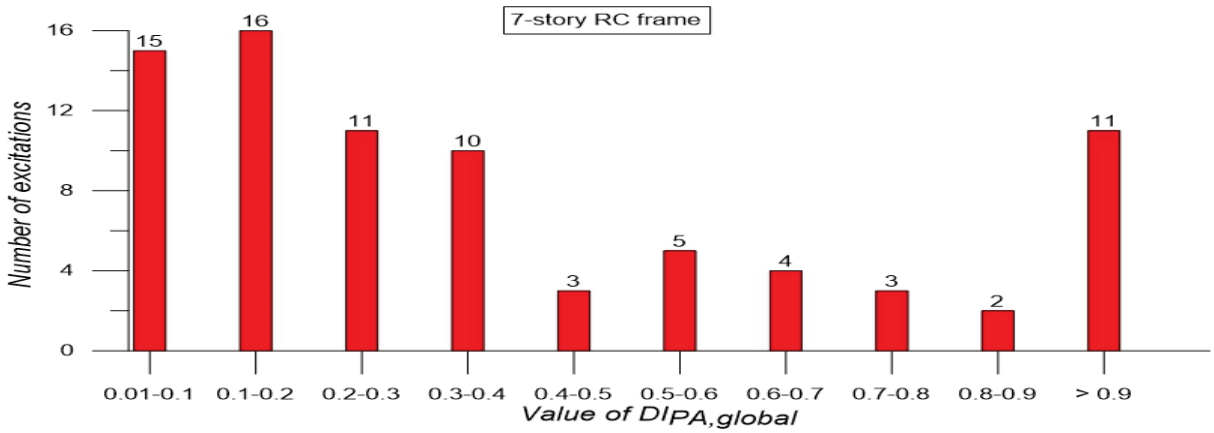

Figure 4a: Number of employed excitations per $DI_{PA,global}$ range for the seven-story frame.

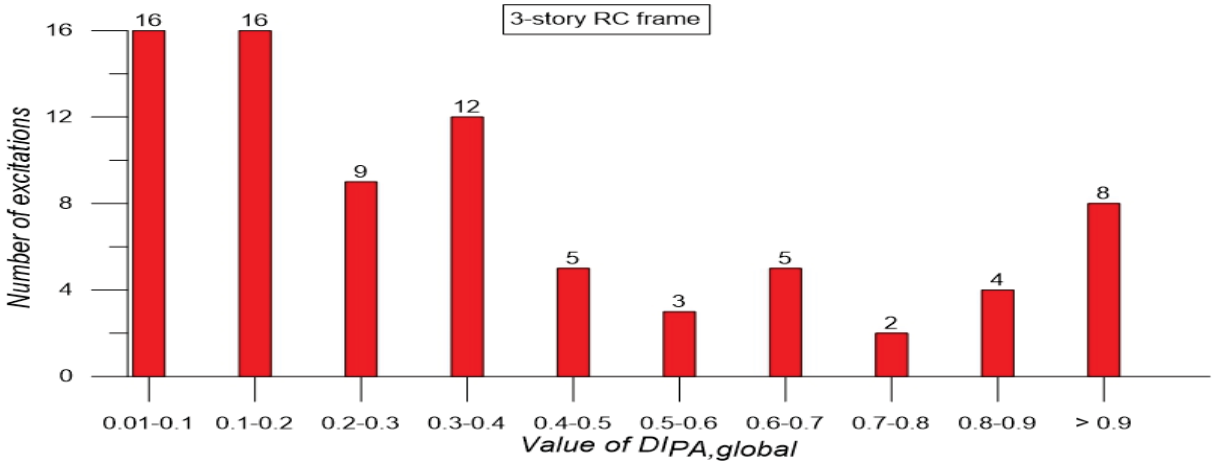

Figure 4b: Number of employed excitations per $DI_{PA,global}$ range for the three-story frame.

Also, the second concrete frame construction with three stories is used to strengthen the reliability of the results that occurred by the new proposed seismic parameters. The three-story reinforced concrete frame structure has a total height of 9 m and presents a similar layout of columns and beams to these of the seven-story RC frame, as shown in Figure 3b. After the application of the same set of seismic excitations to the second concrete frame, a nonlinear dynamic analysis using the software computer program IDARC2D [36] has been also occurred, and the new values of $DI_{PA,global}$ have been evaluated.

8 NUMERICAL RESULTS OF SEISMIC PARAMETERS EVALUATION

Applying the HHT technique to the seismic velocity time-histories of all the examined earthquakes, the instantaneous frequencies and amplitudes as functions of time are calculated using a code of the program MATLAB [38]. From the instantaneous values, time-frequency distributions of amplitude are formed, and thus, the Hilbert Spectrum for every seismic velocity signal is plotted. From the derived Hilbert Spectra, the new parameters for every seismic record are evaluated, and their statistical values are presented in Table 6. In addition, all the conventional seismic intensity parameters are evaluated, and their statistical values are presented in Table 7.

9 INTERDEPENDENCE BETWEEN SEISMIC PARAMETERS AND $DI_{PA,global}$

The dependence of every seismic parameter with the employed damage index (DI) is examined by occurring correlation analysis between them. Correlation analysis reveals if a systematic change in one variable implies a systematic change in the other. Thus, the dependence between the two variables is established, and the occurrence of the one affects the probability of occurrence of the other. For identifying the correlation between every seismic parameter and damage index separately, Pearson r and Spearman ρ correlation coefficients are used. A value of ± 1 for a correlation coefficient indicates a perfect degree of association between the two variables of every examined pair (seismic parameter, damage index), while this relationship becomes weaker when the correlation coefficient value approximates zero. A correlation coefficient above the value 0.5 indicates a low correlation; a coefficient in the range [0.5-0.8] indicates a medium correlation, while a coefficient, higher than 0.8, indicates a strong correlation. The correlation coefficients are calculated by the program STATGRAPHICS Centurion [39].

The Pearson r correlation coefficient measures the degree of linearity between two related variables and is described by the following equation

$$r = \frac{N\sum xy - \sum(x)(y)}{\sqrt{[N\sum x^2 - \sum(x^2)][N\sum y^2 - \sum(y^2)]}} \tag{26}$$

where N is the number of observations, $\sum xy$ is the sum of the products of paired scores, $\sum x$ is the sum of x scores, $\sum y$ is the sum of y scores, $\sum x^2$ presents the sum of squared x scores, and $\sum y^2$ presents the sum of squared y scores.

The Spearman ρ rank correlation coefficient measures the degree of monotone ranking between two related variables and is defined from the following equation.

$$\rho = 1 - \frac{6\sum d_i^2}{n(n^2-1)} \tag{27}$$

Where ρ is Spearman rank correlation, d_i is the difference between the ranks of corresponding variables, and n is the number of observations. The correlation coefficients are presented in Tables 8 and 9.

10 MULTIVARIATE REGRESSION ANALYSIS (MRA)

Multiple Regression Analysis (MRA) allows the assessment of the relationship between one dependent variable (DV) and several independent variables (IVs). Regression techniques can be applied to a data set in which the IVs are correlated with one another and with the DV to varying degrees [39].

The IVs are combined to predict a value of DV for each subject according to the following equation form, and the result of the regression represents the best prediction of a DV from several continuous (or dichotomous) IVs.

$$Y' = A + B_1X_1 + B_2X_2 + \ldots + B_kX_k \tag{28}$$

Y' is the predicted value on the DV, A is the Y-intercept (the value of Y when all the X values are zero), the X_i represents the various IVs (of which there are k), and the B_i (i=1, …, k) are the coefficients assigned to each of the IVs during regression. Although the same intercept and coefficients are used to predict the values on the DV for all cases in the sample, a different Y'value is predicted for each subject as a result of inserting the subject's X values into the equation. The goal of regression is to arrive at the set of B values, called "regression coefficients", for the IVs that bring the Y' values predicted from the equation as close as possible to the Y values obtained by measurement.

In this research, the damage index $DI_{PA,global}$ is used as a dependent variable (DV), and two sets of parameters are used as independent variables (IVs). The first set contains the conventional seismic parameters and the second the HHT-based parameters. A general goal of regression is to identify the fewest IVs necessary to predict the DV, where each IV predicts a substantial and independent segment of variability in the DV. The reduction of the explanatory variables from the initial regression model (with all the conventional or HHT-based parameters as IVs) is accomplished in the present study by a stepwise elimination procedure combined with

an appropriate elimination criterion. Thus, a successive elimination of the IVs is realized with a p-value greater than or equal to 0.05 as long as the Mean Absolute Error (MAE) is getting reduced. The p-value for each term tests the null hypothesis that the coefficient of the variable in the model is equal to zero (no effect). A low p-value (< 0.05) indicates that the null hypothesis is rejected. When a predictor has a low p-value, it constitutes a significant addition to our model because changes in the predictor's value are related to changes in the dependent variable. The elimination method leads to the selection of IVs, which may not present the highest correlation with the DV, but they present the highest power effect (F-ratio) and low collinearity with the other selected IVs, providing so, a more significant model. In the end, the best model considered is the one with the fewest significant IVs, the smallest SEE and MAE, the highest R^2 and adjusted R^2 and with the highest power (F-ratio). The F-ratio indicates how well the model fits the data and tests the null hypothesis when it is compared with F critical values obtained from given F-Tables [39].

The R^2 is a value percent, which indicates that the model as fitted explains the percentage equal to this value of the variability in the DV equation. Adjusted R^2 will always be less than or equal to R^2, and it balances the R^2 value by the number of data points and independent variables in the model. The adjusted R^2 statistic is more suitable for comparing models with different numbers of independent variables. The adjusted R^2 and the adjusted R^2 are getting decreased, adding a useless independent variable in the model.

For the construction of the best regression models, the multiple regression analysis is applied to a subset of seventy seismic excitations, while the other ten excitations are used to test the effectiveness of the constructed models. All the above calculations are also realized by the software program STATGRAPHICS Centurion XVII [39]. The best-attained regression models for the damage index in the study as DV and for each set of IVs separately are presented below.

Models 1 and 2 are the best fitted statistical models, with and without constant term, respectively, to the set of the conventional parameters as IVs and $DI_{PA,global}$ of the seven-story concrete frame as DV. The constructed models are presented in Eqs. (29)-(30).

$$DI_{PA,global} = 0.192123 - 0.170151 \cdot PGA/PGV - 0.0127411 \cdot I_{Arias} - 0.552931 \cdot SV + 1.70315 \cdot SI_K + 0.92999 \cdot EPA \quad (29)$$

$$DI_{PA,global} = -0.0862897 \cdot PGA/PGV - .0146593 \cdot I_{Arias} - 0.582707 \cdot SV + 1.96585 \cdot SI_K + 0.946831 \cdot EPA \quad (30)$$

Investigating the HHT-based parameters was observed that $A_{(max,HHT)}$ and $A_{(dif,HHT)}$ parameters as well $VA_{(max,HHT)}$ and $VA_{(dif,HHT)}$ presented perfect correlation (equal to 1.0) for the excitations in study because of the very small values of $A_{(mean,HHT)}$ parameter. Thus, the parameters $A_{(dif,HHT)}$ and $VA_{(max,HHT)}$ decided to be removed, and the first investigated models were Models (3)-(4) (Eqs 31-32), which consisted of nine HHT-based parameters with and without constant respectively. From Tables (12)-(13) it is obvious that in Models (3)-(4) there are parameters with P-value > 0.05 and for this reason, a reduction of them has occurred until Models (5)-(6) (Eqs 33-34) with five parameters were obtained.

In the end, the best results were attained by removing the parameter $S_{(HHT0)}$, which P-value was 0.0458 close to 0.05. Hence, Models (7)-(8) are the best models with and without constant term obtained from the regression analyses for the set of HHT-based parameters as IVs and the examined damage index for the seven-story structure as DV, using the training sample of the seventy seismic excitations. These models are presented in Eqs (35)-(36).

$$DI_{PA,global} = 0.0181109 + 0.0000436157 \cdot S_{(HHT)} + 0.102817 \cdot V_{(HHT)} - 0.0923962 \cdot V_{(Pos,HHT)} - 0.00181203 \cdot S_{(Pos,HHT)} + 0.637458 \cdot A_{(max,HHT)} - 6.94883 \cdot A_{(mean,HHT)} + 6.79734 \cdot A_{(Pos,HHT)} + 0.163871 \cdot VA_{(mean,HHT)} - 0.0434509 \cdot VA_{(dif,HHT)} \quad (31)$$

$$DI_{PA,global} = 0.0000484984 \cdot S_{(HHT)} + 0.105145 \cdot V_{(HHT)} - 0.0938841 \cdot V_{(Pos,HHT)} - 0.00179545 \cdot S_{(Pos,HHT)} + 0.628084 \cdot A_{(max,HHT)} - 6.83837 \cdot A_{(mean,HHT)} + 6.90182 \cdot A_{(Pos,HHT)} + 0.156813 \cdot VA_{(mean,HHT)} - 0.0433545 \cdot VA_{(dif,HHT)} \quad (32)$$

$$DI_{PA,global} = 0.0179463 + 0.0000631707 \cdot S_{(HHT)} + 0.0678431 \cdot V_{(HHT)} - 0.00196269 \cdot S_{(Pos,HHT)} + 6.79454 \cdot A_{(Pos,HHT)} - 0.0190404 \cdot VA_{(dif,HHT)} \quad (33)$$

$$DI_{PA,global} = 0.000068291 \cdot S_{(HHT)} + 0.0694873 \cdot V_{(HHT)} - 0.00195125 \cdot S_{(Pos,HHT)} + 6.91811 \cdot A_{(Pos,HHT)} - 0.0195237 \cdot VA_{(dif,HHT)} \quad (34)$$

$$DI_{PA,global} = 0.0629837 + 0.064319 \cdot V_{(HHT)} - 0.00129891 \cdot S_{(Pos,HHT)} - 0.0176613 \cdot VA_{(dif,HHT)} + 6.51428 \cdot A_{(Pos,HHT)} \quad (35)$$

$$DI_{PA,global} = 0.0703044 \cdot V_{(HHT)} - 0.00101145 \cdot S_{(Pos,HHT)} - 0.0192978 \cdot VA_{(dif,HHT)} + 6.9586 \cdot A_{(Pos,HHT)} \quad (36)$$

The results of the mentioned models that describe the relationship between the damage index and the conventional parameters are presented in Tables (10)-(11), while the corresponding results that refer to the new proposed parameters are presented in Tables (12)-(17). Tables (18)-(19) present the results of the corresponding variance analyses.

Table 19: Analysis of variance for other investigated models.

In Tables (10)-(13), the results present the 95% confidence intervals for the coefficients in the multilinear models and the estimated standard errors. Each variable coefficient in a model is interpreted as the mean change in the dependent variable based on a one-unit change in the corresponding independent variable keeping all other variables fixed.

Finally, the best models, Models (1)-(2) for the conventional seismic parameters and Models (7)-(8) for the HHT-based parameters were selected and compared. According to these, the detected critical F-value is ranging from 3.76 to 4.14. Thus, observing the calculated F-values in Table 14 (the smallest calculated value is F=58.19) and comparing them with the critical ones, the null hypothesis is rejected, and the increased power of every model is resulting. In Table 14 observing the standard deviation of the residuals (SEE) and the average value of the residuals (MAE) are presented to be smaller in models 3 and 4 which refer to the set of new proposed parameters while the corresponding values of R^2 (or Adjusted R^2) presented to be higher for the last models. Thus, according to the statistical indices models, 3 and 4 accomplish a more extensive and accurate explanation of the $DI_{PA,global}$ than models 1 and 2. These results also become apparent in the figures below.

The scatterplots in Figures (5)-(6) illustrate the results of evaluated $DI_{PA,global}$ using the non-linear dynamic analysis against the estimated values of $DI_{PA,global}$ using the MRA while figures 7-8 present the Standard Errors of Estimation for every $DI_{PA,global}$ estimated by MRA for the two sets of seismic intensity parameters,

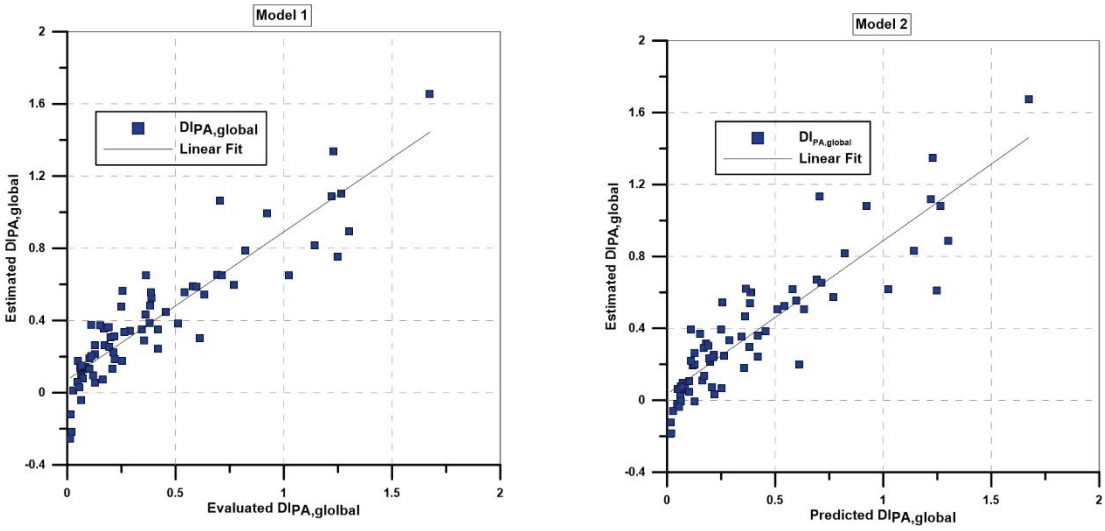

Figure 5: Evaluated vs. predicted $DI_{PA,global}$ resulting from conventional parameters.

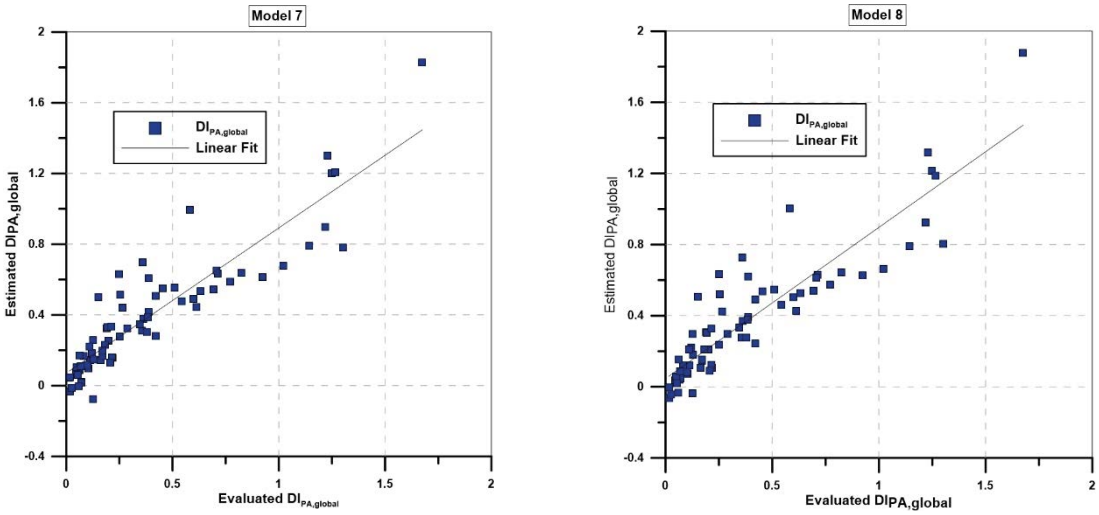

Figure 6: Evaluated vs. predicted $DI_{PA,global}$ resulting from HHT-based parameters.

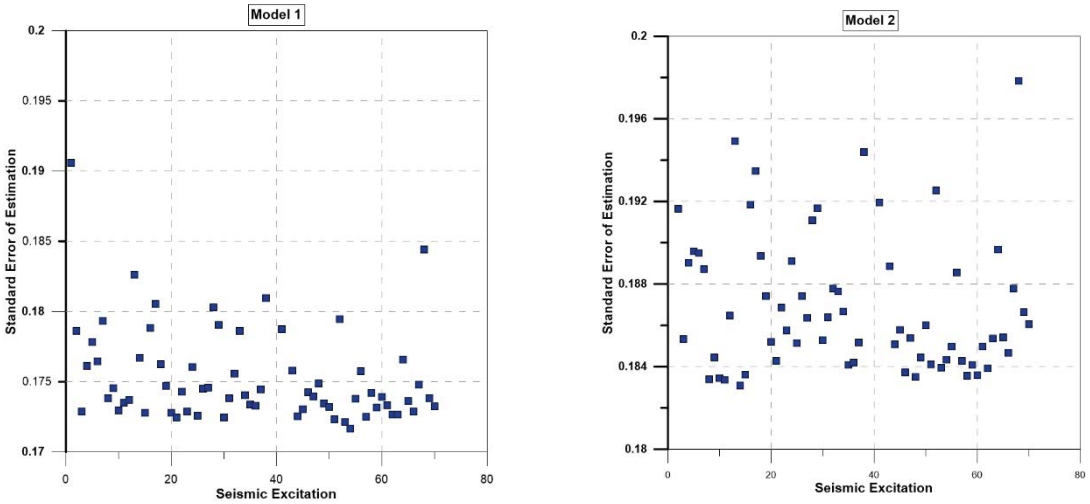

Figure 7: Standard Errors of Estimations for models using conventional parameters.

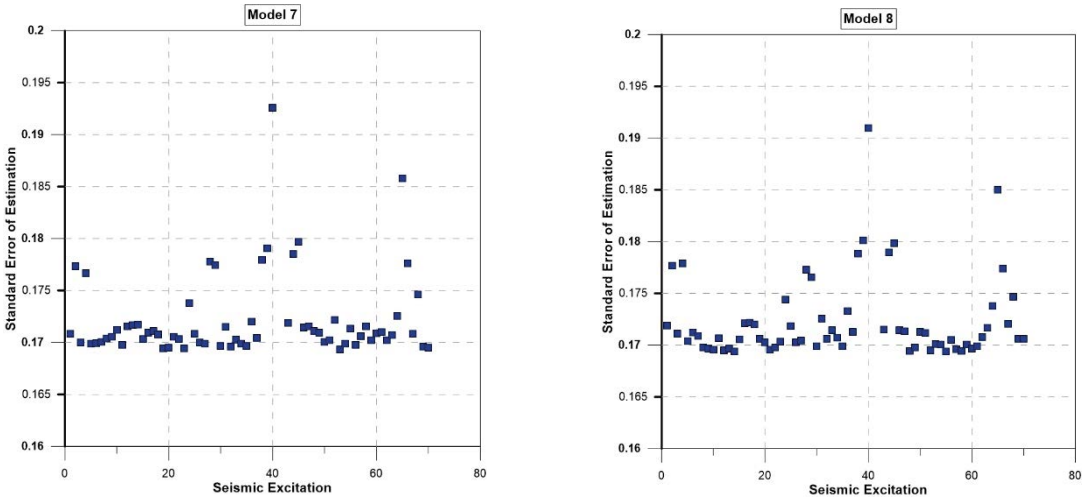

Figure 8: Standard Errors of Estimations for models using HHT-based parameters.

After the comparison between the new HHT-based parameters and twenty well-established parameters for the determination of their effectiveness to the estimation of postseismic damage of a seven-story structure, a new comparison has occurred. Two more regression models, Model 9 and 10, have been constructed using the new HHT-based parameters as IVs and $DI_{PA,global}$ obtained from the second frame as DV, after the application of the same set of seismic excitations. Hence, Models 9 and 10 are the best fitted statistical models, with and without constant term, respectively, to the set of the HHT-based parameters as IVs and $DI_{PA,global}$ of the three-story concrete frame as DV.

$$DI_{PA,global} = -0.0130677 + 1.4473 \cdot A_{(max,HHT)} - 10.0006 \cdot A_{(mean,HHT)} + 1.83459 \cdot VA_{(mean)} + 4.89072 \cdot A_{(Pos,HHT)} \quad (37)$$

$$DI_{PA,global} = 1.4233 \cdot A_{(max,HHT)} - 10.2049 \cdot A_{(mean,HHT)} + 1.85385 \cdot VA_{(mean,HHT)} + 4.88059 \cdot A_{(Pos,HHT)} \quad (38)$$

	Model 9	Model 10
Total Df	69	70
Model Df	4	4
Residual Df	65	66
R^2 (%)	82.1478	90.3628
R^2-Adjusted (%)	81.0492	89.9247
F-Ratio	74.78	154.71
SEE	0.1843	0.1831
MAE	0.1208	0.1189

Table 20: Analysis of variance for Models 9-10.

From Table 20 becomes obvious that the results of the second frame are similar to these obtained from the first one (Models 7-8). Thus, it can be concluded that the utilization of HHT-based parameters for the estimation of seismic damage of the three-story frame is so efficient as for damage estimation of the seven-story frame. Consequently, the presented HHT-based parameters used for the determination of seismic vulnerability to be equally effective to tall and short buildings.

11 PREDICTION OF $DI_{PA,global}$ USING THE CONSTRUCTED MODELS

As aforementioned, a set of ten seismic excitations is utilized to test the effectivity of the constructed statistical models. Thus, every one of the best-derived models for the seven-story concrete frame is applied to the set of ten earthquake excitations independent of the set of seventy earthquakes used for the regression analysis. From the new seismic excitations, the two sets of parameters are evaluated, and after their application to the equations of the best models, the values of $DI_{PA,global}$ are predicted using STATGRAPHICS Centurion XVII program. The results of the predicted values and their classification, according to the damage levels (DL) described in Table 2, are presented below. Specifically, in Table 21, the evaluated by nonlinear dynamic analysis damage index and its classification for these seismic excitations are displayed as opposed to the predicted ones from the constructed regression models.

Seismic Excitations	Evaluated Values	DL	Model 1		Model 2		Model 3		Model 4	
			Fitted Values	DL	Fitted Values	DL	Fitted Values	DL	Fitted Values	DL
Friuli	0.541	M	0.452	M	0.363	M	0.470	M	0.453	M

Amberley New Zealand	0.895	T	0.597	M	0.617	G	0.707	G	0.787	G
Amberley New Zealand	1.424	T	1.252	T	1.315	T	0.907	T	0.954	T

Table 21: Predicted values of $DI_{PA,global}$ oppose to evaluated ones.

The observation of the results reveals that a very significant approximation of the damage level is achieved. From the predicted values of $DI_{PA,global}$ the damages are not correctly classified for only one earthquake for both sets of parameters.

12 CONCLUSIONS

Hilbert Huang Transform is a time-frequency analysis technique that offers more detailed and accurate frequency resolution as a function of time considered to be an improved procedure for non-stationary and nonlinear signal events as the seismic excitations. Several numbers of natural seismic signals are analyzed utilizing HHT analysis, and their Hilbert Spectra are derived. Physical and geometric features from these spectra are connected with seismic features, and new HHT-based seismic intensity parameters are conducted.

The new proposed seismic parameters are evaluated for all the velocity-time histories of the seismic excitations in the study, and an application of them is presented, revealing a strong interrelation with the structural damage caused by an earthquake excitation. Park and Ang overall structural damage index $DI_{PA,global}$, evaluated by nonlinear dynamic analysis, is used to express the earthquake damage of a seven-story and a three-story reinforced concrete structure in the study. The powerful interdependence between the new seismic parameters and the utilized damage index is validated by two statistical procedures the correlation analysis and the multiple linear regression analysis. The correlation analysis interrelates the evaluated $DI_{PA,global}$ with the investigated parameters, while the multilinear regression analysis is utilized to prove that these parameters can attain a significant estimation of the postseismic structural damage. This ability is also tested by the application of a set of new seismic signals to the best statistical models obtained from the multiple regression analysis in order to be predicted the caused damage level of the structure.

The obtained results from the statistical procedures for the set of the new proposed parameters are compared with the corresponding ones extracted from a set of established parameters, and their effectiveness presented to be of the same significance with the last ones.

Finally, according to all the above results, the ability of the new HHT-based seismic parameters to assess the seismic vulnerability of a structure with high approximation accuracy is certified. Consequently, the proposed set of the seismic intensity parameters based on Hilbert-Huang Transform can be considered one more powerful tool for the scientific community in order to early postseismic damage in structures to be accomplished and crucial decisions before and after an earthquake to be made.

Keywords: typhoon risk assessment; typhoon risk prioritization; Cultural Heritage; climate change.

Abstract. *Cultural Heritage (CH) assets are especially vulnerable to natural hazards (e.g., earthquake-induced ground shaking, typhoon-induced strong wind, and flooding) due to the lack of hazard-resistant features and to aging-induced extensive structural degradation. These considerations, together with their high historical/cultural value, justify the prioritization/implementation of disaster risk reduction (DRR) and resilience-enhancing strategies for the preservation of such assets.*

This paper proposes a probabilistic, simulation-based framework for the derivation of wind fragility relationships for CH roofs. Roof-panel pullout and pullover failure modes are used to model the progressive failure of the roof system, thus enabling the integration of fastener corrosion effects and load redistribution into the proposed fragility model. Monte-Carlo sampling is used to propagate the uncertainties related to wind-induced demands and roof component (i.e., fasteners and panels) capacities. Climate projections are used to assess the impact of climate change on wind hazard variations, and ultimately on the asset wind risk profile over time.

An illustrative application of the proposed procedure is presented with reference to 25 heritage buildings in Iloilo City, Philippines.

1 INTRODUCTION

The 2019 Pacific typhoon season was the costliest ever recorded. It was an above-average year with a total of 17 typhoons recorded in the Philippine Area of Responsibility (PAR, the northwestern Pacific area where the Philippines' national meteorological agency, PAGASA, monitors weather occurrences). The costliest event was the typhoon Kammuri (locally known as Tisoy), which caused PHP 5.9 billion (USD 116 million) of damage to crops and agriculture [1]. In addition, more than 68,000 houses, schools, and other structures were reported destroyed and at least 463,000 were also damaged, including several cultural heritage (CH) assets. Various studies available in the scientific literature discuss how climate change is going to affect the frequency and intensity of future tropical cyclones in the Philippines [2, 3], with a shift towards stronger storms with an estimated intensity increases of 2-11% by 2100, as well as changes in their paths [4, 5]. This, in turn, will lead to an increase in typhoon-induced economic losses [6].

Typhoon-related economic losses in the Philippines are not just due to the adverse environmental conditions. Rapid population growth along the coast together with highly-vulnerable structures/infrastructure contribute to intensify the typhoon-risk of Filipino buildings [7]. Particularly vulnerable in this sense are CH asset roofs (i.e., wood frame and light-weight metal sheet, LWMS) because of the general lack of any hazard-resistant design considerations, presence of non-engineered structures/detailing, and material/structural degradation due to aging. In particular, non-engineered CH roofs have been recognized as the most vulnerable component in the building envelope due to typhoon-induced wind uplift. In addition, CH assets have a fundamental role for local communities. They contribute to creating citizens' sense of place, which is key to form a community's identity, and to promoting local, sustainable jobs related to cultural tourism – a priority sector in several developing countries.

The Filipino government, as well as other stakeholders, are promoting disaster risk reduction (DRR) strategies to improve the resilience of the country and its built environment. This requires a deep understanding of the risk associated to the built environment as well as its variation over time due to degradation/aging and potential effect of climate change. Several methods for typhoon risk assessment/prioritization at building specific and portfolio level, respectively, are available in the scientific literature (e.g., [8, 9]). Those adopted for building-specific risk assessment usually rely on refined numerical models and require specific data (e.g., roof geometry, number/location of purlins/fasteners, material properties) to be performed/collected. They allow an analyst to model material degradation as well as uncertainties in the definition of both structural capacity and wind-induced demands but with a high computational cost [10]. However, the required information is hardly available when CH assets located in developing countries are analysed. High population density, the adaptive reuse of CH assets for private/commercial activities, and diffused material degradation/lack of any maintenance plan all act as disruptive factors during data collection. On the other hand, scoring-based risk prioritization methods are commonly adopted at portfolio level (i.e., for the assessment of a large number of structures in a given region of interest) [11, 12]. These approaches require only few data about the assets under investigation, but they do not properly consider the variation of the risk during the time due to climate change and material degradation.

A simplified probabilistic, simulation-based framework for the calculation of typhoon risk for CH asset roofs in the Philippines is herein proposed to address the above-mentioned gaps. The proposed approach can be used both for risk prioritization at portfolio level and for preliminary risk assessment at building specific level. In fact, by considering a simplified geometry of the roof, the proposed method allows corrosion of fasteners and LWMS as well as fastener

failure progression to be explicitly modelled with relatively low computational cost and requiring only few basic data about the structure.

The proposed procedure is tested in this study on 25 CH assets in Iloilo city, Philippines, which is an important heritage hub for tourism in the Philippines. It is one of the most highly urbanized cities of the south-eastern tip of Panay island in the Philippines [13] and also capital city of the province. Fine examples of historic luxury buildings constructed in the first half of the 20th century during the American colonization can be found in the historic street Calle Real [14].

2 FILIPINO CULTURAL HERITAGE ASSETS

The procedure proposed in this study has been developed within the *Cultural Heritage Resilience & Sustainability to multiple Hazards* (CHeRiSH) project [7], funded by the UK Newton Fund. This project aims to develop a multi-level risk and resilience assessment framework for CH assets in the Philippines exposed to multiple natural hazards.

The definition of CH assets is usually based on both tangible (e.g., architectural/ historical value) and intangible (e.g., socio-cultural factors) criteria [15]. However, the Filipino law considers only the building year of construction as the main criterion for the eligibility of a structure as CH asset [16]. Structures which are at least fifty years old can be declared to be a "Heritage House", so that fairly recent reinforced concrete (RC) frame-type structures and unreinforced masonry (URM) buildings are often part of the Filipino CH portfolio.

The twenty-five CH assets analysed in this study (Figure 1) have been surveyed during a field trip in Iloilo City, Philippines, in July 2019 by a research group composed of members from the University College London (UCL, United Kingdom), the De La Salle University (DLSU, Philippines) and Central Philippines University (CPU, Philippines) [7].

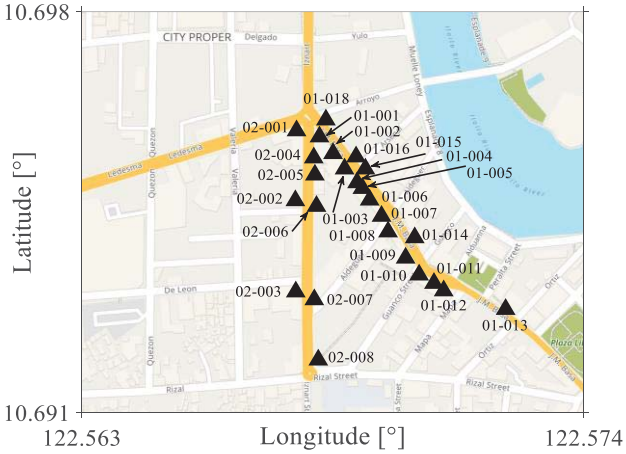

Figure 1: Surveyed CH buildings in Iloilo city, Philippines.

The surveyed CH portfolio is composed of 24 RC structures and one URM building date back to the first half of the 20th century. Most of them are two-story, plan-regular buildings and part of construction blocks with different shapes (e.g., triangular, rectangular) and compositions (i.e., a block can be the result of building aggregation during the time, or not).

Nineteen CH roofs out of twenty-five are made of timber frames with LWMS and metal fasteners (i.e., screws or nails). This represents the most common and vulnerable Filipino CH roof typology, and then it is the focus of the present study. Post-event surveys in the Philippines highlight that most economic losses in high-wind hazard areas are due to the breach of the building envelope [17]. This includes roof panel uplift, roof-to-wall connection failure and roof system damage, among others. Once the roof is damaged or even collapsed, walls lose lateral

supports and the global stability of the construction is heavily compromised. The local capacity of fasteners and LWMS clearly play a fundamental role in the determination of the global capacity of the roof. Corrosion phenomena, which can affect the strength of both fasteners and LWMS, must then be considered in the typhoon-risk quantification both at building specific and portfolio level. As shown in Figure 2, most of the surveyed CH roofs were characterised by diffused and heterogeneous corrosion levels [7].

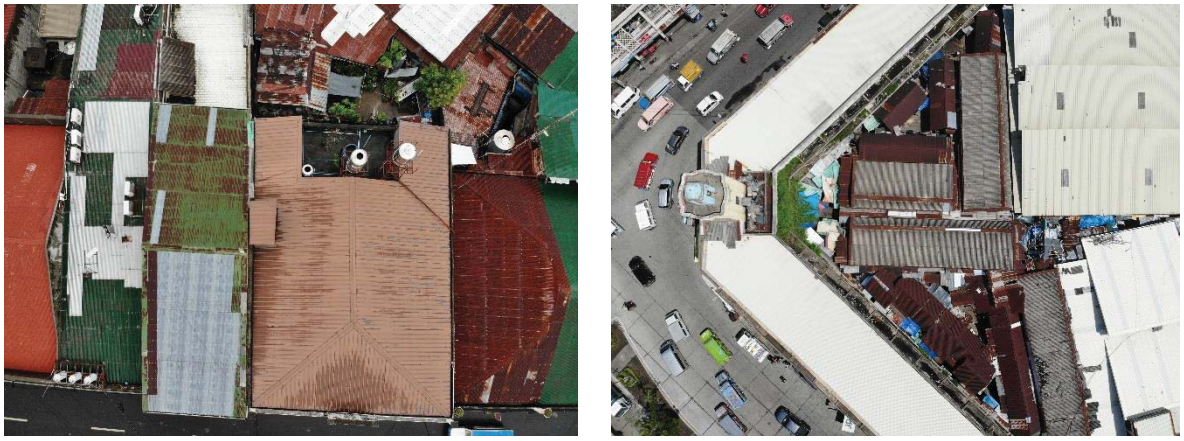

Figure 2: Two samples of Filipino CH roofs.

3 TYPHOON RISK ASSESSMENT FOR FILIPINO CULTURAL HERITAGE ASSET ROOFS AND CLIMATE CHANGE IMPACT

3.1 Typhoon risk assessment framework

In this study, Performance-Based Wind Engineering (PBWE) [18] is used as the conceptual framework to define the typhoon risk of CH asset roofs. In the context of PBWE, the performance of a structure/structural component is assessed through the probabilistic description of a set of decision variables, DVs [19]. Each DV is a quantitative proxy for the specific structural performance/damage in terms of metrics of interest for various stakeholders and/or the society in general, e.g., repair cost, downtime, and people affected (casualties/injuries). Once an intensity measure, IM (stochastically describing the hazard intensity at a site of interest), a relevant engineering demand parameter, EDP (synthetically expressing the structural response to wind loads), and a damage-measure parameter, DM (quantifying the structural damage due to wind load in relation to the considered performances and EDP) are defined, risk can be computed as the mean annual frequency (MAF) (or annual probability) of exceeding a specified value in terms of a relevant DV,

$$\lambda[DV] = \int\int\int G[DV|DM]\, dG[DM|EDP]\, dG[EDP|IM]\, |d\lambda[IM]| \,. \qquad (1)$$

In the previous equation $\lambda[\cdot]$ is the mean annual rate of exceedance, while $G[\cdot]$ indicates the complementary cumulative probability distribution function (CCDF) [19].

In this study, the 3-sec gust speed (v) at 10 m height in open terrain [20] is used as IM while the ratio between damaged LWMS and their total number R_{damage} is used as DM. In this way, the term $dG[DM|IM]$ in Equation 1 can be directly derived (as discussed in the following), rather than using $dG[DM|EDP]\, dG[EDP|IM]$.

Damage-to-loss (or consequence) models [21], which describe the relationship between DM and DV, are then needed to derive $G[DV|DM]$. Since no damage-to-loss models are specifically available for Filipino buildings, those developed by the Federal Emergency Management

Agency (FEMA, 2014) [22] in terms of direct repair cost for residential buildings in the USA are used in this study. This assumption is somehow justified by the fact that the prescriptions included in the Filipino building codes [19] are fully consistent with the recommendations of US building codes [7], across the years. Moreover, the damage-to-loss curves reported in Figure 3 are defined in terms of percentage of building replacement value rather than in absolute terms. Hence, even if this specific aspect will require more investigation in future studies, it still allows one to illustrate/test the validity of the proposed procedure and to obtain loss results for relative comparisons/risk prioritization exercises for the selected case-study portfolio.

The damage-to-loss curves adopted in this study consider direct repair costs associated to roof covering, roof framing and content. It is worth noting that the damage-to-loss curves presented in this section represents the expected loss L given R_{damage}, that is $\mathbb{E}[L|R_{\text{damage}}]$.

Details of the proposed fragility analysis framework and the approach to model climate change impact on wind hazard are presented in the next two sections.

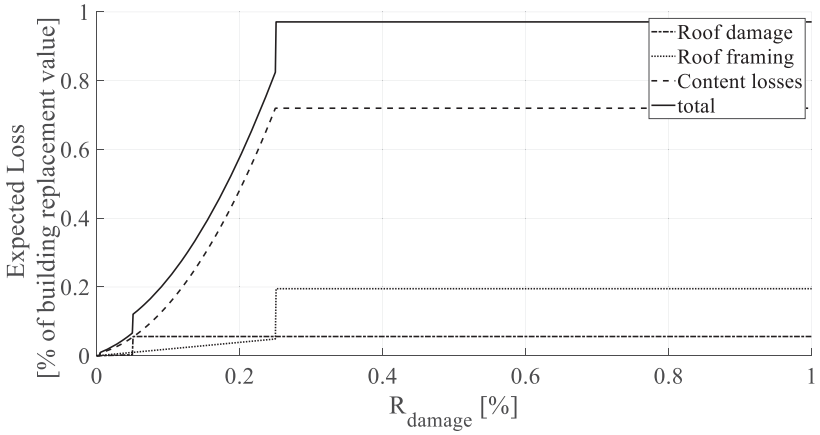

Figure 3: Damage-to-loss curves adopted in this study.

3.2 Impact of climate change on wind hazard

One of the specific objectives of this study is to investigate climate change impact on the typhoon risk assessment outputs for Filipino CH roofs. Climate change is leading to a rise in the temperature of the world's oceans. As their surface temperature increases, oceans provide more energy to convert into tropical cyclones [23]. This is the thermodynamic phenomenon due to climate change that will cause the globally averaged intensity of tropical cyclones to shift towards stronger storms, from being a category 3 (severe tropical storm) to a category 4 (typhoon) by the end of the 21st century. Not only the intensity of tropical storm is going to be affected by climate change, but also their frequencies, paths and velocities [5].

These variations of the environmental conditions may affect the wind hazard of the country and ultimately the wind risk profile of building roofs. The Type I (Gumbel) distribution is typically adopted in the scientific literature (e.g., Garciano et al., 2005 [24]), and in structural codes (e.g., the National Structural Code of the Philippines, NSCP, 2015 [20]) to model probabilistically the 3-sec gust speed (v) at 10 m height in open terrain. Climate change effects can be incorporated in the hazard model by modifying the cumulative distribution function (CDF) of the 3-sec gust speed, $\mathrm{F}_v(v,t)$, through a function $\gamma_{\text{mean}}(t)$ expressing the time-dependent percentage change in the considered gust wind speed [10],

$$\mathrm{F}_v(v,t) = \exp\left(-\exp\left(-\left(\frac{\frac{v}{1+\frac{\gamma_{\mathrm{mean}}(t)}{100}}-v_g}{\sigma_g}\right)\right)\right). \quad (2)$$

In the previous equation, v_g and σ_g are the location and scale parameters of the CDF, respectively. In Iloilo City, where the case-study buildings considered in this paper are located, these parameters can be assumed as $v_g = 25.21$ m/s and $\sigma_g = 5.75$ m/s [24]. Recent studies assume a time-dependent linear change in wind speed $(\gamma_{\mathrm{mean}}(t))$ and discuss how the use of different functions does not really affect the the wind risk profile [10, 23]. The projected changes in wind speed over the next 50 years is assumed equal to 4%; this climate scenario is in agreement to the studies available in the scientific literature for similar geographical locations [25].

4 PROPOSED FRAGILITY MODEL

4.1 Overview

The fragility model proposed in this study is based on a simplified geometry of the roof, which is divided into N_{ms} LWMS, each of which is supported by a constant number of purlins (N_p) and connected through a constant number of fasteners (N_f). LWMS are also assumed not interacting with each other, thus allowing the parallelization of the procedure and a further reduction of the computational burden. Only a few information about the roof are thus needed to perform the fragility analysis, namely: number of LWMS, number of purlins, number of fasteners, distance between purlins (d_p), fastener typology/geometry, LWMS typology/geometry and dead load (D). Once the roof geometry is defined, the limit state function for a given damage state, $g(R,Q)$ (i.e., R is the component capacity, while Q is the wind-induced demand), is derived at fastener level in order to facilitate the integration of failure progression and degradation into the fragility model.

Specifically, when the number of fasteners failing under a given load condition reaches a specific threshold, treated as random variable as well, the LWMS is assumed to fail. Only refined numerical models can properly consider all the factors affecting such a threshold value, such as wind direction, location of the failed fasteners and wind pressure distribution. However, in this study a triangular probability distribution bounded by 10% and 80% (the average is 33.3%) is adopted for the definition of the threshold, as proposed in [27]. Once the safety of each LWMS is checked, R_{damage} is calculated as ratio of failed LWMS over N_{ms}. This procedure is repeated varying the wind speed v needed for the definition of Q.

Monte Carlo sampling is used to propagate the considered uncertainties. Once a wind-speed value v is selected, the uplift loads W are randomly generated for each fastener of each LWMS. For the same elements, pullout and pullover capacities are randomly generated as well (as discussed in the following). A corrosion model is implemented to reduce the resisting sections of fasteners and LWMS over time, thus reducing the capacity R. The starting degradation level is treated as random variable to consider the heterogeneity of the 'health' state of different metal sheets as observed during the field trip.

4.2 Wind load

Assuming that LWMS, purlins and fasteners can be considered as components and claddings (C&C), the uplift wind load W (N/m^2) is defined according to the American Society of Civil Engineers (ASCE 7-10, 2010) [28] and NSCP (2015) [19], that is

$$W = q_h\left(GC_p - GC_{pi}\right). \tag{3}$$

In the previous equation, q_h (N/m^2) is the velocity pressure evaluated at the mean roof height of h; G is the gust factor; C_p (NSCP 2015 Figures 207E.4-2A to 207E.4-7) is the external pressure coefficient; and C_{pi} (NSCP 2015 Table 207A.11-1) is the internal pressure coefficient. In both codes, q_h is evaluated as:

$$q_h = 0.613\, K_h\, K_{zt}\, K_d\, v^2, \tag{4}$$

where K_h (NSCP 2015 Table 207E.3-1) is an exposure factor accounting for the terrain exposure condition; K_{zt} is a topography factor; and K_d (NSCP 2015 Table 207A.6-1) is a wind directionality factor accounting for the reduced probability of unfavourable building orientation and wind direction.

In this study, the parameter needed for the definition of the wind load W are treated as random variables in order to properly account for the uncertainties (Tables 1 and 2).

Table 1: Statistical model of the wind load parameters.

Parameters	Category	Mean	Coefficient of Variations (CoV)	Statistical model	Reference
GC_p		see Table 2		Normal	
GC_{pi}	Partially enclosed	0.46	0.33	Normal	Ellingwood and Tekie, 1999 [29]
K_h	Exposure B (0 – 9.1 m)	0.71	0.19	Normal	
K_d		0.89	0.16	Normal	
K_{zt}		Deterministic (= 1)			

Table 2: Statistics of the gust pressure coefficient GC_p.

Metal sheet panel position		Mean	Coefficient of Variations (CoV)	Reference
(Wind from all directions) 	a	−1.768	0.12	Lee and Rosowsky, 2005 [30]
	b	−1.455	0.12	
	c	−1.425	0.12	
	d	−0.855	0.12	

4.3 Dead and total loads

The value of the dead load D needed for the calculation of the demand Q depends on the weights of roof panel material and the roof system. This load counteracts the effect of wind uplift, thus contributing to stabilize the roof and increase its resistance. In this study, the dead load is modelled as a deterministic value equal to 0.2 kN/m^2 and assumed to remain constant in time (added weight due to re-roofing, if any, is not considered here).

4.4 Uplift resistance

The uplift failure of the system fastener-LWMS is governed by two main mechanisms: pullout and pullover failure modes. The resistance R mainly depends on the fastener typology (i.e., screws or nails), material strengths as well as the geometry of the structural system (e.g., distance between fasteners, distance between purlins). If the forces due to the wind uplift act parallel to the length of the fasteners and perpendicular to the holding members, the nominal pullover resistance per screw and nail ($P_{n,\text{over}}$ in N) is computed as

$$P_{n,\text{over}} = 1.5\, t\, d_w\, F_{u1}, \tag{5}$$

Where, in the case of screws, t (mm) is the thickness of the member in contact with the screw head, d_w (mm) is the larger of the diameter of the washer and the screw head and F_{u1} (MPa) is the ultimate tensile strength of the member in contact with screw head or washer. Whereas, in the case of nails, d_w is the diameter of the nail head.

The definition of the pullout resistance for screws ($P_{n,\text{out,screw}}$ in N) is based on the design criteria provided by the NSCP (2015),

$$P_{n,\text{out,screw}} = 0.85\, t_c\, d\, F_{u2}, \tag{6}$$

where t_c (mm) is the lesser of the depth of penetration and thickness of the element not in contact with the screw head, d (mm) is the nominal screw diameter, and F_{u2} (MPa) is the ultimate tensile strength of the member not in contact with the screw head or washer.

In the case the roof structure consists of wood purlins, nails are generally used as fasteners. In this case, according to the National Design Specification (NDS) for Wood Construction (AWC, 2017) [31], the pullout capacity for single smooth shank nail used as wood-to-wood and metal-to-wood connections ($P_{\text{out,nail}}$ in N) can be expressed as

$$P_{\text{out,nail}} = K_w\, G_{\text{out}}^{5/2}\, d_s\, P, \tag{7}$$

where, G_{out} is the specific gravity of the wood based on oven-dry weight, d_s (mm) is the shank diameter of the nail, P (mm) is the penetration of the nail in the member holding the nail point, and K_w is a constant having a value of 9.515, which is converted from the original value of 1380 (in empirical unit) for SI unit consistency.

The parameters needed for the definition of the roof panel capacity are treated as random variables to properly account for the epistemic uncertainties involved in the fragility calculation and to 'balance' the simplified geometry of the proposed model. In particular, the geometric parameters of the resisting elements (i.e., d_w, t_c, d, d_s, P) are considered normally distributed with mean values equal to the nominal values assumed during the analysis or measured during field surveys. More specifically, 4d and 8d fasteners (i.e., nominal diameters equal to 2.9 and 3.3 mm, respectively) are usually found for such a roof typology [25, 32]. Therefore, if observed data are not available, fastener typology and size can be randomly generated. Whereas, the coefficients of variations are derived from studies related to Filipino roofs available in the scientific literature [8, 33]. Table 3 summarises the statistical model for the pullout/pullover capacity adopted in this study.

Table 3: Statistical model of the capacity parameters.

Parameters	Mean	Coefficient of Variations (COV)	Statistical model
t	0.79 mm	0.1	Normal
d_w	Nominal or assumed value	0.05	Normal
d	Nominal or assumed value	0.05	Normal
d_s	20% of d	0.025	Normal
P	Nominal or assumed value	0.25	Normal
F_{u1}	147 MPa	0.35	Log Normal

F_{u2}	215 MPa	0.1	Log Normal
t_c	Nominal or assumed value	0.025	Normal
G_{out}	Nominal or assumed value	0.25	Normal

4.5 Load redistribution and corrosion effects

Load redistribution among fasteners and corrosion effects are key issue to derive system-level capacity. When a fastener fails, its load is redistributed among the closest resisting elements until the equilibrium is achieved. 90% of the load of the failed fastener is redistributed between those located on parallel purlins, while the remaining 10% goes to fasteners which are on the same purlin. In the proposed procedure, the load is redistributed until the equilibrium is achieved each time that a fastener fails and if the metal sheet is still safe [10]. Once the load is redistributed to other fasteners, these can fail and a rapid damage progression can occur.

Corrosion affects the effective section of fasteners and LWMS, thus reducing the uplift resistance of the roof panels over time. The corrosion model adopted in this study is the one proposed by Nguyen et al. (2013) [34], which considers two types of corrosions: embedded and atmospheric. The former is generated by corrosive agents that are within the surrounding wood, such as wood acidity and timber moisture content. Only parts inside the wood, such as the shank of nails are affected. Whereas, the atmospheric corrosion is due to corrosive agents within the surrounding air, such as airborne salinity and airborne pollution agents. The parts of the cladding exposed to the air, such as the heads of nails and screws as well as the LWMS surfaces, are affected by this type of corrosion. The parameters needed for the definition of the corrosion model are derived from the environmental data provided by PAGASA [35].

5 RESULTS

5.1 Fragility analysis

The fragility analysis has been carried out for all the 19 CH assets previously introduced by varying the gust wind speed v from 0 to 100 m/s with 2 m/s steps and by increasing the corrosion depths by considering 10-year steps from 0 to 50 years (i.e., observation year, y). Moreover, ten-thousand steps are considered within the Monte Carlo sampling, while the log-normal CDF is used to fit the analysis results by applying the maximum likelihood estimation (MLE) method [36]. For the sake of clarity, only the fragility curves for building with ID ‘01-001’ and ‘02-003’ (Figure 4) are discussed in this section. The building ‘01-001’ has 2.6-mm shank diameter screws with a 500-mm spacing, while the building ‘02-003’ has 2-mm shank diameter nails with 250-mm spacing. When the fragility curves are derived for year 0, so without increasing the initial corrosion depths, the two CH asset roofs show similar fragility relationships. When time passes, the corrosion affects more the roof ‘02-003’ (Figure 4b) than the roof ‘01-001’ (Figure 4a); in fact, the distance among fragility curves is larger in Figure 4b. This is mainly due to the fact that nails are affected by both embedded and atmospheric corrosion, because of the use of wood purlins. Whereas, screws are generally subjected to only atmospheric corrosion, which usually achieves value smaller than the embedded one [34]. In general, the fragility curves derived in this study show that CH roofs with nails as fasteners are more sensitive to corrosion than the screw ones.

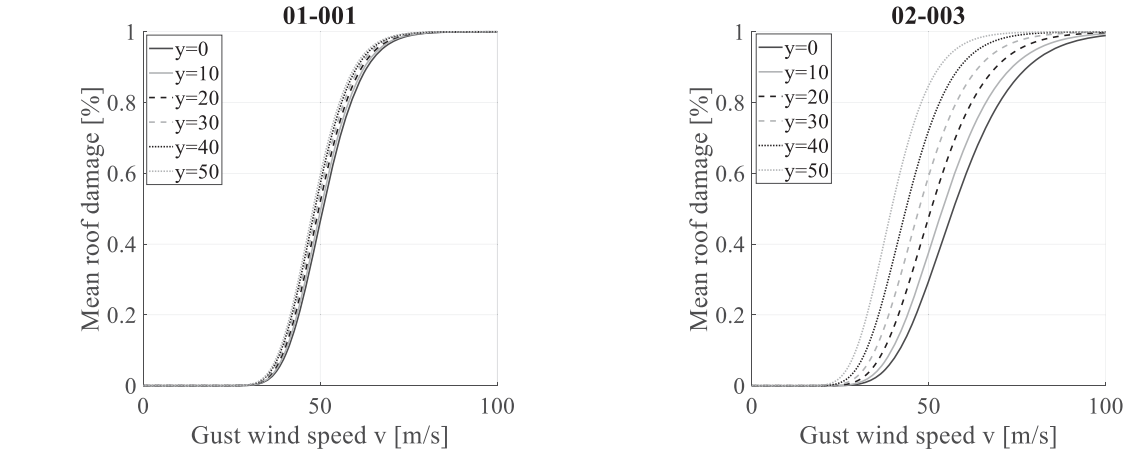

Figure 4: Fragility curves derived for different observation years (y): a) building 01-001 (screws), b) building 02-003 (nails).

5.2 Risk assessment

The results of the fragility analysis are then used to calculate the expected loss in terms of percentage of building replacement value as a function of the mean annual frequency (MAF) of the 3-sec gust speed v (i.e., simplified loss curves are derived, Figure 5). The calculation is repeated by varying the reference year from 0 to 50 years to account for both corrosion effects and climate change impact.

Loss curves calculated considering the reference year equal to 0 are very close, thus reflecting the result obtained for the fragility curves. The variation of the reference year affects more the roof '02-003' (nails) than the '01-001' one (screws). This is mainly due to the corrosion effect rather than the climate change, as explained before.

It is worth noting that the loss curves presented in this section are derived considering the expected values of damage-to-loss curves $\mathbb{E}[L|R_{\text{damage}}]$ (section 3.1). A comprehensive discussion of this problem would require considering the uncertainty related to the damage-to-loss curves, that means to consider $p[L|R_{\text{damage}}]$.

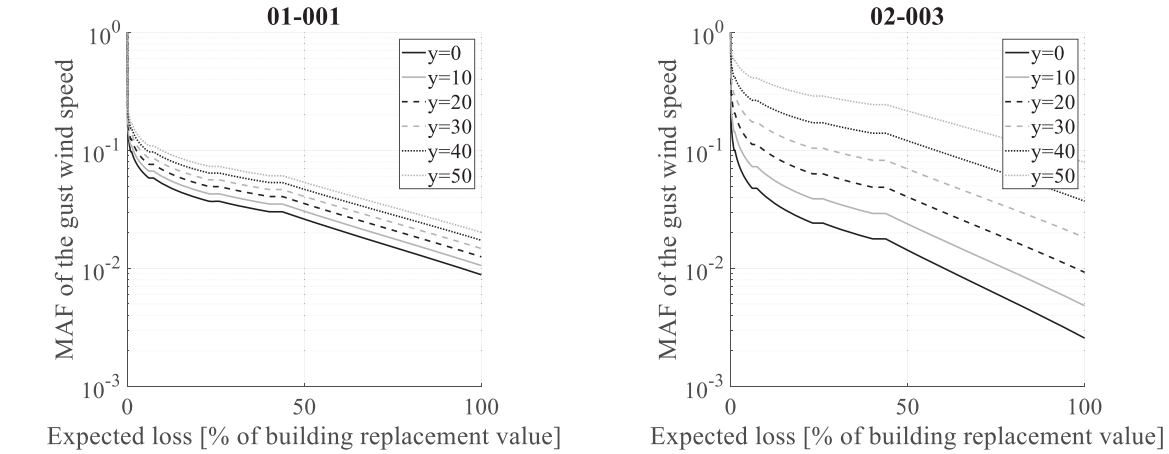

Figure 5: Loss curves: a) building 01-001 (screws), b) building 02-003 (nails).

5.3 Risk prioritization

The previous results are finally used to calculate the expected annual loss (EAL) [37] for each CH asset by varying the reference year. The resulting EAL are then used to prioritize the building portfolio by proposing a typhoon risk prioritization index I_{TR}. The index related to the k-th CH assets considering the i-th reference year is defined as,

$$I_{TR,i,k} = \frac{(100-1)}{(\mathrm{EAL}_{\max,i} - \mathrm{EAL}_{\min,i})} \left(\mathrm{EAL}_{i,k} - \mathrm{EAL}_{\min,i}\right) + 1, \quad (8)$$

where, $\mathrm{EAL}_{\max,i}$ and $\mathrm{EAL}_{\min,i}$ are the maximum and minimum EAL within the analysed portfolio. The resulting indices are arbitrarily categorized in three groups, respectively "green, yellow and red tags" by defining two thresholds. As a proof of concept, in this study the thresholds are selected to be equal to 33% and 66% for the calculated typhoon risk index. The results reported in Figure 6 show that the variation of the reference year of analysis leads to a small variation of the prioritization index. This fact indicates that even if corrosion and climate change affect the risk analysis at building-specific scale (previous section), the initial conditions of the analysed CH assets are more important for the definition of the typhoon risk prioritization scheme.

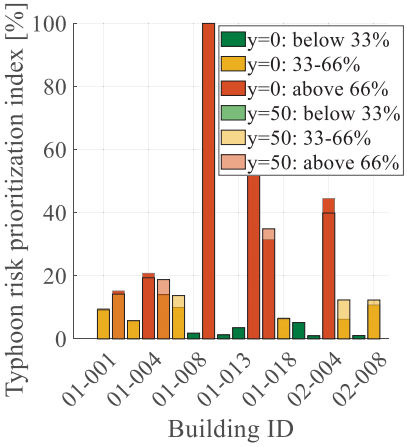

Figure 6: Typhoon risk prioritization index.

6 CONCLUSIONS

The Philippines is particularly prone to natural hazards, such as typhoons and earthquakes. Last catastrophic events have emphasized that the Filipino built environment is highly vulnerable to typhoons. This is likely to be worsened in the future because of the impact of climate change on typhoon intensities, frequencies and paths. Among the most vulnerable buildings, CH assets deserve special attention because of their intangible value for local communities, and their fundamental role in sustaining cultural tourism. Hence, typhoon risk assessment methods at building specific level and typhoon risk prioritization schemes at portfolio level, suitably defined for CH assets, are fundamental to prioritize disaster risk reduction and resilience-enhancing strategies.

This paper has presented a simulation-based approach for CH roof fragility derivation in which roof panel pullout and pullover failure mechanisms, corrosion effects and load redistribution (after fastener failure) have been explicitly modelled. Filipino CH asset roofs are made of timber frames and light-weight metal sheet (LWMS) with steel screws and nails used as fasteners; this structural typology has been the main focus of the study. A simplified model for the roof geometry, at the base of the proposed approach, has enabled 1) to reduce the required computational burden for fragility assessment; and 2) to probabilistically model

capacities/demands. The proper balance between refinement level and uncertainty consideration/propagation makes the proposed approach especially suitable for both risk prioritization and preliminary risk assessment at building specific level.

The analysis of 25 CH assets in Iloilo City, Philippines, has shown the feasibility of the proposed approach and has enabled the evaluation of the impact of the climate change on the risk assessment at building specific level and on the prioritization scheme. The results of the analysis have revealed that corrosion may strongly affect the fragility results for the considered CH roofs. Therefore, given the lack of maintenance activities in several developed countries corrosion around the world, corrosion effect must be considered in the typhoon fragility/risk assessment. Results of the analysis have also shown that climate change affects more the risk assessment estimates at building specific level than the prioritization scheme.

7 ACKNOWLEDGMENTS

This study was performed in the framework of the "CHeRiSH: Cultural Heritage Resilience & Sustainability to multiple Hazards" project funded by the UK British Council. The University of the Philippines Visayas (UPV), the Central Philippine University (CPU), and the De La Salle University (DLSU), Manila, are acknowledged for the technical support during the fieldwork.

Abstract. *The paper addresses the modal properties of a wooden floor consisting of a plywood board fastened by screws to timber joists. The overall aim of the study has been to examine how well finite-element models can be calibrated to match the dynamic properties of a mock-up, studied in the laboratory in a scale of 1:2. The paper proposes the use of output-only modal analysis, also known as operational modal analysis (OMA), using brushes of various stiffnesses to excite the floor. In order to avoid uncertainties related to the supports, free–free boundary conditions are considered. This has been modelled experimentally by suspending the test specimens in rubber bands. Modes up to about 500 Hz were extracted, using an array of accelerometers, and the experimental results were then used as a basis for model calibration and model validation. Two overall approaches to finite-element modelling of the wooden floor are studied in the paper. The first approach employs a solid model with all parts of the structure (plywood and joists) modelled as orthotropic, linear elastic materials. The second approach considers a structural model with the plywood leaf modelled as a laminate shell using Mindlin thick-plate theory and the joists modelled using Timoshenko beam theory. Firstly, the finite-element models of each individual component of the floor, i.e. each beam or plate, are updated with the use of the measured modal properties. Secondly, in order to validate the finite-element models of the assembled floor, their modal properties are compared with the results obtained experimentally. In the validation step, no further updating is performed, but various configurations of the connections between the wooden beams and the plywood board are included in the study. An artificial elastic layer and modelling of the individual lines of screws are introduced within the solid model to allow more realistic modelling of the connection. In this context, the kinematic constraints enforced within the shell–beam model are discussed.*

1 INTRODUCTION

Vibrations in a floor can be caused by walking on the floor as well as other sources inside or outside a building. At low frequencies from 1–80 Hz, this can be felt as whole-body vibrations or heard, for example, as rattling noise. In the frequency range 20–250 Hz, the structure-borne vibrations lead to reradiated noise. The noise and vibration may cause annoyance to the inhabitants of a building and, in severe cases, health problems [1–3].

The vibrations of a floor and the related reradiated structure-borne noise are greatly influenced by the modal properties of the floor. These properties are subject to large uncertainties due to natural variations in the material [4,5] and the usage of the floor [6–9] as well as the support conditions and internal joints [10,11]. This entails detailed information about the individual floor if a reliable computational model of the floor is to be constructed. Without such knowledge, the error in the estimate of the natural frequency of a floor may exceed 20 %.

Before a computational model based on, for example, the finite-element (FE) method can be calibrated to match the modal properties identified from measured accelerations, the model must first be able to represent the dynamic response in the frequency range of interest. This paper concerns the frequency ranges relevant to whole-body vibration and reradiated structure-borne noise. For low vibration levels at these frequencies, reinforced concrete floors may be modelled as shells with isotropic, linear elastic material behaviour of the concrete, accounting for the steel reinforcement as layers with additional stiffness in the direction of the rebar. However, a similarly simple approach cannot be used for wooden floors. Timber is an orthotropic material, and the position and orientation of each joist or layer in a plywood laminate must be accounted for explicitly. Furthermore, the uncertainties of the material properties as well as the internal joints between the beams and the plates must be addressed.

The purpose of the paper is to analyse whether FE models based on different overall concepts can be used to model the dynamic behaviour of a wooden floor consisting of a single-leaf plywood board attached to four timber beams by screws in different configurations. Free–free conditions and an empty floor have been considered to avoid additional uncertainties related to the supports and usage of the floor. An experimental campaign has been conducted with the aim of extracting the modal parameters of a mock-up built in scale 1:2. The modal properties of the individual components, i.e. the timber beams and the plywood board, have also been determined experimentally to allow a stepwise model updating. Usually, the modal properties would be obtained by experimental modal analysis (EMA) [12–15], but this paper proposes the use of output-only modal analysis—or operational modal analysis (OMA)—as an alternative to this [16,17], applying diffuse white-noise excitation with soft and medium-stiff brushes.

Two FE modelling concepts are considered: a) a solid FE model and b) a structural FE model. The models are compared regarding their ability to represent the modal properties of the individual components before validating the FE models of the assembled floor with various configurations of the connections.

The overall geometry, connectivity and material properties of the studied wooden floor are presented in Section 2. Section 3 provides an overview of the experimental campaign. Firstly, the experimental setup and testing procedure for each of the tests are described, and then the results are presented. Next, Section 4 introduces the FE models. The geometry, material modelling, discretization, and assembly strategy are all described with focus on the solid FE models. The calibration and validation of the FE models then follow in Section 5. A sensitivity study is first performed to quantify the importance of each material property in the orthotropic material models. A model updating of each beam and the plate is conducted, before the models of the assembled floors with different configurations of screws are validated. Finally, a short summary, the main conclusions, and suggestions for future work are presented in Section 6.

2 DEFINITION OF THE FLOOR MODEL

Ideally, to examine how well an FE model may replicate the modal properties of a wooden floor structure, the FE model should be compared to and validated by a physical floor model in full scale. However, a full-scale model of a floor requires a considerable amount of space and time to build in a laboratory. Further, as the experimental campaign was conducted in the Dynamics Laboratory of Aarhus University School of Engineering, the mock-up of the floor panel should fit into the available test stand. Hence, it was chosen to construct the mock-up in smaller scale, approximately 1:2 compared to a full-size floor. While this allowed easier handling of the timber beams and the plywood plates constituting the floor panel, it still provided an experimental model representative of the kinematic and dynamic behaviour that can be expected for a full-size floor. The geometry and dimensions of the down-scaled model are shown in Figure 1. All beams (*Södra reglar*) came from the same badge in order to get insight into the variation in material properties that can be expected even in that case. Also, two plywood boards (*Keflico Selex Radiata Pine Krydsfiner*) from the same badge were tested to examine the variation in material properties before the modelling of the assembled floor panel.

Prior to conducting the tests and setting up the FE models, it was necessary to have an initial idea of the material properties as well as their upper and lower bounds to be used in the model updating and calibration process. With the initial values, FE analysis and simple hand calculations could be carried out for the beams as well as the boards in order to get insight into the eigenfrequencies and the related eigenmodes, such that the sampling frequency, recording time, and the position of accelerometers used for measurements could be chosen on an informed basis. The upper and lower bounds could be used in the FE model updating (calibration) procedure.

Tables 1–2 show the material properties of the timber beams, based on two different overall assumptions. Thus, for the beams, two sets of parameters are given assuming that the wood is either isotropic (Table 1) or orthotropic (Table 2). In any case, the material is assumed to

undergo linear elastic deformation given the very low excitation levels associated with the experiment. It should be noted here that wood is behaving as an orthotropic material. Modelling the wood as isotropic will overestimate the shear moduli as well as the Young's moduli in the directions orthogonal to the grain. The intervals for the values are chosen based on the previous study by Flodén et al. [14], and the initial values are a qualified guess based on the mass density that has been provided by the supplier.

Next, Tables 3–4 show the material properties for the plywood boards in terms of lower and upper bounds as well as the assumed initial values. Here, it was judged that an isotropic material behaviour would be inappropriate, even for the first few eigenmodes. Instead, two alternatives based on orthotropic behaviour were considered: a "smeared-out model" with a single-layer plate (Table 3) and a model with five plies, or laminae, with identical properties by having different orientation of the grain (Table 4). Here, the material properties were inspired by the work on Scots Pine carried out by Gerrand [18]. It is noted that, for the individual lamina, E_1 is the Young's modulus in the grain direction while E_2 is the Young's modulus in the transverse direction parallel to the annual rings. In the single-layer plate model, E_1 is the Young's modulus in direction 1 in which most of the laminae have the grain direction, and E_2 is then the in-plane direction orthogonal to direction 1. The difference between E_1 and E_2 is assumed to be small, since three laminae are present in direction 1, whereas two laminae are present in direction 2.

In addition to the material properties, the assembly between the individual parts of the floor must also be modelled correctly in an FE model. In the present analyses, the plywood board was attached to the beams by screws of the brand Carl Ras (Panel Twistec Ruspert with Fibercut Point no. 4848-0653). The screws had the length 40 mm, and the head had a diameter of 4.0 mm. A total of six configurations were considered for the assembly:

- Panel A: One line of screws per beam, c–c distance of screws: 191 mm
- Panel B: One line of screws per beam, c–c distance of screws: 95.5 mm
- Panel C: One line of screws per beam, c–c distance of screws: 47.8 mm
- Panel D: Three lines of screws per beam, c–c distance of screws: 191 mm
- Panel E: Three lines of screws per beam, c–c distance of screws: 95.5 mm
- Panel F: Three lines of screws per beam, c–c distance of screws: 47.8 mm.

At the ends of the beams, the screws were placed 40 mm from the edges.

Figure 2 shows the overall placement of the screws in Panel A. Further, in the lower–right corner of the figure, an encircled area can be found, indicated by the letter A. This refers to

Figure 3 which provides an overview of the screw positions in all six cases, i.e. Panels A–F. As described below, a part of the research has focused on testing whether a single screw present in the width direction of each beam (Panels A–C) provide a line coupling. Also, it has been examined whether three screws present across the beams (Panels D–F) provide a rigid coupling such that the beams can be considered fully merged with the board.

3 EXPERIMENTAL SETUP AND TESTING

The overall purpose of the experimental campaign was to collect reliable data that could be used for the validation and calibration of the FE models. For real floors, constituting a part of a building, uncertainties are associated not only with the material properties but also the support conditions and the usage of the floor, as discussed, for example, by Andersen and co-workers [7–10]. In order to minimize the possible influence of such uncertainties, an empty floor was considered, and so-called free–free conditions (i.e. an unsupported floor) were assumed. In practice, this was established by suspending the test specimens in rubber bands tied at one end to the test rig. Following the procedure suggested by Dickow [19], the other end of the rubber bands was tied by a knot to the eyebolts installed in the test specimens (see Figures 6, 8 and 10). This provides well-defined connections with no sliding or uncertain mechanisms involved.

The experiments were carried out as Output Only Modal Analysis (OMA) [16], using brushes to excite the test specimens. To allow a stepwise calibration of the FE model, updating the material properties of the beams and the boards before analysing the assembled floor, the experimental campaign was conducted in three main steps:

- OMA of the four timber beams, one at a time, conducting four tests for each beam (see Subsection 3.1)
- OMA of the two plywood boards, one at a time, conducting four tests for each board (see Subsection 3.2)
- OMA of the assembled floor, using Board no. 2 and Beams no. 1–4, conducting three to four tests for each of the six panel configurations (see Subsection 3.3).

The specimens were not dismounted between the different tests. For the OMA of the individual beams and boards, a soft brush was utilized for excitation, and for the assembled floor, the same brush as well as a medium soft brush were applied to excite a wider range of frequencies.

The data collection was performed with sensors from Brüel & Kjær (B&K) and a data acquisition system National Instruments (NI):

- 20 pcs. B&K Type 4508-B-002, Piezoelectric CCLD Accelerometer, 1000 mV/ms^{-2}
- 1 pc. B&K Type 4508-B, Piezoelectric CCLD Accelerometer, 100 mV/ms^{-2}
- B&K Type UA-1407, Plastic Mounting Clips
- B&K Type 4294, Accelerometer Calibrator, hand-held
- NI Type cDAQ-9178, CompactDAQ Chassis
- 5 pcs. NI Type 9234, C Series Sound and Vibration Input Module
- Stanley 0-77-030 Moisture Meter
- TinyTag Type TGP-4500, Temperature and Relative Humidity Logger.

Furthermore, a level was used to make sure that the various specimens were mounted in a horizontal position, and a scale was used to determine the weights.

The experimental data were recorded using NI SignalExpress [20] with DAQ Assistant [21] installed. Analyses were carried out using ARTeMIS Modal Pro [22], and a quick pre-analysis of the recorded data was performed in MATLAB [23] using the OMA Toolbox [16] to see whether reasonable eigenfrequencies modes were obtained. In the instrumentation of the specimens, care was made to place accelerometers such that global as well as local modes of vibration would be registered. For the assembled floor, accelerometers should therefore not be placed only on top of the beams, but also on the boards in the mid-spans between the beams. Examples of global bending and local vibration modes for the assembled floor can be seen in Figure 4.

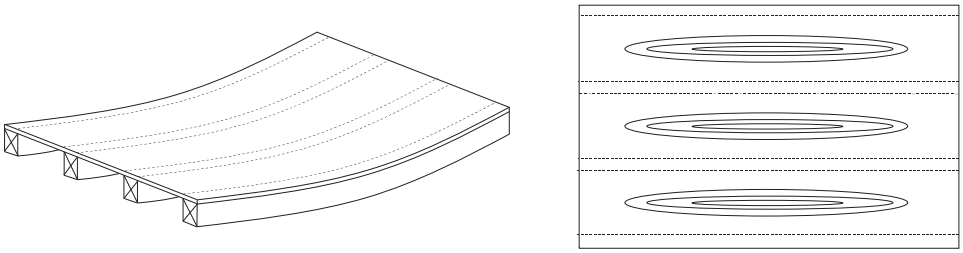

Figure 4: Example eigenmodes of panel: Global bending (left); local plate deflection between joists (right).

3.1 Output-only modal analysis of the individual beams

Figure 5 shows the position of the accelerometers mounted on each single beam in the first step of the experimental campaign. Further, Figure 6 shows the experimental setup with one of the beams mounted in the test rig. Nine accelerometers were placed on the top flange of the beam and another nine accelerometers were placed on one side. No accelerometers were placed on the bottom flange or on the other side, since no modes with significant deformation of the cross-section were expected within the considered frequency range. All wires were carefully attached to a wooden rod placed above the beam to avoid any collisions with the beam during the experiment. Each test lasted 30 s, and the data was acquired at a sampling frequency of 2 049.2 Hz. The soft brush was applied for excitation.

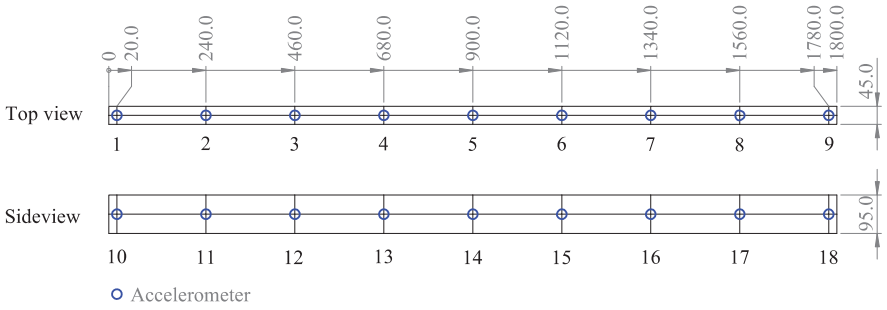

Figure 5: Position of the accelerometers mounted on each single beam.

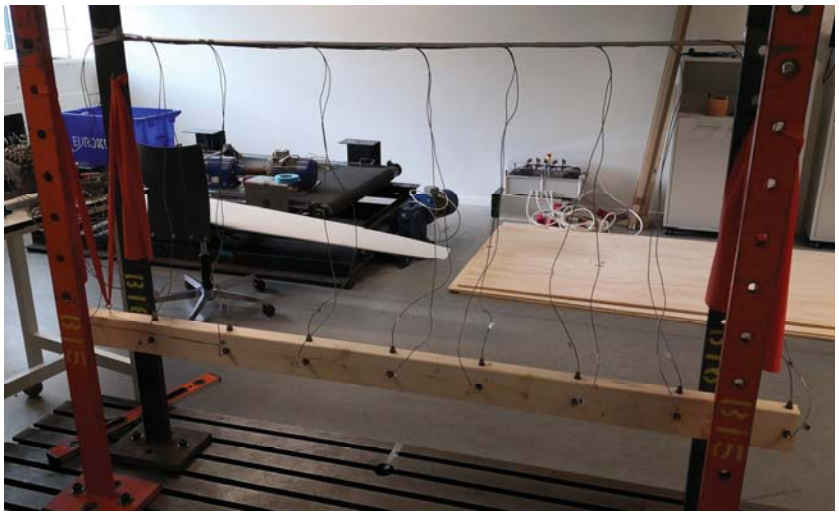

Figure 6: One of the wooden beams placed in the test stand.

3.2 Output-only modal analysis of the board

Figure 7 shows the positions of the eyebolts and the accelerometers mounted on each single plywood board. Figure 8 illustrates the experimental setup with one of the boards mounted in the test rig. It should be noted that Figure 7 indicates the positions at which the beams were later placed (the sides as well as the centre lines of the beams). The accelerometer positions were carefully chosen to capture as many modes as possible within the considered frequency range. Also, the eyebolts were placed at the positions where preliminary analyses based on the initial material properties in Table 4 indicated a small deflection in the first eight eigenmodes. Each test lasted 120 s, and the sampling frequency was set to 1 652.9 Hz. The soft brush was applied for excitation.

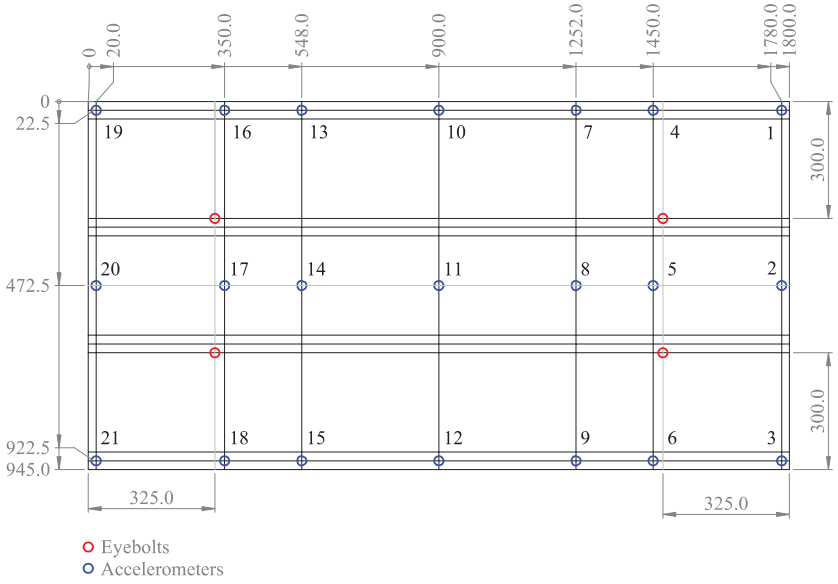

Figure 7: Position of the accelerometers on each of the plywood boards (top view).

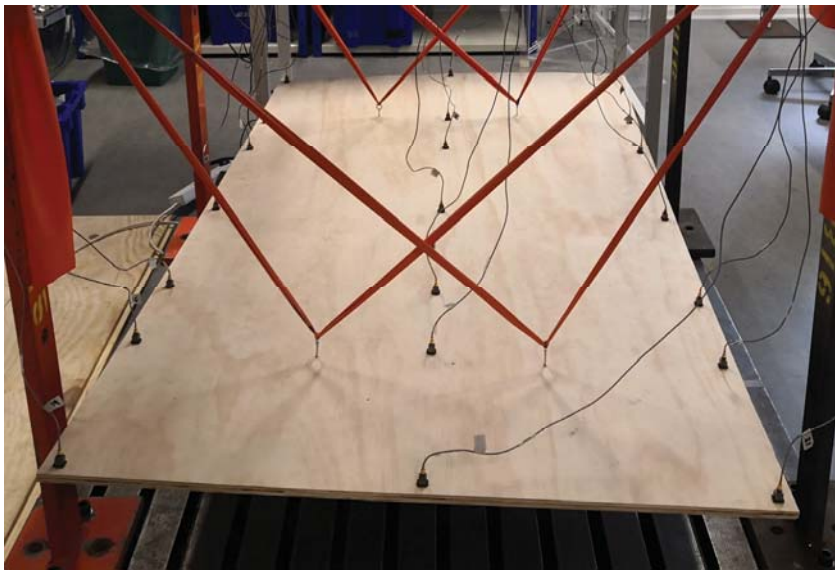

Figure 8: One of the plywood boards placed in the test stand.

3.3 Output-only modal analysis of the complete floor panel

The positions of the accelerometers and the eyebolts mounted on the assembled floor panel are shown in Figure 9. Again, the positions have carefully been selected based on a preliminary FE analysis using the initial material properties for the timber beams (Table 2) and the plywood

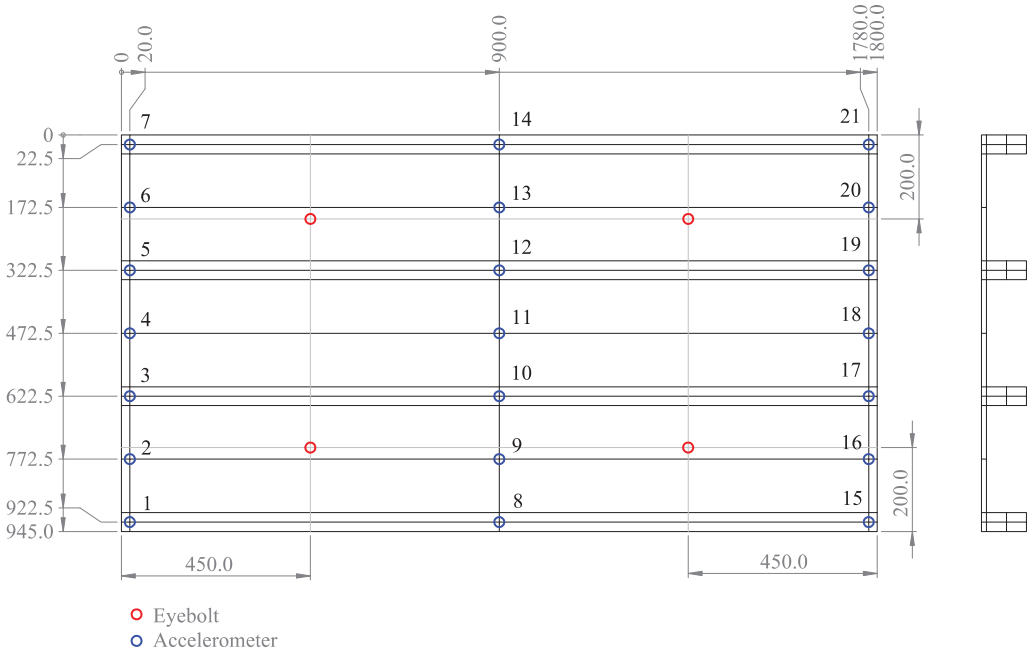

Figure 9: Position of the accelerometers on the assembled floor (top view).

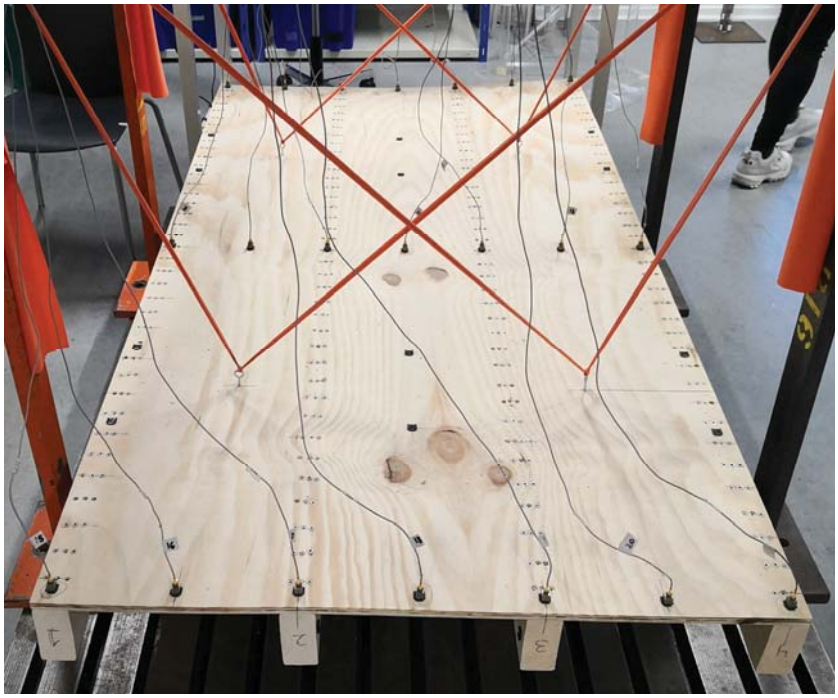

Figure 10: The mock-up of the floor (Panel F) mounted in the test rig.

board (Table 4). Figure 10 shows the setup with the assembled floor panel installed in the test rig. The photograph illustrates Panel F, i.e. the configuration with three screws over the width of each beam and with 47.8 mm between the screws in the longitudinal direction. Among the considered panel configurations, this is the most rigid connection between the beams and the board. Each test lasted 45 s, and the sampling frequency was set to 1 652.9 Hz. The soft and medium soft brushes were applied for excitation.

3.4 Results of the experimental campaign

The mass densities of the individual beams were found to be 415.32, 539.19, 444.31, and 442.85 kg/m^3, for Beams 1, 2, 3, and 4, respectively. Thus, Beam 2 had a relatively high mass density compared to the other beams, even though all beams came from the same badge. The mass densities of the boards were 490.09 and 483.25 kg/m^3, for Plates 1 and 2, respectively.

A full report of the experimental results is beyond the scope of the paper. However, information about the mean values of the eigenfrequencies extracted for each of the components as well as for the assembled floor are given in Tables 5–7. The first eigenfrequency of the beams is related to bending in the horizontal plane, i.e. with respect to the weak axis of the cross section, and it lies close to 70 Hz. Mode 2 relates to bending in the vertical plane, i.e. with respect to the strong axis. As expected, the corresponding eigenfrequency is approximately twice as high as the eigenfrequency related to Mode 1. It is furthermore interesting to note that Modes 4 and 7 are the first and second torsional modes according to the finite-element models. Given the instrumentation of the beams, these modes were not captured in the OMA. This explains that these modes are missing in Table 5.

The plates (plywood boards) were much more flexible than the beams. Here, the first ten eigenmodes had frequencies in the interval from around 10 Hz to approximately 80 Hz. With the chosen position of the accelerometers, all the first ten modes could be captured by OMA. It is noted that the first mode at around 10–12 Hz relates to torsion, whereas the second mode relates to bending of the plates. Except for Modes 4 and 5, Plate 1 had a stiffer response than Plate 2, i.e. the extracted eigenfrequencies for Plate 1 are higher than those for Plate 2.

Finally, Table 7 shows that the eigenfrequencies related to the first ten modes of the assembled floor panels lie in the range 15 Hz to 200 Hz. By comparison with FE models of the six panels, it was identified that Mode 2 of Panel B was not captured by the OMA. The same problem occurred for Modes 1 and 2 of Panel D. Interestingly, the eigenfrequencies related to some of the modes, e.g. Modes 1, 4, 5 and 10, are close to being identical for the various configurations of the screws. For Mode 10, only Panel A with the smallest amount of screws has a significantly lower eigenfrequency than the other configurations. However, for some of the modes, e.g. Modes 7 and 9, there is a marked difference between the panels with few or many screws. The number of screws in the longitudinal direction and the number of screws across each beam are equally important. It should in this context be mentioned that the first eight eigenmodes of the full panel do not involve bending of the beams which are relatively stiff.

Further, the relative variations in the extracted eigenfrequencies of all specimens are shown in Figure 11. For a given eigenmode of the beams it can be observed that the associated eigenfrequencies of the individual beams differed up to about 5 percent from the mean value based on all four beams. As also seen in Table 5, Beam 2 provided consistently higher eigenfrequencies than the other beams for the first four modes. The higher mass density of Beam 2 is therefore associated with an even higher stiffness. For the plates, some variation also occurs, and it can be observed that none of the boards provides frequencies that are consistently higher than the other board. This indicates that the eigenfrequencies are very sensitive to variations of the material properties in the different laminae and in different directions or planes.

	Beam 1	Beam 2	Beam 3	Beam 4
Mode 1	69.04	73.67	68.91	68.54
Mode 2	144.75	147.34	142.83	145.08
Mode 3	187.77	195.86	180.73	191.28
Mode 4 (5)	351.54	376.22	367.59	358.37
Mode 5 (6)	372.88	360.58	354.83	382.39
Mode 6 (8)	573.50	590.22	558.82	570.83
Mode 7 (9)	650.37	660.26	682.02	673.72
Mode 8 (10)	831.65	836.11	795.96	805.30

Mode 9	161.82	168.45	172.41	170.73	174.93	175.91
Mode 10	191.32	198.41	200.79	197.23	200.29	200.42

Table 7: Average eigenfrequencies (Hz) for the panels based on three to four OMA tests on each panel.

Figure 11 shows that some of the panel configurations provide eigenfrequencies that are significantly lower than other configurations. Especially, in eigenmode 2, Panel A (which has the smallest amount of screws) provides an eigenfrequency that is about 20 percent lower than that of Panel F (which has the largest amount of screws). This clearly demonstrates that the connectivity between the beams and the plate has a large impact on the modal properties of the floor, even for the first eigenmodes. It should again be noted that Mode 2 of Panel B and Modes 1 and 2 of Panel D were not captured during the experiments.

Finally, Figure 11 shows that there was a small scatter in the repeated recordings for the individual structural members as well as the floor panels. Part of this variation can be attributed to the changing environmental conditions caused, primarily, by an irregularity in the operation

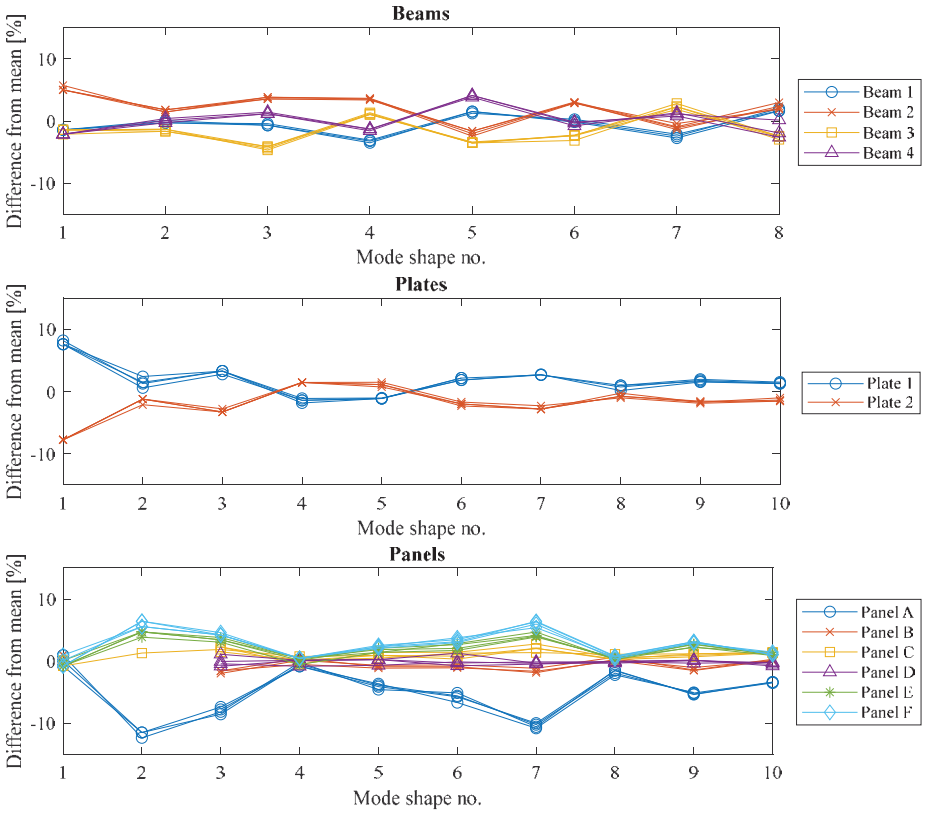

Figure 11: Relative variations in the experimentally measured eigenfrequencies.

of the ventilation system in the laboratory. During the experimental campaign, the temperature varied between 20.2 °C and 22.6 °C, and the relative humidity varied between 28.6 % and 50.3 %. It was observed that one of the plywood boards, Plate 1, warped because of a change in moisture content, and for this reason, only Plate 2 was used for the floor assembly.

4 FINITE-ELEMENT ANALYSIS OF THE WOODEN FLOOR PANEL

The finite-element modelling process followed the same steps as the experimental campaign in order to allow a direct comparison, validation and calibration of the FE models. Thus, as a first step, the individual beams and plates were modelled. Two overall concepts were applied: a three-dimensional (3D) solid FE model of each part developed in Abaqus, and a 3D structural FE model developed of each individual part developed in MATLAB.

The MATLAB model of the beam was based on two-node Timoshenko beam elements using the standard cubic Hermite interpolation functions. Linear interpolation was used for the axial and torsional deformations, assuming Saint-Venant torsion. Since the beam theory assumes that cross sections remain undeformed, only E_1, G_{12} and G_{13} influence the stiffness when utilizing an orthotropic material model. It is noted that the torsional stiffness depends on a combination of G_{12} and G_{13}, whereas transverse shear depends on either G_{12} or G_{13}, depending on direction.

For the plywood boards, the MATLAB model employed Mindlin thick-plate theory. Nine-node elements with quadratic Lagrange interpolation of the displacements and rotations were utilized. Selective integration was applied for the in-plane directions of the element to avoid locking, and a three-point Gauss quadrature rule was applied over the thickness of each ply. The model allows the introduction of a laminate composite with orthotropic behaviour of each

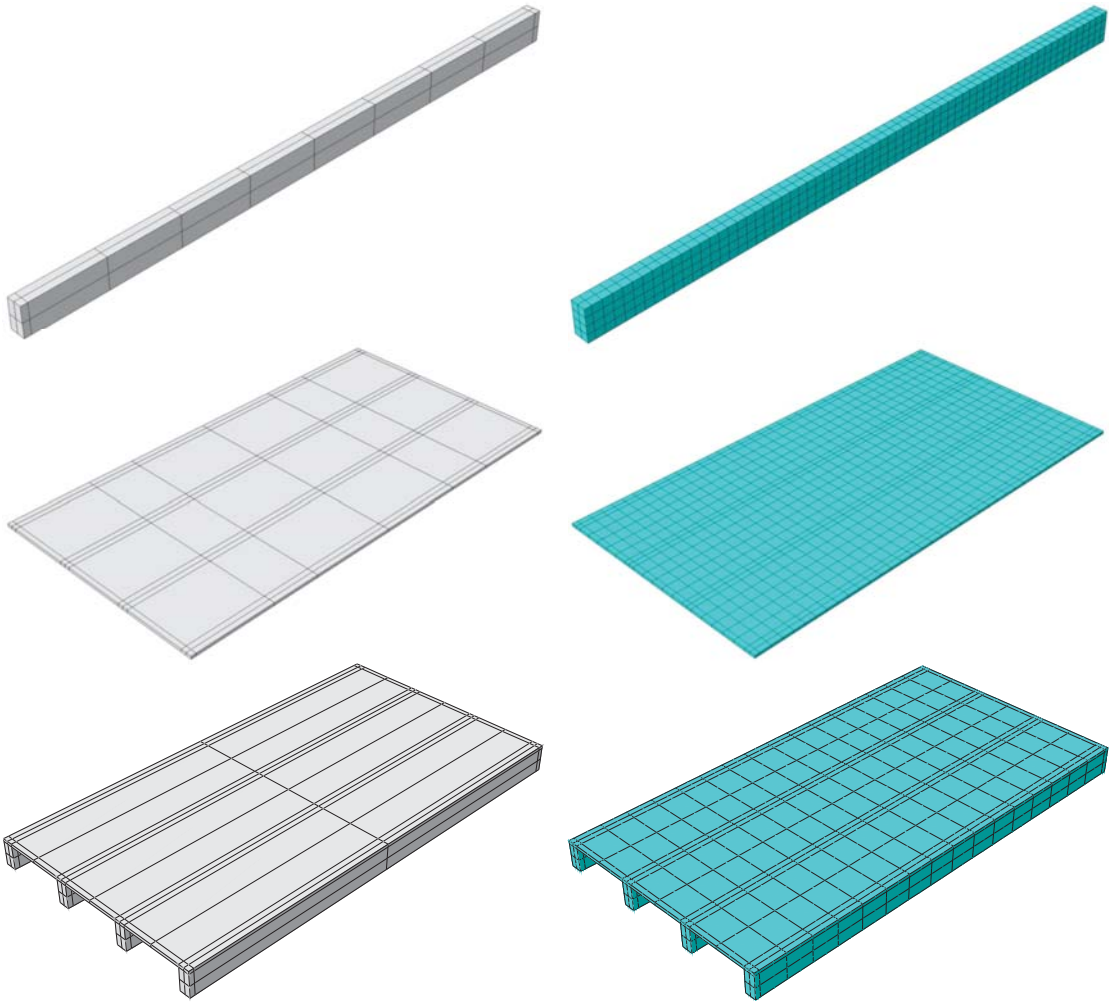

Figure 12: Solid finite-element models of a single beam (top), a plate (middle), and a floor panel (bottom). Left: Division of the geometry. Right: Structured mesh with solid cubes.

layer, or ply. A layup with a 0°–90°–0°–90°–0° configuration was implemented, assuming that the thickness of each ply was the same, corresponding to one-fifth of the plate thickness.

The Abaqus solid FE models of a beam and a plate are illustrated in Figure 12 which also shows a model of an assembled floor panel in which the beams are simple merged with the plate. Generally, the divisions of the models were introduced to allow the evaluation of the displacements at the positions where the accelerometers were placed in the experimental tests. The same strategy was used for the beams and plates in MATLAB. It is noted that the accelerometers were not modelled in any of the models. This implies a modelling uncertainty, but the errors related to the modal properties are assumed to be small.

The 3D solid models are based on 20-node iso-parametric brick elements with quadratic Lagrange interpolation of the displacements and full integration. The Abaqus models were implemented via Python scripting to allow easy modification of material properties and geometry. Further, the input files for Abaqus/Standard are directly transferable to FEMtools [24]. As explained in Section 5, this was later used for automatic model updating aimed at identification of the material properties. However, it should be noted that orthotropic material behaviour must be treated with care, because Abaqus and FEMtools order the material properties differently.

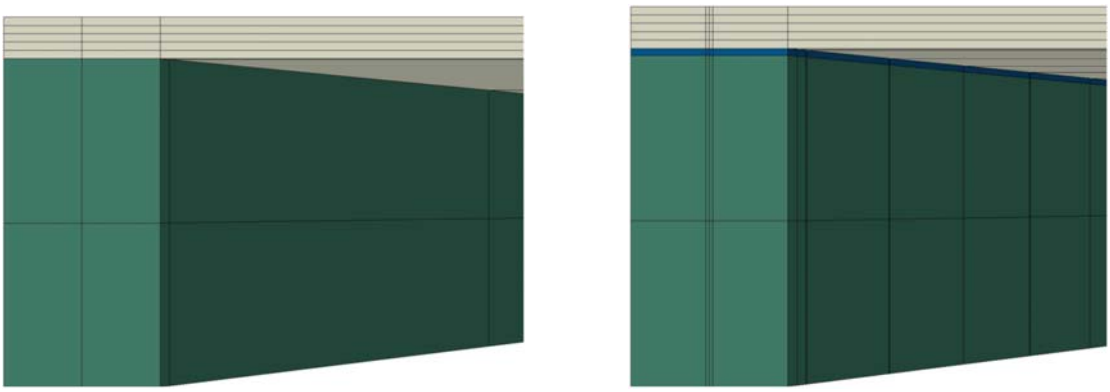

Figure 13: Configurations of the coupling between the beams and the plate in the 3D solid finite-element model. Left: Merged model with direct coupling of the beams to the plate. Right: Coupling via an artificial layer.

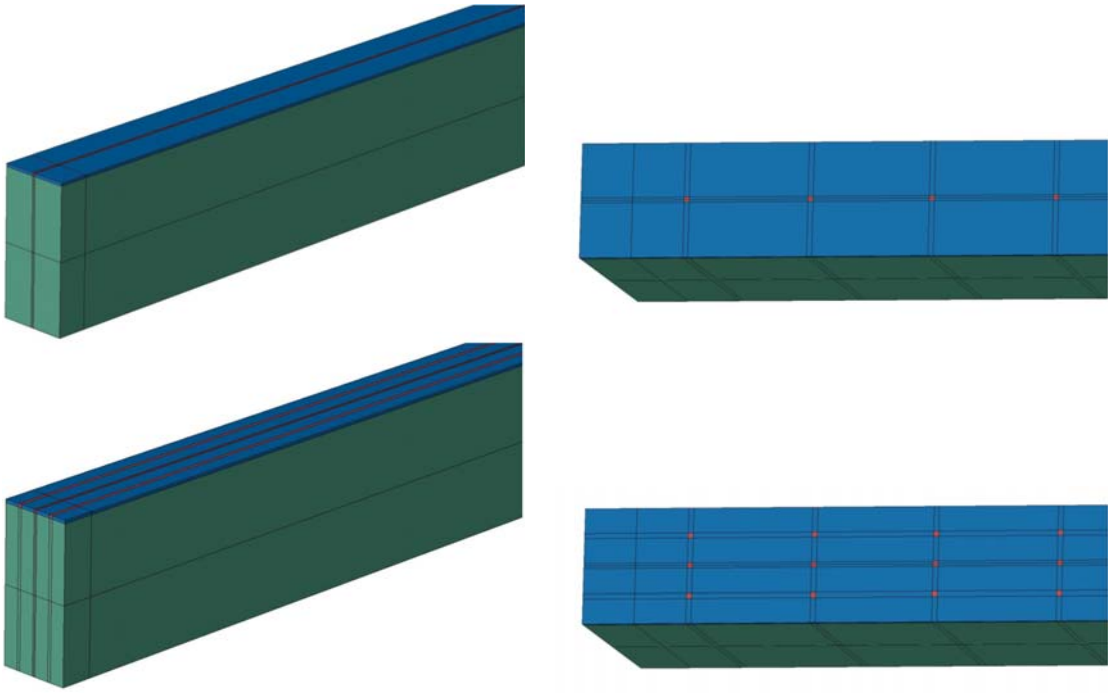

Figure 14: Modelling approaches for the screwed connections between the beams and the plate. "Line" couplings (left) and "point" couplings (right) for a single line of screws (top) or three lines of screws (bottom).

Different approaches to coupling of the beams and the plate were tested in the solid FE model. The simplest configuration merely introduced a full coupling by merging the beams with the plate. To allow a more realistic modelling of the coupling, a 2 mm thick artificial elastic layer was introduced in the remaining models, as illustrated in Figure 13. Based on a previous study by Dickow et al. [25], the layer was assumed to have a mass density of 450 kg/m^3, a Young's modulus of 4 MPa, and a Poisson's ratio of 0.05.

As shown in Figure 14, two strategies were used to model the screws: "line" couplings with 4 mm wide zones resembling the single lines of screws in Panels A–C or the three lines of screws in Panels D–F; "point" couplings with 4 mm × 4 mm zones at the positions of the individual screws. The material in the zones representing the screws was assumes to be steel with the mass density 7 850 kg/m^3, the Young's modulus 210 000 MPa, and the Poisson's ratio 0.30.

5 MODEL CALIBRATION AND UNCERTAINTIES

Based on the experimental tests, reported in Section 3, the FE models of Section 4 were calibrated by updating the material properties. The strategy was to first calibrate the models of the beams and plates separately and then to couple the various parts as suggested in Section 4 without additional modification of the properties. A comparison can then be made of the results obtained using the initial properties (see Tables 1–4) and the optimized values. The properties of the artificial coupling layer were not modified in this process, and as such the comparisons serve as a validation of the material properties and modelling approach for this layer.

Before the model calibration, a preliminary sensitivity study was performed to quantify the importance of each material property. The solid model of each part was employed for this analysis. In the following model calibration, only the material properties with significant influence on the eigenfrequencies were included as variables. This ensured a robust optimization at a relatively low computational cost while still exploiting close to the entire potential for fitting the models to the results of the experimental tests. In any case, the material in each beam, and in each ply of the boards, was assumed to be homogeneous.

For the beam with isotropic material behaviour, the Young's modulus is equally important for all modes, whereas Poisson's ratio only influences modes dominated by shear – since in this case $G = E/(2 + 2\nu)$. However, the isotropic beam models were found to provide a poor match to the test results with no possibility to fit more than the first four to five modes within a reasonable accuracy. Hence, only the orthotropic model was used for further analysis. Here, Figure 15 (left) shows the results of the sensitivity analysis. Clearly, the Young's modulus E_1 in the grain direction has a strong influence on four of the first five modes. Mode 4 is dominated by the shear moduli G_{12} and, especially, G_{13}. It is noted that this is the first torsional mode, which explains the weak dependence on E_1. In any case, none of the remaining six material properties have any significant impact, i.e. only E_1, G_{12} and G_{13} are important for the orthotropic beams.

For the plywood board, Figure 15 (right) shows the results of the sensitivity study. Interestingly, G_{12} is very important for Mode 1, and it also has a strong influence on Modes 3 and 5. Mode 1 is the first torsional mode of the board which lies at a frequency slightly below that of the first bending mode (Mode 2). For Modes 2–5, E_1 has the larger impact on the eigenfrequencies. A weak influence can be seen from E_2, G_{23} and ν_{12}, while the remaining properties have no or extremely little influence. However, it may be expected that G_{12} and G_{13} are important for the eigenfrequencies related to higher modes where shear in bending becomes pronounced.

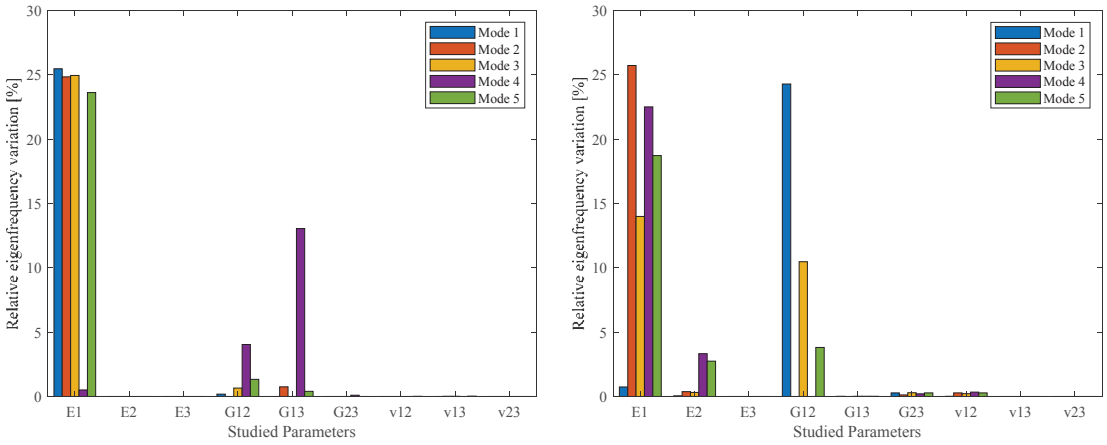

Figure 15: Change in the first five eigenfrequencies due to a variation of each material property by about ±25 % relatively to the initial values suggested for the beams in Table 2 (left) and for the plates in Table 4 (right).

The model updating was performed in FEMtools using, as input, the experimental results from ARTeMIS and the FE models from Abaqus. The initial values as well as the upper and lower bounds for the material properties given in Tables 2 and 4 were used. However, the mass densities found for each specimen using the scales were employed (see Subsection 3.4). As already mentioned, the isotropic beam models will not be analysed further. Likewise, the plate model with a single layer of orthotropic material will not be further regarded in the present analysis, although model updating showed that fair results could be achieved with this type of model for the first few modes of the individual plywood boards.

The model updating was performed based on a comparison of the eigenfrequencies f_i as well as the mode shapes $\{\boldsymbol{\Phi}_i\}$, using the Modal Assurance Criterion (MAC) [26]:

$$\mathrm{MAC}_{ij} = \frac{\left|\left\{\boldsymbol{\Phi}_i^{\mathrm{FE}}\right\}^H \left\{\boldsymbol{\Phi}_j^{\mathrm{EX}}\right\}\right|^2}{\left\{\boldsymbol{\Phi}_i^{\mathrm{FE}}\right\}^H \left\{\boldsymbol{\Phi}_i^{\mathrm{FE}}\right\} \left\{\boldsymbol{\Phi}_j^{\mathrm{EX}}\right\}^H \left\{\boldsymbol{\Phi}_j^{\mathrm{EX}}\right\}}. \tag{1}$$

Here *H* denotes the Hermitian of the vector, the superscripts FE and EX refer to "Finite-Element model" and "Experimental test", respectively, and the indices *i* and *j* refer to Modes *i* and *j*. A MAC value of (nearly) 1 implies that there is (almost) correspondence between the modal vectors for Mode *i* of the FE model and mode *j* of the experiment. This does not guarantee that the modes are (nearly) identical. For example, the related eigenfrequencies may be different, and the response at points that are not included as nodes in the vectors may deviate. On the other hand, if the MAC value is (close to) zero, it can be expected that the modes are inconsistent.

For each structural component, i.e. Beams 1–4 and Plates 1 and 2, the following updating procedure was applied:

- The nodes of the FE model (FE nodes) corresponding to the positions of the accelerometers (experimental nodes) were identified.
- The FE nodes and the experimental nodes were paired in FEMtools.
- The eigenmodes of the FE model and experiment were compared and the modes with MAC values of at least 60 % were included as basis for the model updating.
- A maximum of five iterations were performed to optimize the selected material properties.
- In each iteration, a normalized sensitivity matrix, $[\mathbf{S}]$, was determined, defining the dependence of each observed eigenfrequency on each of the material properties, e.g.,

$$S_{12} = \frac{\partial f_2}{\partial E_1}\frac{E_1}{f_2}. \tag{2}$$

  Here f_2 is the second eigenfrequency of the FE model and E_1 is the value of the Young's modulus in the grain direction of the considered beam or ply based on the previous iteration. See, for example, [17, 18] for further details.
- The change in the material properties was found as $\{\Delta\mathbf{P}\}_{k+1} = [\mathbf{S}]_k^{-1}\left(\left\{\mathbf{f}_k^{\mathrm{EX}}\right\} - \left\{\mathbf{f}_k^{\mathrm{FE}}\right\}\right)$.
- The material properties were updated as $\{\mathbf{P}\}_{k+1} = \{\mathbf{P}\}_k + \{\Delta\mathbf{P}\}_{k+1}$.
- If the difference between the eigenfrequencies of the experiment and the FE model was overall below a given threshold, or if the improvement from one iteration to the next was below a given tolerance, the iteration was terminated even if five iterations had not been reached. The standard values EPS1 = 0.01 and EPS2 = 0.001 were used in FEMtools.

It is noted that the process corresponded to a gradient-based optimization procedure, using a least-squares approach, since there were more eigenfrequencies than material properties.

Table 8 and Figure 16 show the results of the model calibration for the beams. Here, only E_1, G_{12} and G_{13} have been used as variables in the optimization. Compared to the initial values, Young's in the grain direction, E_1, was reduced for Beams 1, 3 and 4, whereas an increase was necessary for Beam 2 in order to provide an optimal fit to the experiment. For all beams, the shear moduli G_{12} and G_{13} were reduced significantly. With reference to Figure 16, the solid FE models developed in Abaqus and the Timoshenko beam FE model implemented in MATLAB provided very similar results for the first seven modes when using the initial values of the material properties. However, the eigenfrequencies deviated about 10 % from the measured values. For Mode 8, there is a large discrepancy between the results of the two FE models. It is noted that this mode occurred at around 800 Hz (see Table 5), i.e. at a very high frequency. After the model updating with the use of FEMtools, a much better fit was obtained. It was thus possible to fit the first eight eigenfrequencies within a relative error of 0–5 %, compared to the experiments for the respective beams. It should be mentioned that an optimization of the MATLAB model was achieved by the introduction of a torsional shear modulus, $G_T = \alpha(G_{12} + G_{13})$. With a proper tuning of the parameter α, a good match of the MATLAB model with the Abaqus model could be obtained, regarding the torsional modes that were not captured experimentally.

Table 9 and Figure 17 show the results of the model updating for the two plywood boards. Poor results were achieved with the initial values of the material properties, but after the model updating with FEMtools, a fair fit was obtained for the first ten modes. It can be observed that the five-layer solid model developed in Abaqus and the Mindlin-shell-element model developed in MATLAB provide similar results both before and after the updating process. Slightly better results were obtained for Plate 2, compared to Plate 1, and as mentioned above, Plate 1 could

Property		Initial value	Beam 1	Beam 2	Beam 3	Beam 4	Average
E_1	(MPa)	12 440	9900	14 256	10 360	10 810	11 332
G_{12}	(MPa)	1 136	635	679	582	531	607
G_{13}	(MPa)	1 136	631	592	815	809	711

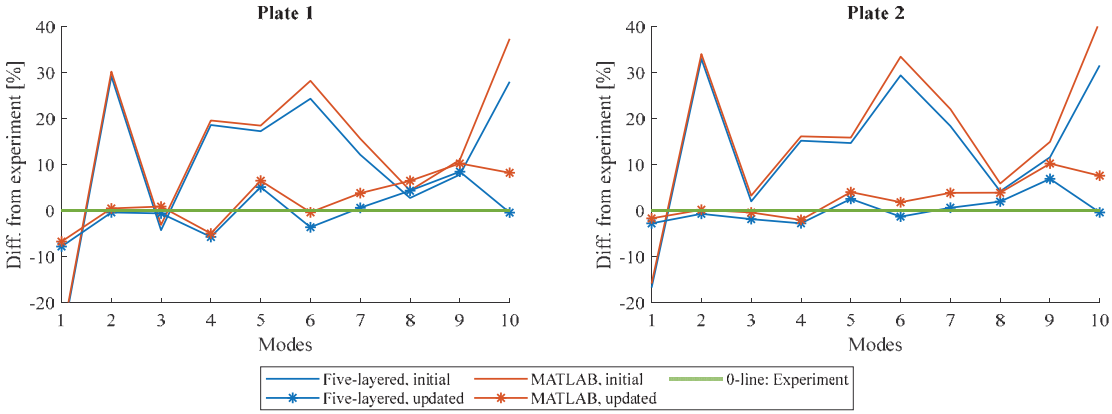

Figure 17: Eigenfrequencies for Modes 1–10 of the plywood boards – deviation from the test results.

not be used in the subsequent assembly of the floor panels, since it was twisted due to uncontrolled variations of the environmental conditions (temperature and humidity) in the laboratory.

Finally, the FE models of the assembled floor panels were compared with the experimental results. Figure 18 shows the results for Panels A–F, based on three different sets of material properties:

- The initial values based on a qualified guess and literature study (see Tables 2 and 4)
- The average updated values of the material properties (see Tables 8 and 9, the last columns)
- The exact updated values of the material properties for each of the structural components (see Tables 8 and 9, the columns for Beams 1–4 and Plate 1).

The deviations from the test results are quantified in terms of the Normalized Relative Frequency Difference (NRFD) [12]:

$$\mathrm{NRFD}_i = \frac{\left| f_i^{\mathrm{FE}} - f_i^{\mathrm{EX}} \right|}{f_i^{\mathrm{EX}}} \cdot 100\ \%\,, \tag{3}$$

where f_i^{FE} and f_i^{EX} are the eigenfrequencies of Mode i obtained by FE modelling and experimental testing, respectively.

The general trend in Figure 18 is that the NRFD is about 30 % for the models employing the initial values of the material properties. For Panel A, the merged FE model provides a very poor result. This was to be expected, given that Panel A has the weakest coupling of the beams and the plate with only a single line of screws for each beam and with almost 200 mm distance between the screws. However, even when modelling the connection between the beams and the plate more realistically, the initial values of the properties lead to erroneous results.

A significant improvement in the accuracy of the FE models was achieved by using the average material properties obtained by model updating. Except for three modes of Panel A, the first ten eigenfrequencies of all the considered panel configurations have an NRFD below 15 % when the beams are merged to the plate within the FE models. When the connections were modelled appropriately, NRFD values below 5 % were obtained with the average values

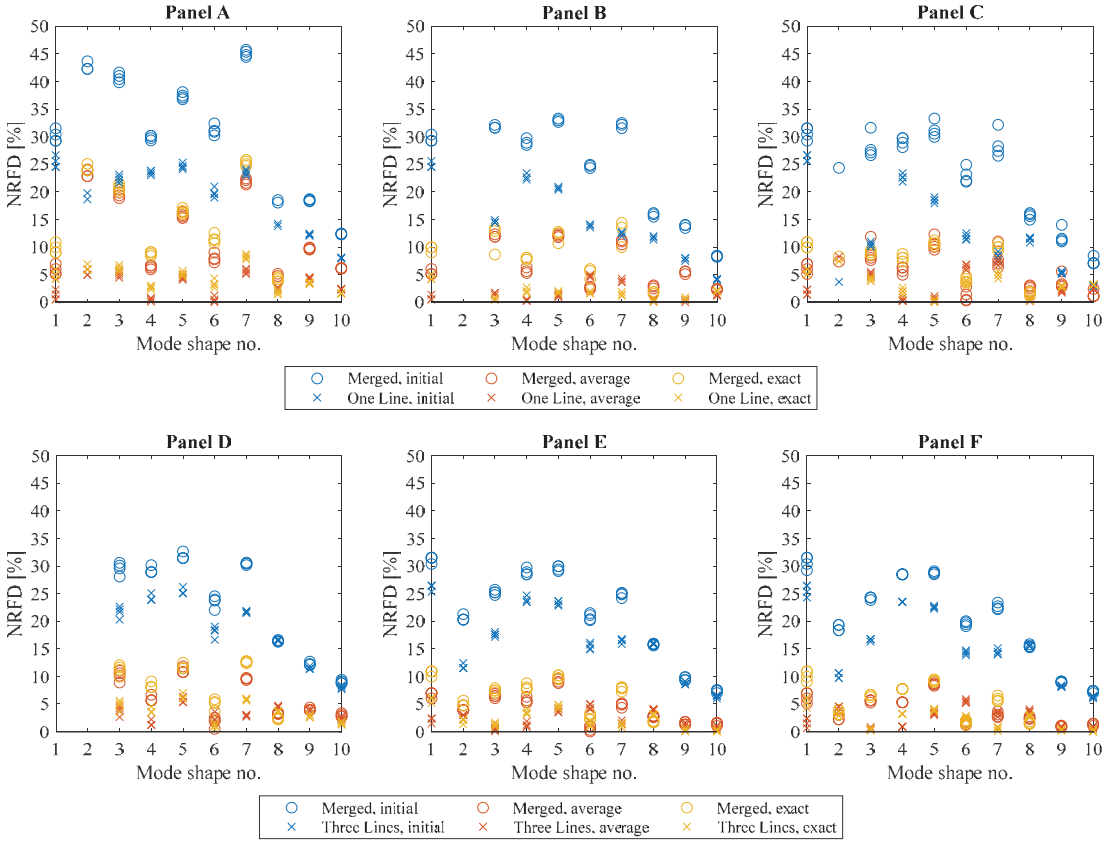

Figure 18: Normalized Relative Frequency Difference (NRFD) plots for the solid FE models of Panels A–F.

of the material properties. Interestingly, no significant improvement could be achieved by using the exact updated values for the individual structural components. For some of the modes, in some of the panels, the average material properties provided the better match, and for the other combinations of modes and panels, the exact updated values resulted in a more accurate fit.

As an alternative to the solid models of the floor panels, a structural FE model based on Timoshenko beam and Mindlin shell elements was implemented in MATLAB. The coupling of the beam and shell elements was introduced in terms of Lagrange multipliers, assuming a rigid link between the nodes of the beams and the nodes of the shell to which they were tied. Kinematically, this introduces a severe constraint, since the beams cannot rotate relative to the shell. Hence, the structural FE model was only able to produce useful results for Panels D–F. For Panels A–C (especially Panels A–B) with the single line of screws coupling each beam to the board, some modes of vibration could not be represented by the MATLAB model.

6 CONCLUSIONS AND SUGGESTIONS FOR FURTHER RESEARCH

A mock-up of a single-leaf floor panel consisting of four timber beams and a plywood board was analysed. An output-only modal analysis (OMA) was conducted for the individual structural components, and it was found that a significant variation in the eigenfrequencies can exist for similar beams coming from the same badge. One of the tested beams was about 25 % heavier than the other beams, and the difference in stiffness was even higher. Hence, some of the eigenfrequencies of the beam with the larger density were higher than the corresponding eigenfrequencies of the other beams.

Three-dimensional finite-element (FE) models were developed in Abaqus and MATLAB, in both cases assuming orthotropic material properties of the wood and modelling the plywood with five layers of the same material. In Abaqus, a solid model was used for the plywood boards and the beams, whereas the MATLAB models were based on structural finite elements employing Timoshenko beam theory and Mindlin plate theory. It was found that only three material properties, E_1, G_{12} and G_{13}, have significant influence on the modal properties of the beams, and only E_1, E_2 and G_{12} are important for the plywood boards.

The results of the experiments and the finite-element models developed in Abaqus were used as input for a model update utilizing the software FEMtools. It was possible to obtain a good match of the first eight eigenfrequencies of the individual beams and the first ten eigenfrequencies of the individual plywood boards within five iterations of the gradient-based updating procedure. Post analysis showed that the MATLAB models provided almost equally accurate results for the individual components when using the updated material properties.

Six configurations of the assembled floor were considered. In all cases, the plywood board was fastened to the beams by screws. Three different distances between the screws in the longitudinal direction were considered, and either one single or three lines of screws were used per beam. The panels were all analysed by OMA, and the panel with single lines of screws and the largest distance between the screws was found to have significantly lower eigenfrequencies than the panel with shorter distance between the screws and three lines of screws per beam.

The experimental results for the floor panels were used to validate the FE models of the panels. It was found that the FE models performed poorly when the plywood board was simply merged with the beams within the models. When introducing an artificial soft elastic layer and a model of the screws into the FE models, higher accuracy could be obtained. A further improvement was achieved by using the updated material properties. However, no conclusion could be made whether the exact values extracted for each individual component should be used, or if average values based on all beams or plates should be employed. In any case, the relative error between the eigenfrequencies of the mock-ups and the FE models of the floor panels were about 0–5 %.

It was found that an FE model based on structural finite elements, i.e. beam and shell elements, could not represent the response of the panels with only single lines of screws and the longer distances between the screws. With a direct coupling between the nodes of the beams and those of the plate, the link is too rigid. One idea for future research is to develop a model with a flexible link between the beams and the plate, using the existing OMA results to calibrate the translational and rotational springs of this coupling.

Further, the present analyses all assumed that the material in each beam is homogeneous, and that the material in all layers of the plywood boards is identical and homogeneous within each layer. Obviously, wood is a heterogeneous material with significant variations of the properties from one position to another. This was demonstrated, for example, by the variation in material density between the four beams in this study. Future research on the heterogeneity of timber and plywood, and its impact on the modal properties of floor panels, is proposed. Identification based on the mode shapes, not only the eigenfrequencies, should be performed.

Abstract. *The ductility factor in terms of R/C cross-sections' curvatures ($\mu_{1/r}$ or μ_{ϕ}) possesses a significant role in the framework of the Greek code for structural intervention (KAN.EPE.). This factor is used for the classification of the verification methods in either those which are expressed in terms of forces or deformations, for the calculation of the required mechanical volumetric ratio of the confining reinforcement in case of interventions aiming to increase the local ductility of R/C members and for the estimation of the ductility in terms of chord rotations μ_{θ}. The factor μ_{θ} is, according to KAN.EPE., the parameter which better describes the inelastic deformations at the ends of R/C members where the flexural deformations coexist with shear deformations and rotations of end-sections due to anchorage slip of the reinforcement bars. Due to the fact that $\mu_{1/r}$ and μ_{θ} factors are crucial for the evaluation of R/C members' seismic performance, KAN.EPE. provides different methodologies for their estimation. In the present paper a primary comparative evaluation of them is attempted, with emphasis on the investigation of the equation that is proposed by KAN.EPE. for the relation between μ_{θ} and $\mu_{1/r}$. For this investigation, a R/C column with rectangular cross-section and different concrete grades, and levels of longitudinal and transverse reinforcement is examined. The results of the analyses performed herein can be characterized only as indicative for the range of the values of $\mu_{1/r}$ and μ_{θ} factors which can be extracted by the methods proposed by KAN.EPE. Thus, the results of the present paper provide a motivation for further investigations about more proper alternative relations between the $\mu_{1/r}$ and μ_{θ} factors.*

1 INTRODUCTION

In the provisions of the code for structural interventions (KAN.EPE.) [1] which is applied in Greece for the evaluation of seismic capacity and the interventions of Reinforced Concrete (R/C) buildings, the seismic performance of the linear R/C structural members which are characterized as "quasi-ductile" is verified in terms of deformations, in case of inelastic analysis procedures. Additionally, one of the potential types of interventions for the critical regions of linear R/C members (when the target is the improvement of their capacity against flexure with axial force) is the increase of their local ductility. In both aforementioned cases, the chord rotations in the critical regions of the linear R/C members at flexural yield (θ_y) and failure (θ_u) must be estimated. To this end, KAN.EPE. recommends equations (derived through regression analyses of validated experimental results) which lead to the required estimation of the values of θ_y and θ_u and subsequently the estimation of the ductility in terms of chord rotations (μ_θ). Based on the available local ductility μ_θ KAN.EPE. classifies the failure mechanisms as "quasi-ductile" or "brittle" ones.

Another significant parameter which is used in KAN.EPE. for the assessment and redesign of linear "quasi-ductile" R/C structural members is the curvature ductility $\mu_{1/r}$ (the symbol μ_φ is also used for the same parameter). More specifically, $\mu_{1/r}$ is used for the classification of failure mechanisms as "quasi-ductile" or "brittle" ones, for the determination of the required mechanical volumetric ratio of confining hoops in the critical regions of the linear R/C members (where the increase of the local ductility is required), and for the verification of the selected values for the local R/C members' ductility "m". Thus, KAN.EPE. provides alternative methods for the calculation of $\mu_{1/r}$.

It must also be stressed that according to KAN.EPE. the relation between μ_θ and $\mu_{1/r}$ is used for the estimation of the available plastic chord rotation in critical regions of R/C structural members after the interventions, as well as the for the determination of the appropriate mechanical volumetric ratio of confining hoops when the chord rotations are utilized to define the targeted performance level.

The scope of the present investigation is a primary comparative evaluation of the different methodologies which KAN.EPE. proposes for the estimation of $\mu_{1/r}$, with emphasis on the equation that is proposed for the relation between μ_θ and $\mu_{1/r}$. To this end, a R/C column with rectangular cross-section and different concrete grades, and levels (mechanical volumetric ratios) of longitudinal and transverse reinforcement was used.

2. BRIEF PRESENTATION OF THE PROVISIONS OF KAN.EPE. ABOUT THE ESTIMATION OF THE DUCTULITY OF R/C MEMBERS

It is well-known that in the framework of earthquake resistance design of new R/C structures, as well as for the seismic evaluation of existing ones, the estimation of the ductility of R/C members (i.e. their ability to deform plastically without significant loss of strength) is a process of paramount importance. Generally, the ductility is defined in terms of displacements ($\mu_\delta=\delta_u/\delta_y$), rotations of members' ends ($\mu_\theta=\theta_u/\theta_y$) and curvatures of cross-sections ($\mu_{1/r}=\varphi_u/\varphi_y$), (e.g. [2], [3]). Recognizing this fact, KAN.EPE. provides (see comments of §7.1.2.1) that for the critical failure mechanism in crucial regions of structural members due to bending moments (with or without axial force) the parameters which are appropriate for the simulation of their mechanical behavior are the bending moments (M) as stress measure and the curvatures 1/r as deformation measure. However, theoretical and experimental studies indicate that especially in case of R/C members' crucial regions when the inelastic behavior is controlled by flexure (i.e. bending moments with or without axial force) the parameter which better describes their deformation is the chord rotation "θ" at the ends (see KAN.EPE. §7.1.2.1 com-

ments). This is based on the fact that in R/C elements the flexural deformations coexist with shear deformations and rotations of end-sections due to anchorage slip of the reinforcement bars in the region of their ends (e.g. [4], [5]). The definition of the chord rotation θ_{ch} of a R/C member is illustrated in Fig. 1. Therefore, in Chapter 7 KAN.EPE. provides equations for the estimation of the chord rotation at flexural yield (θ_y), as well as at flexural failure (θ_u). Using these equations one can estimate the ductility of R/C members in terms of chord rotation ($\mu_\theta=\theta_u/\theta_y$).

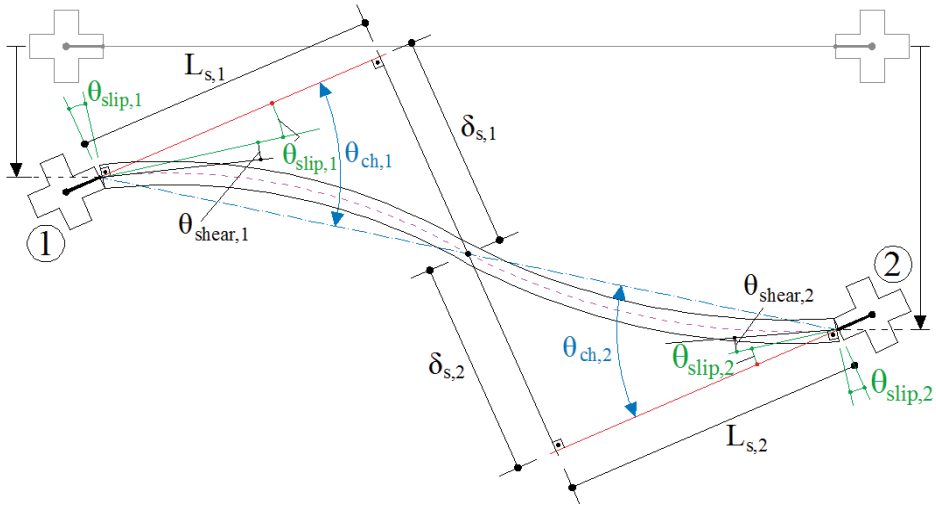

Figure 1: Definition of the chord rotation θ_{ch} at the ends of a R/C member

However, despite the fact that the utilization of the chord rotations at the ends of R/C members is considered as more efficient for the evaluation of their inelastic flexural behavior, KAN.EPE. in §8.2.3 (where provisions about the interventions with the objective to increase the local ductility are given) states that the required mechanical volumetric ratio of the confining reinforcement must be estimated through a selected target value of the curvature ductility $\mu_{1/r,req}$ (§8.2.3c) for all the critical cross-sections of primary members. Besides, in §8.2.3d it is stated that when the redesign objective is expressed in terms of required maximum permitted values of chord rotations θ_d, then the corresponding curvature ductility $\mu_{1/r}$ (which is used for the calculation of the confining reinforcement) can be estimated using reliable relations between μ_θ and $\mu_{1/r}$. To this end, it is permitted in the comments of §8.2.3d the utilization of the Eq. (1):

$$\mu_{1/r} = 3\cdot\mu_\theta - 2 \tag{1}$$

According to the comments of §8.2.3d, the values of μ_θ ($=\theta_u/\theta_y$) in Eq. (1) are calculated on the basis of the skeleton behavior diagram of Appendix 4.4 (Fig. 2).

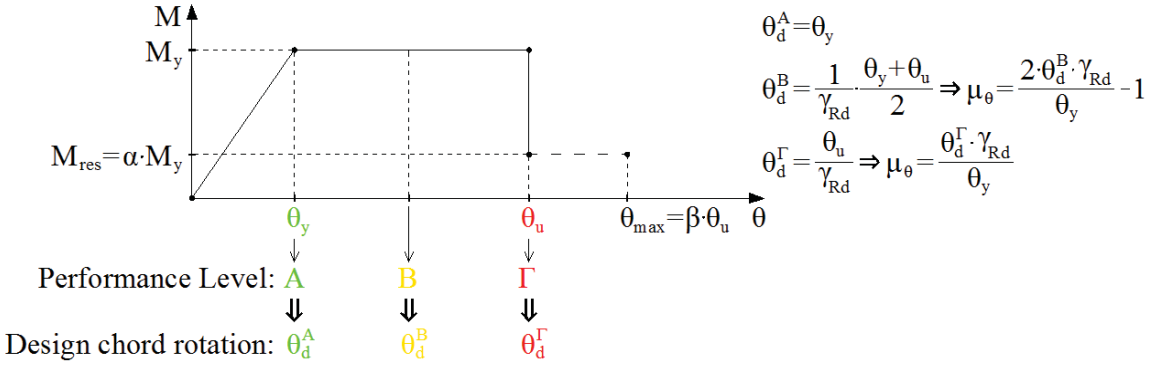

Figure 2: Calculation of the design values of θ for the three performance levels proposed by KAN.EPE.

Eq. (1) is also proposed (solved for μ_θ) in the comments of §6.5 for the approximative estimation of the available plastic chord rotation in the critical regions of R/C members after the required interventions (according to the comments of §6.5, μ_θ is approximately equal to ductility in terms of displacements μ_δ, i.e. $\mu_\theta \cong \mu_\delta$).

The available curvature ductility $\mu_{1/r}$ is also used for the choice of the proper verification method. The verification methods are classified in methods which are expressed in terms of forces or deformations. This classification is based on the anticipated type of members' failure (ductile or brittle). More specifically, in §4.1.4iii KAN.EPE. states that if the available ductility $\mu_{1/r}$ is greater than 3.0, then the members' behavior is characterized as "quasi-ductile", and the proper verification method in this case is expressed in terms of deformations.

Obviously, the estimation of the curvature ductility $\mu_{1/r}$ is of great interest within the framework of KAN.EPE. Therefore, the following methods are proposed for its calculation:

- Using the cross-sections' moment-curvature (M-1/r) diagrams (§6.4, see Fig. 3). The sequence of the steps which should be performed is described in §6.4b (a modified sequence for the case in which the member's ductility is achieved through external confinement using steel components or FRP is presented in §6.4c). However, the calculation of the (M-1/r) diagrams requires the utilization of cross-sections' analysis dedicated software.

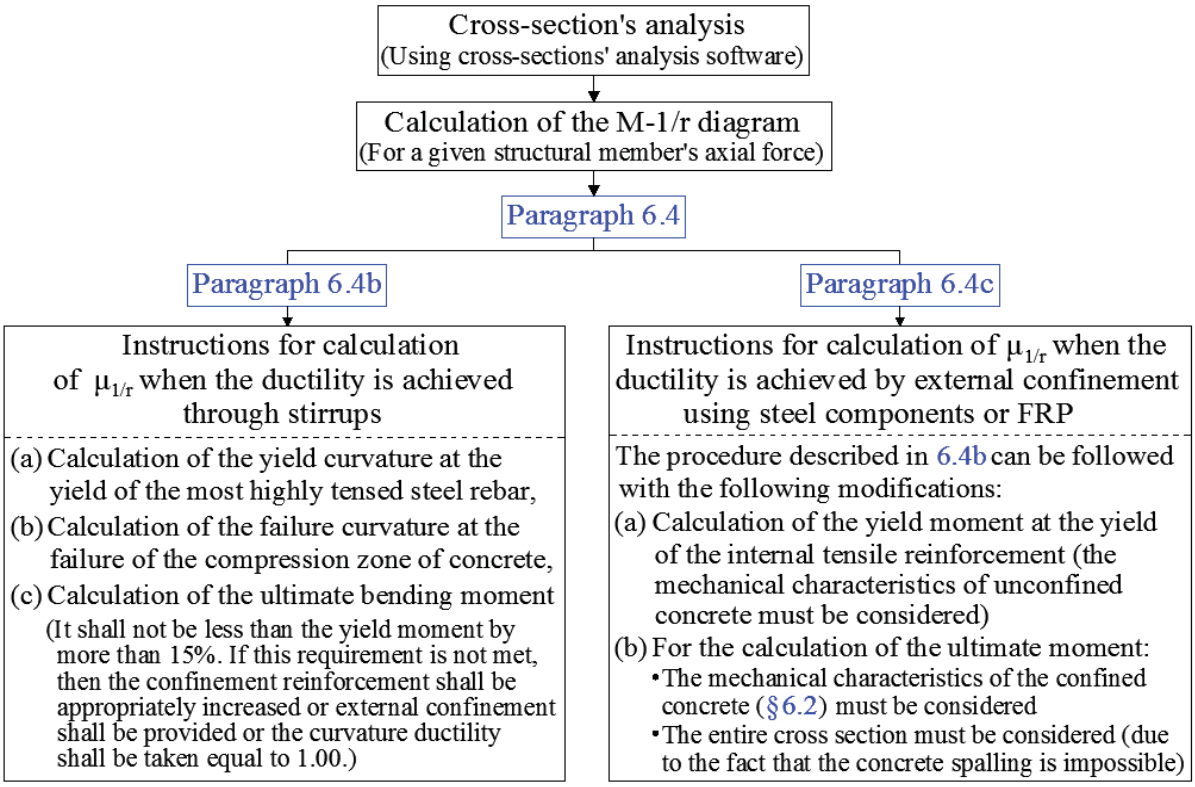

Figure 3: The provisions given by KAN.EPE. for the estimation of $\mu_{1/r}$ using the M-1/r diagrams

- Utilizing the φ_u and φ_y values which can be calculated using the provisions of §7.2.4 and §7.2.2 respectively (see comments of §6.4b). In these paragraphs it is stated that the calculation of φ_y and φ_u can be optionally accomplished using the methods that are given in Appendices 7A and 7E. These methods are based on specific assumptions and for this reason are not always applicable. It must be noted that regarding the calculation of φ_y, approximate semi-empirical expressions are also given in Appendix 7A.
- Using approximative (but reliable) closed-form expressions from the literature (comments of §6.4). As an example, KAN.EPE. recommends the expression:

$$\mu_{1/r} = \frac{f_{cc}}{f_c} \cdot \frac{\lfloor \varepsilon_{cu,c} - (\varepsilon_{cc}/3) \rfloor}{1.75 \cdot \nu \cdot \varepsilon_{sy}} \text{ with } (\varepsilon_{cu,c} \geq 0.004) \quad (2)$$

Where: f_{cc} and f_c are the strength of the confined and the unconfined concrete respectively, $\varepsilon_{cu,c}$ is the compressive failure strain of the confined concrete in the cross-section's core, ε_{cc} is the compressive strain of concrete which corresponds to the strength of the confined concrete f_{cc}, ε_{sy} is the yield strain of the longitudinal rebars' steel, and ν is the normalized axial force.

Eq. (2) is applied to the spalled cross-section in case of confinement through stirrups or continuous steel laminates and to the entire cross-section in case of confinement through steel cage, jacket of FRP. In the latter case Eq. (2) takes the following form:

$$\mu_{1/r} = \frac{f_{cc}}{f_c} \cdot \frac{\varepsilon_{cu,c}}{2.6 \cdot \nu \cdot \varepsilon_{sy}} \quad (3)$$

Figure 4 illustrates the methods for the estimation and the applications which are provided by KAN.EPE. for the curvature ductility $\mu_{1/r}$.

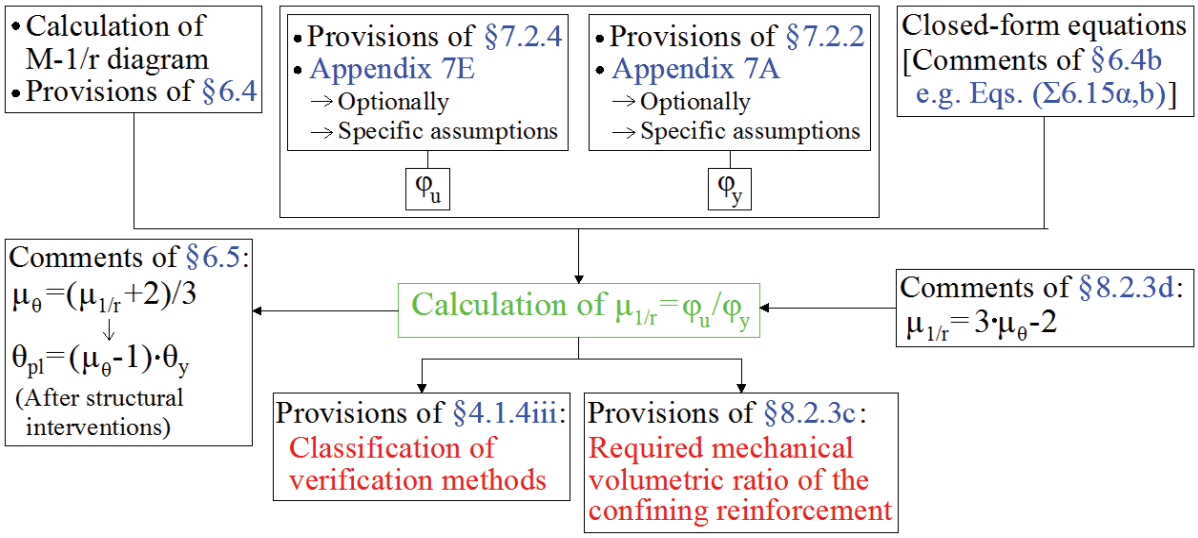

Figure 4: Ductility $\mu_{1/r}$ – methods for estimation and the corresponding applications proposed by KAN.EPE.

3. PARAMETRIC INVESTIGATIONS

3.1 Data, details and description of the parametric investigations

In order to evaluate the different procedures which are proposed by KAN.EPE. for the estimation of the curvature ductility $\mu_{1/r}$, a R/C column with rectangular cross-section and different characteristics regarding the concrete grade as well as the longitudinal and transverse reinforcement was used. Figure 5 illustrates the data of the examined column. The clear length of the column was taken equal to 3m, whereas as construction year 1990 was considered.

It must be noted that the assumed stress-strain diagram for the confined concrete was based on the model which KAN.EPE. provides in §6.2.1. The corresponding diagram for the unconfined concrete was based on the model presented in EN1992-1-1 [6]. As regards the assumed stress-strain diagram for the steel of rebars and stirrups, the model which is proposed in Appendix 7E was considered. The combination of the different assumptions for the concrete grades, the longitudinal reinforcement and the transverse reinforcement led to 64 different

analysis cases. For each case the curvature ductility $\mu_{1/r}$ and the chord rotation ductility μ_θ were calculated for 18 values of column's normalized axial force between ν=0.0 and ν=0.85.

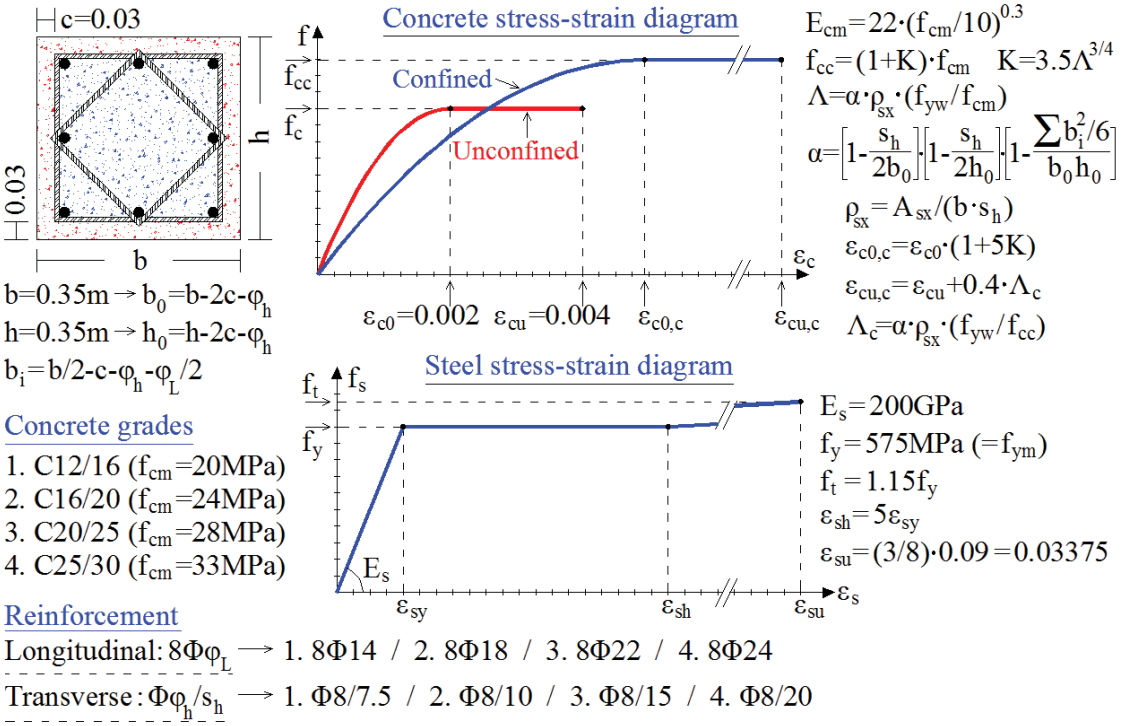

Figure 5: The different cases and the corresponding parameters which are considered in the investigation

Regarding the M-1/r diagrams, two different approaches were followed (Fig. 6):

- Consideration of a bi-linearized equivalent elasto-plastic diagram which results from the analytically evaluated (through cross-section analysis) curve assuming a horizontal branch after the effective yield curvature $\varphi_{y,eff}$ (Fig. 6a). In this case the ultimate moment M_u is taken as equal to the effective yield moment $M_{y,eff}$. It also must be noted that in this case M_u and $\varphi_{y,eff}$ are calculated using the "equal areas" rule.
- Consideration of a bi-linearized equivalent elasto-plastic diagram which results from the analytically evaluated (through cross-section analysis) curve assuming a sloping branch after the effective yield curvature $\varphi_{y,eff}$ (Fig. 6b). The ultimate moment M_u is taken as equal to the ultimate moment evaluated by the cross-section analysis. In this case, the yield curvature $\varphi_{y,eff}$ and the slope (αK_{el}) of the branch after the effective yield are calculated using the "equal areas" rule.

In both cases the assumption that the initial stiffness (K_{el}) is determined as the secant stiffness that corresponds to a moment equal to the 60% of $M_{y,eff}$ was made.

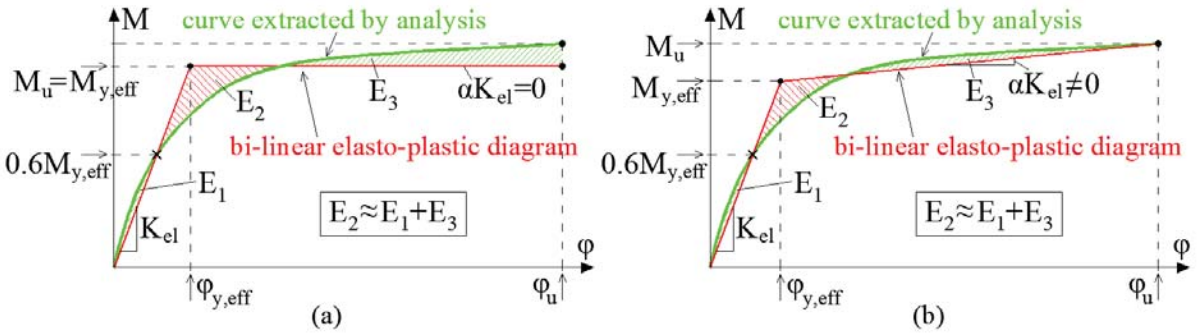

Figure 6: The two utilized approaches for the bilinearization of the M-1/r diagrams

For the cross-sections' analyses the XTRACT software [7] was utilized, whereas for all other required calculations (for example the implementation of flow charts of Appendices 7A and 7E) appropriate computer programs using the Fortran programming language were developed.

3.2 Results of the parametric investigations

In this section the results of $\mu_{1/r}$ and μ_θ calculations for the cross-sections which are illustrated in Fig. 5 on the basis of KAN.EPE. provisions are presented in three stages:

- At the first stage (Subsection 3.2.1) the results pertaining to the calculation of the curvature ductility $\mu_{1/r}$ are presented and briefly discussed.
- At the second stage (Subsection 3.2.2) the results pertaining to the calculation of the curvature in terms of the members' ends chord rotation μ_θ are presented and briefly discussed.
- Finally, at the third stage (Subsection 3.2.3) the proposed relation between $\mu_{1/r}$ and μ_θ (Eq. 1) is implemented and compared with the relations provided directly from the various $\mu_{1/r}$ and μ_θ calculation methods that are used in stages one and two.

3.2.1 Comparison between the methods provided by KAN.EPE. for the $\mu_{1/r}$ calculation

As it was mentioned in section 2, the three methods for the estimation of $\mu_{1/r}$ (Fig. 4) which are provided by KAN.EPE. are compared using the data of Fig. 5. It must be noted that regarding the method which is based on the calculation of the M-1/r diagram, both approaches illustrated in Fig. 6 for its bilinearization were implemented. Thus, the following four different values of curvature ductility $\mu_{1/r}$ for each one of the 64 different examined cases were calculated (the symbol μ_φ instead of $\mu_{1/r}$ will be used from now on in the present paper, i.e. $\mu_\varphi=\mu_{1/r}$):

(a) μ_φ^{SBH}: the value of the curvature ductility $\mu_{1/r}$ which is based on the bilinearization of the M-1/r diagram considering a horizontal branch after the effective yield curvature (Fig. 6a).
(b) μ_φ^{SBI}: the value of the curvature ductility $\mu_{1/r}$ which is based on the bilinearization of the M-1/r diagram considering an inclined branch after the effective yield curvature (Fig. 6b).
(c) μ_φ^{KAP}: the value of the curvature ductility $\mu_{1/r}$ which is based on the procedures which are proposed by KAN.EPE. in Appendices 7A and 7E for the estimation of φ_y and φ_u respectively.
(d) μ_φ^{KAE}: the value of the curvature ductility $\mu_{1/r}$ which is based on the closed-form expression proposed by KAN.EPE. (Eq. 2).

The diagrams of Figs. 7, 8, 9 illustrate the variation of the calculated μ_φ values in relation to the normalized axial force $\nu(=N/bhf_c)$. It must be noted that after the initial evaluation of the μ_φ-ν curves it was observed that the results which correspond to cross-sections with confinement reinforcement Φ8/7.5 and Φ8/10 were qualitatively almost the same. Thus, only the results that correspond to confinement reinforcement Φ8/7.5 along with the results extracted considering confinement reinforcement Φ8/15 and Φ8/20 will be illustrated. Moreover, for the same reason the results which correspond to the longitudinal reinforcement 8Φ24 are omitted because are qualitatively almost the same with the results for longitudinal reinforcement 8Φ22. Finally, almost the same conclusion is valid regarding the concrete grades C20/25 and C25/30. Thus, the presentation of the results concerning the concrete grade C25/30 is also omitted. The three above initial observations constitute conclusions that can be mentioned in the framework of the present investigation, namely the behavior of the μ_φ-ν curves extracted from the methods proposed by KAN.EPE. presents no significant qualitatively chances in the case of high-level confinement, in the case of high ratios of longitudinal reinforcement and in the case of high concrete grades.

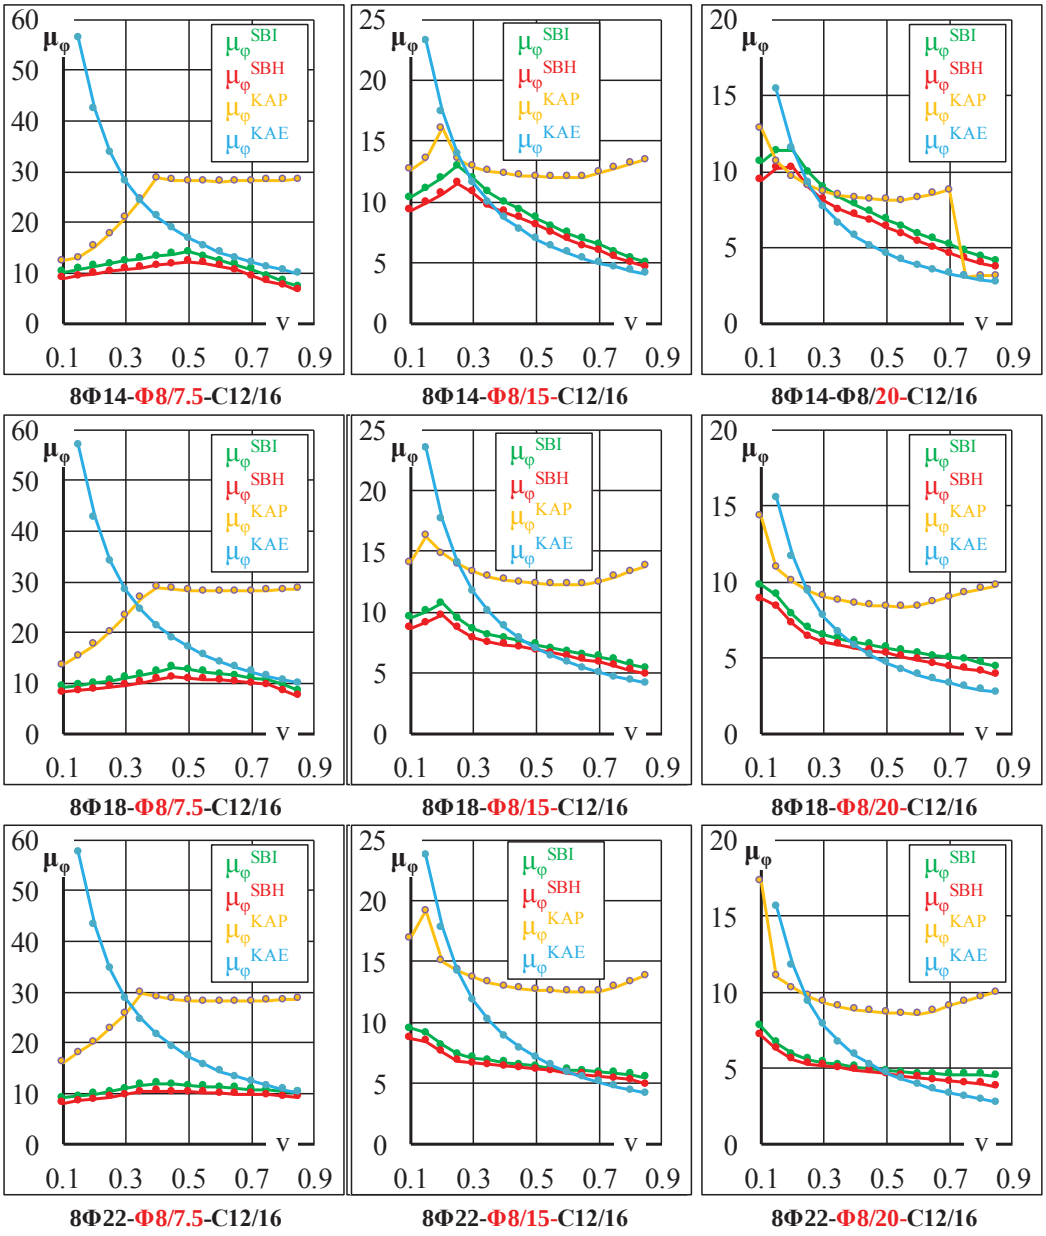

Figure 7: Variation of the μ_φ values calculated through the examined methods in relation to ν – Concrete C12/16

From the study of Fig. 7 the following main conclusions can be extracted:

- The differences between μ_φ^{SBH} and μ_φ^{SBI} values are very small, as it was expected because the only difference between the two methods of bilinearization is the calculation of the effective yield curvature $\varphi_{y,eff}$ (in both cases the values of φ_u are equal). These differences (of $\varphi_{y,eff}$ and consequently of μ_φ) fluctuate between 8% and 17% for the 64 studied cases.
- The μ_φ^{SBH} (or μ_φ^{SBI}) and μ_φ^{KAE} values have small differences for ν>0.5. This means that the approximative closed-form Eq. 2 is capable to provide results which are close to the results based on the reliable method of the calculation of M-1/r diagram in the range ν=0.5-0.85. On the contrary, use of Eq.2 leads to extremely large (and nonrealistic) values for μ_φ in the range ν=0.1-0.3. The above described behavior of the μ_φ values which are extracted from Eq. 2 (rapid decrease of μ_φ for small ν values and small decrease for large values of ν) is due to the fact that this equation consists of a quotient that contains the normalized axial force ν in the denominator.

- The methods which are based on the bilinearization of M-1/r diagrams (values μ_φ^{SBH} and μ_φ^{SBI}) extract relatively constant values (almost horizontal μ_φ-ν curves mainly in cases of longitudinal reinforcement 8Φ18, 8Φ22) in comparison with the other two studied methods.
- The curve μ_φ^{KAP}-ν consists of two distinguishable branches especially in case of high confinement level (Φ8/7.5). In the first branch (ν≈0-0.37) the values of μ_φ are increasing, whereas for ν>0.4 the corresponding values remain almost constant. For medium confinement level the curve μ_φ^{KAP}-ν has also two braches but the first one is stopped for ν≈0.15. Finally, for low level confinement level (Φ8/20) the curves μ_φ^{KAP}-ν have intense downward trend for (ν≈0-0.15), whereas for ν>01.5 remain almost constant. The only exception regards the case of low ratio of longitudinal reinforcement (8Φ14) in which after the value ν=0.7 the curve μ_φ^{KAP}-ν shows an abrupt decrease.
- Finally, regarding the differences between the μ_φ^{SBH} (or μ_φ^{SBI}) and μ_φ^{KAP} values, it must be noted that are in general much higher from all other comparison cases for ν>0.3.

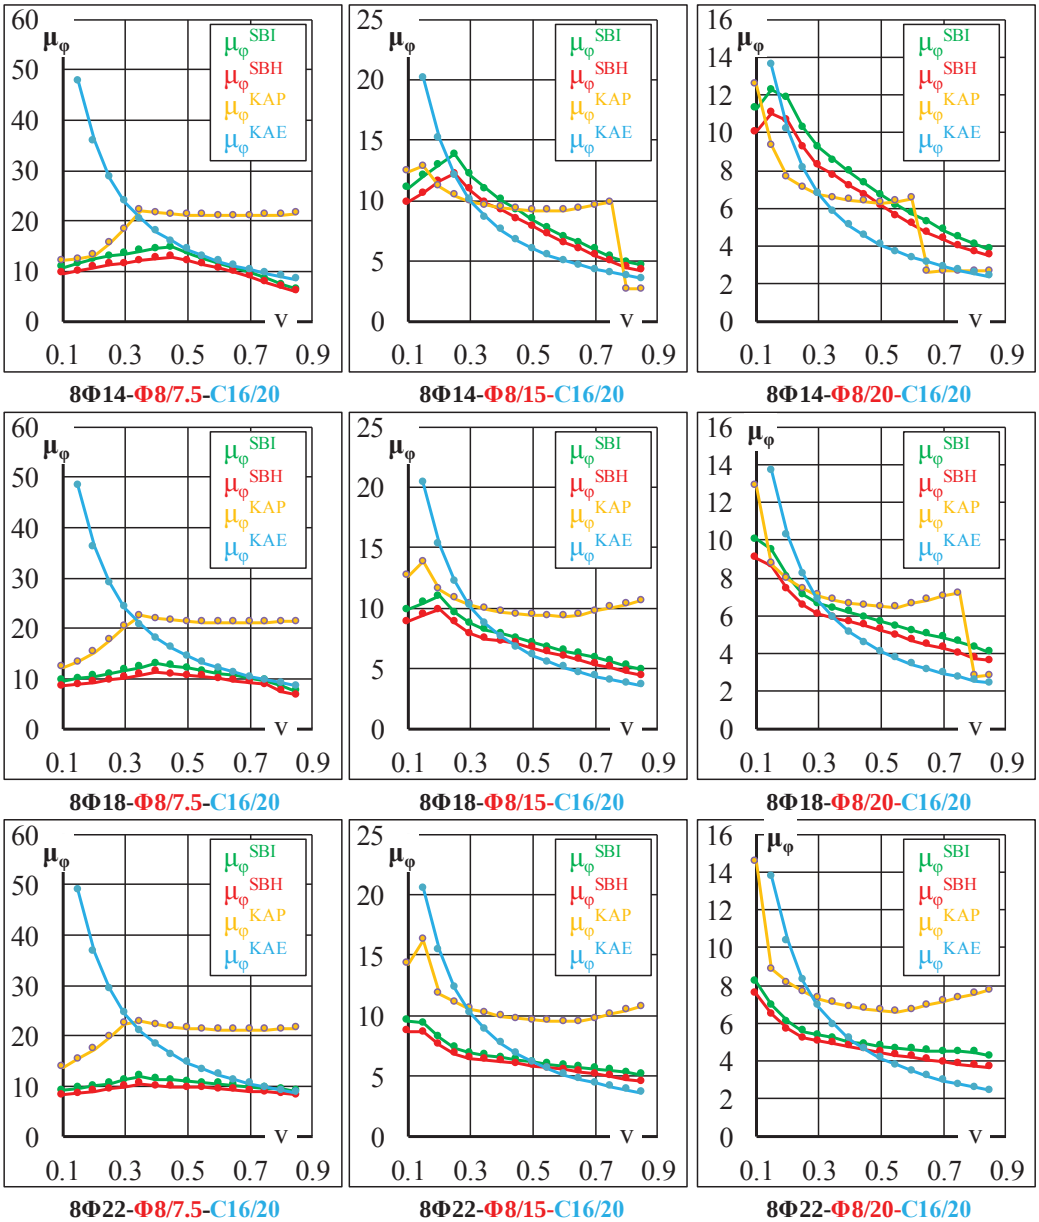

Figure 8: Variation of the μ_φ values calculated through the examined methods in relation to ν – Concrete C16/20

From the combined study of Figs. 7 and 8 the following significant differences regarding the conclusions which were already presented above can be referred:

- In cases of transverse reinforcement Φ8/7.5 and Φ8/10 the only significant diversification is the reduction of the differences between the values μ_φ^{SBH} (or μ_φ^{SBI}) and μ_φ^{KAP}.
- In case of transverse reinforcement Φ8/20 the μ_φ^{KAP} values significantly converge to μ_φ^{SBH}, μ_φ^{SBI} and μ_φ^{KAE}, especially for low and medium longitudinal reinforcement ratio in the entire range of ν values.
- With the exception of the case of transverse reinforcement Φ8/7.5, the closed-form expression (Eq. 2) provides values closer to the values that are extracted from the other more detailed methods proposed by KAN.EPE. especially for ν>0.2.
- The abrupt drop of μ_φ^{KAP} values appears mainly in cases which correspond to low ratios of transverse reinforcement and low and medium ratios of longitudinal reinforcement.

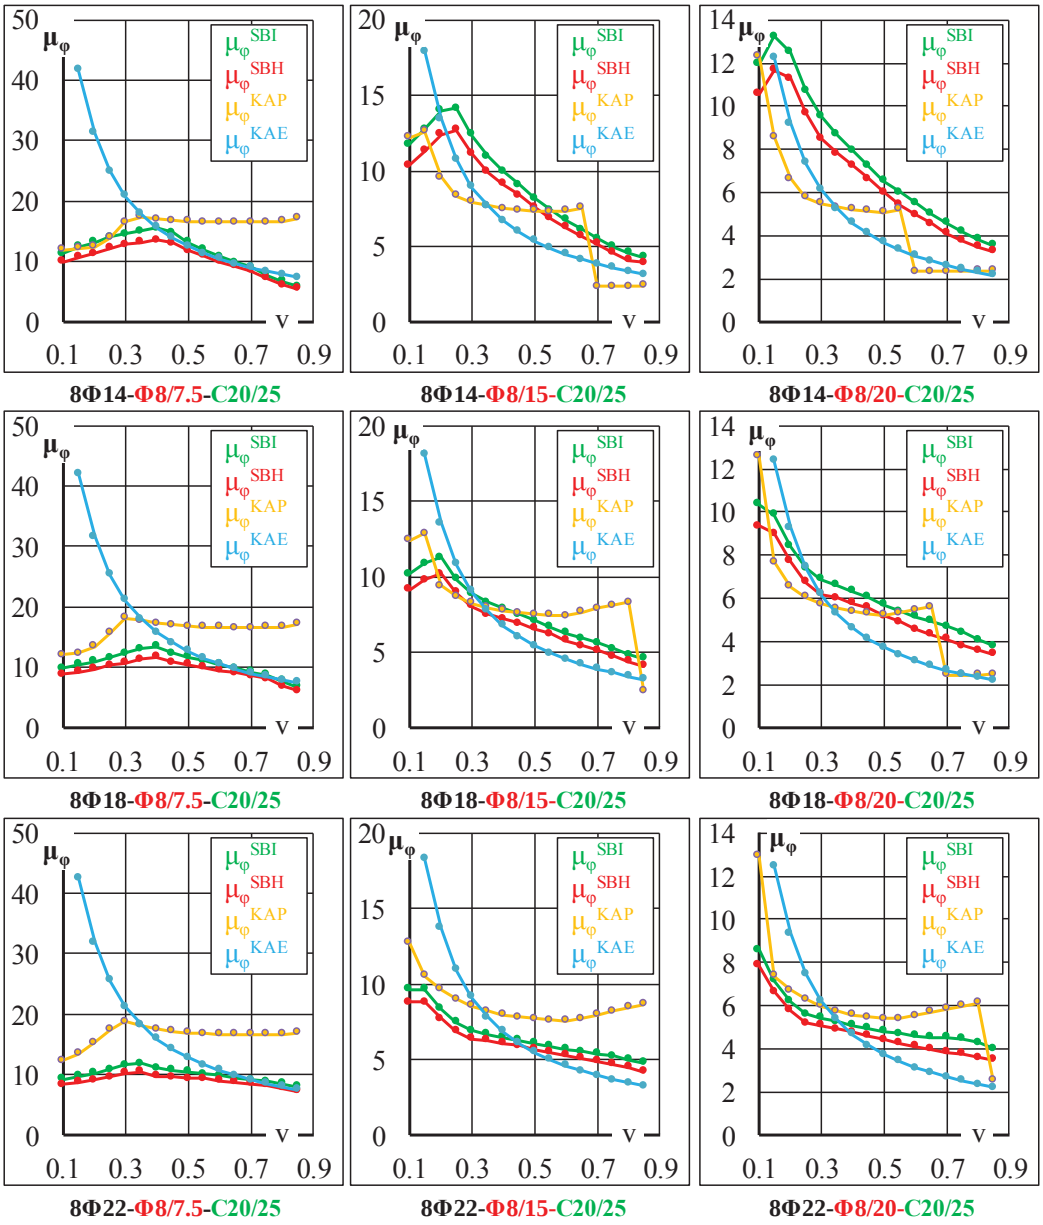

Figure 9: Variation of the μ_φ values calculated through the examined methods in relation to ν – Concrete C20/25

Finally, from the combining study of Figs. 8 and 9 the following significant differences are observed:

- The differences between the μ_φ^{SBH} (or μ_φ^{SBI}) and μ_φ^{KAP} values are even smaller in case of the higher concrete grade C20/25.
- The occasionally observed abrupt drops of the μ_φ^{KAP} values appear more often and for lower values of ν in case of the higher concrete grade C20/25.

3.2.2 Comparison between the methods provided by KAN.EPE. for the μ_θ calculation

As it was mentioned in section 2 of the present paper, KAN.EPE. provides closed-form expressions for the estimation of the chord rotation at flexural yield (θ_y, equation Σ.2a for beams and columns), as well as at flexural failure (θ_u, equation Σ.11a). Moreover, as it was also mentioned in section 2, KAN.EPE. in §6.5 provides the implementation of the ductility in terms of chord rotation ($\mu_\theta=\theta_u/\theta_y$) for the relation between μ_θ and μ_φ through Eq. 1. The examination of equation Σ.2a (comments of §7.2.2d of KANE.EPE) leads to the conclusion that the estimation of θ_y requires the calculation of the yield curvature φ_y (or $(1/r)_y$), whereas the estimation of θ_u on the basis of equation Σ.11a (comments of §7.2.4b of KANE.EPE) is independent from φ_u. Thus, the different approaches regarding the estimation of μ_θ are focused on the method that is used for the calculation of φ_y. In other words, in the framework of the present investigation the equation proposed by KAN.EPE. for the estimation of θ_y is considered as a function of φ_y (i.e. $\theta_y=\theta_y(\varphi_y)$). Consequently, the ductility in terms of chord rotation μ_θ is also considered (only for the scope of the present investigation) as a function of φ_y (i.e. $\mu_\theta=\mu_\theta(\varphi_y)$). For this reason, three different approaches for the estimation of μ_θ (on the basis of equations Σ.2a and Σ.11a) were examined for the 64 cases of Fig. 5:

- $\mu_\theta^{SBH}=\mu_\theta(\varphi_y^{SBH})$: the value of μ_θ estimated using the value of $\varphi_{y,eff}$ extracted from the bilinearization of M-1/r diagram considering a horizontal branch after the effective yield curvature (Fig. 6a).
- $\mu_\theta^{SBI}=\mu_\theta(\varphi_y^{SBI})$: the value of μ_θ estimated using the value of $\varphi_{y,eff}$ extracted from the bilinearization of M-1/r diagram considering an inclined branch after the effective yield curvature (Fig. 6b).
- $\mu_\theta^{KAP}=\mu_\theta(\varphi_y^{KAP})$: the value of μ_θ estimated using the value of φ_y extracted from the procedure proposed by KAN.EPE. in Appendix 7A.

The initial evaluation of the diagrams μ_θ^{SBH}-ν, μ_θ^{SBI}-ν and μ_θ^{KAP}-ν, indicates that the greater differences between the three investigated approaches for the calculation of μ_θ are those between μ_θ^{SBH} (or μ_θ^{SBI}) and μ_θ^{KAP}. This conclusion was expected since the differences between $\theta_y(\varphi_y^{SBH})$ and $\theta_y(\varphi_y^{SBI})$ are significantly smaller than the corresponding differences between $\theta_y(\varphi_y^{SBH})$ (or $\theta_y(\varphi_y^{SBI})$) and $\theta_y(\varphi_y^{KAP})$.

Another significant observation is that the greater differences between μ_θ^{SBH} (or μ_θ^{SBI}) and μ_θ^{KAP} correspond generally to the case of transverse reinforcement Φ8/7.5. Thus, only the diagrams μ_θ-ν extracted from the cross-sections with Φ8/7.5 are illustrated in Fig. 10.

The main conclusions which arise from the study of Fig. 10 are the following:

- The curves μ_θ^{SBH}-ν and μ_θ^{SBI}-ν are in any case descending, which means that the ductility in terms of chord rotations is reduced as the normalized axial force ν increases.
- The curves μ_θ^{KAP}-ν are also in the majority of the studied cases descending, but the corresponding decrease of μ_θ^{KAP} values is generally lower than the decrease of the μ_θ^{SBH} and μ_θ^{SBI} values. However, mainly in case of the lower ratio of longitudinal reinforcement 8Φ14 (and secondarily in case of 8Φ18) the curves μ_θ^{KAP}-ν do not have the same behavior in the entire range of the ν values. More specifically, for ν<0.2-0.3 the μ_θ^{KAP}-ν curves drop significantly, but for greater ν values remain almost constant.

- In the vast majority of the examined cases the μ_θ^{KAP} values are greater than the μ_θ^{SBH} and μ_θ^{SBI} values, with the exception the cases of concrete grades C16/20, C20/25 and C25/30 and for ν values lower than 0.2-0.3.
- Generally, the differences between the μ_θ^{KAP} values and the μ_θ^{SBH} and μ_θ^{SBI} values decrease as the concrete grade increases.

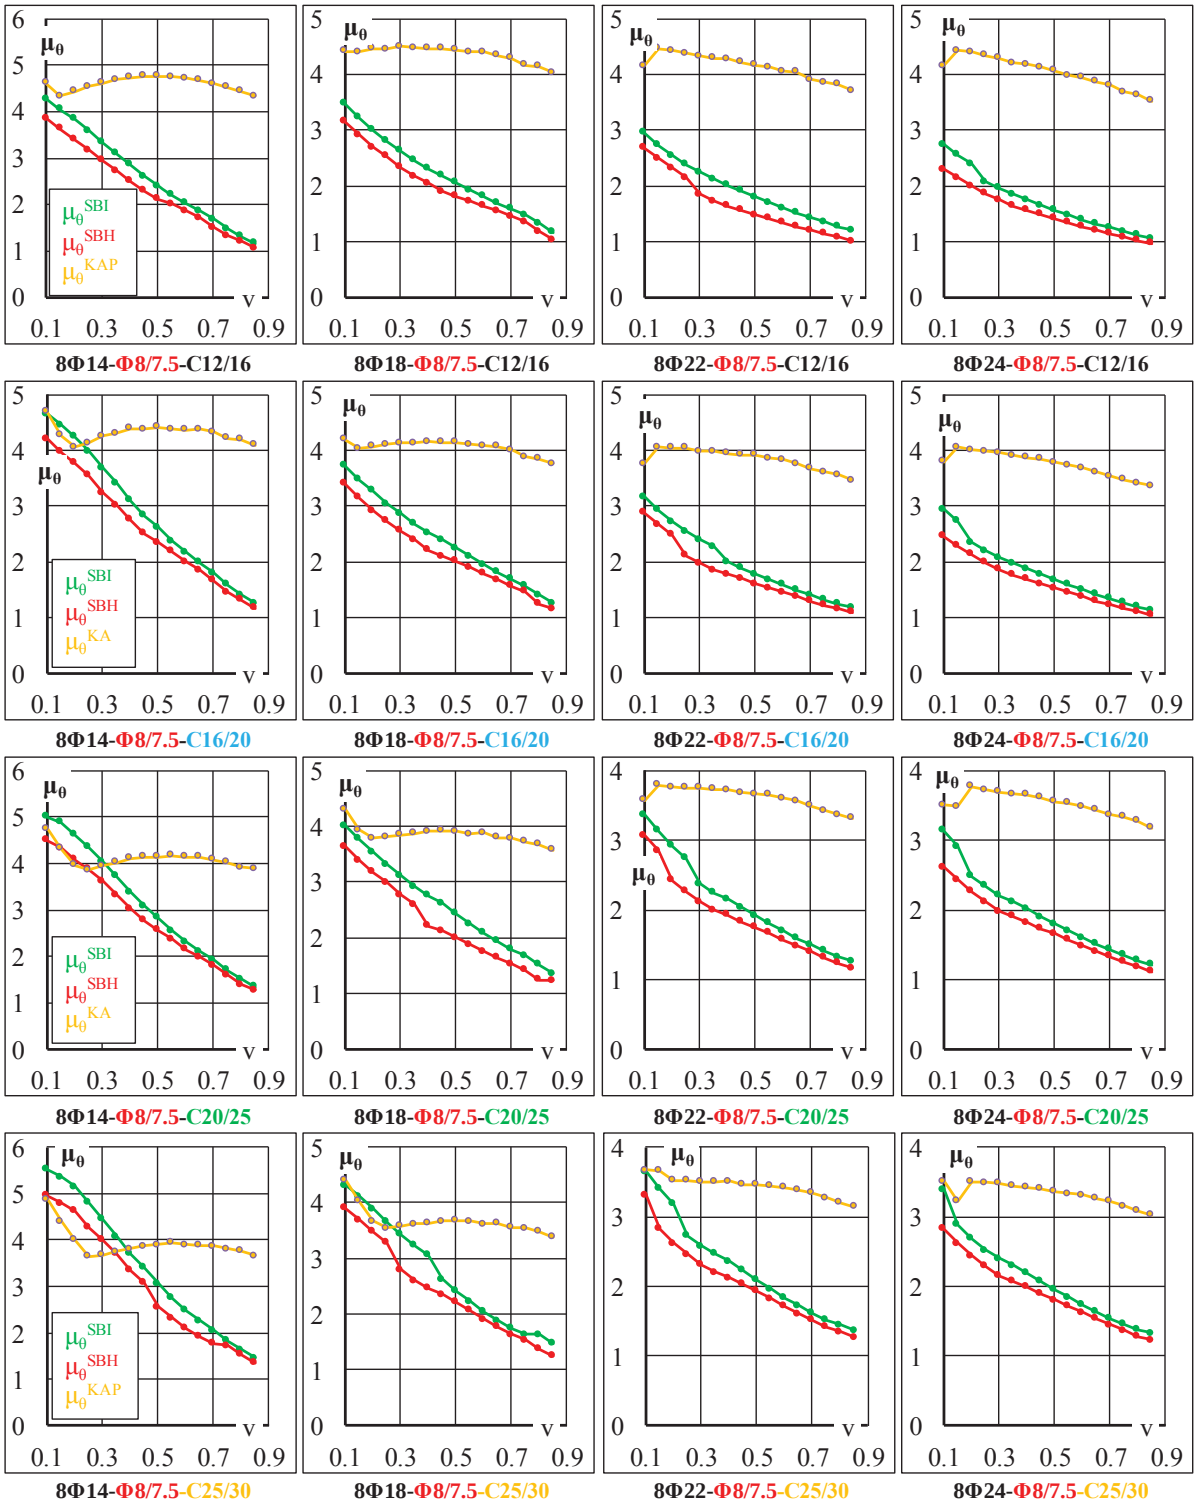

Figure 10: Variation of the μ_θ values calculated through the examined methods in relation to ν

3.2.3 Investigation of the relation between $\mu_\varphi(=\mu_{1/r})$ and μ_θ proposed by KAN.EPE.

In section 2 it was stressed that according to KAN.EPE. one of the applications of the ductility factor μ_φ is the estimation of ductility factor μ_θ using Eq. 1. Besides, one of the main targets of the present paper is the examination of this relation. Thus, in this subsection the results of this examination are presented.

Four different approaches for the estimation of μ_θ were examined and compared. Two of them are based on equations Σ.2a (comments of §7.2.2d of KANE.EPE) and Σ.11a (comments of §7.2.4b of KANE.EPE). The first one [$\mu_\theta(\varphi_y^{SBH})=\theta_y(\varphi_y^{SBH})/\theta_u$] is based on the estimation of φ_y from the bilinearization of M-1/r diagram considering a horizontal branch after the effective yield curvature (Fig. 6a), whereas the second one [$\mu_\theta(\varphi_y^{KAP})=\theta_y(\varphi_y^{KAP})/\theta_u$] is based on the estimation of φ_y from the procedure which are proposed by KAN.EPE. in Appendix 7A. These approaches were already used for the comparison between them in the previous subsection 3.2.2. The other two approaches for the estimation of the ductility factor μ_θ are based on the utilization of the relation between μ_θ and μ_φ proposed by KAN.EPE. (Eq. 1). More specifically, Eq. 1 was implemented twice using the values of μ_φ^{SBH} and μ_φ^{KAP} (see subsection 3.2.1) as follows:

$$\mu_\theta\left(\mu_\varphi^{SBH}\right)=\frac{1}{3}\cdot\left(\mu_\varphi^{SBH}+2\right) \tag{4a}$$

$$\mu_\theta\left(\mu_\varphi^{KAP}\right)=\frac{1}{3}\cdot\left(\mu_\varphi^{KAP}+2\right) \tag{4b}$$

The aforementioned four approaches for the estimation of ductility factor μ_θ were compared in two pairs. Each one of these pairs consists of one μ_θ value calculated on the basis of equations Σ.2a and Σ.11a and one μ_θ value calculated using the Eqs. (4a), (4b). More specifically the following two pairs of μ_θ values were compared:

- The values $\mu_\theta(\varphi_y^{SBH})$ and $\mu_\theta(\mu_\varphi^{SBH})$
- The values $\mu_\theta(\varphi_y^{KAP})$ and $\mu_\theta(\mu_\varphi^{KAP})$

The comparisons were performed for the 64 cases of Fig. 5 and for 18 values of column's normalized axial force between ν=0.0 and ν=0.85. Thus, the relation between the μ_θ values calculated through the theoretical definition $\mu_\theta=\theta_y/\theta_u$ (considered as reference values) and the corresponding values calculated approximately though Eqs. (4a), (4b) was investigated for a great range of ν values. In substance, the ability of the proposed by KAN.EPE. Eqs. (4a), (4b) to approach effectively the reference values of μ_θ calculated by the theoretical definition for various levels of normalized axial force was investigated. Due to the fact that the presentation of all μ_θ-ν curves leads to very complex diagrams which are very difficult for studying, only the curves which correspond to maximum and minimum differences between $\mu_\theta(\varphi_y^{SBH})$ and $\mu_\theta(\mu_\varphi^{SBH})$ values (as well as between $\mu_\theta(\varphi_y^{KAP})$ and $\mu_\theta(\mu_\varphi^{KAP})$ values) are presented in Figs. 11, 12.

From the study of the diagrams of Fig. 11, the following conclusions can be mentioned:

- Generally, the approximative Eq. (4a) provides greater values for μ_θ ($\mu_\theta(\mu_\varphi^{SBH})$) than the application of its theoretical definition ($\mu_\theta(\varphi_y^{SBH})$). However, there are few cases in which the opposite occurs. These cases correspond to ν<0.1-0.2 in combination with high level of transverse reinforcement (i.e. Φ8/7.5 or Φ8/10) or to the lower level of transverse reinforcement (i.e. Φ8/20) in combination with high grades of concrete (i.e. C20/25 or C25/30).
- The method which is based on the theoretical definition of μ_θ ($\mu_\theta(\varphi_y^{SBH})$) provides declining μ_θ-ν curves for the entire range of ν values. On the contrary, the approximative Eq. (4a) provides μ_θ-ν curves which are ascending for ν values between 0.1 and 0.3-0.5, and declin-

ing for greater ν values mainly in case of high level of transverse reinforcement (Φ8/7.5 or 10).

- In all examined cases the maximum differences between $\mu_\theta(\varphi_y^{SBH})$ and $\mu_\theta(\mu_\varphi^{SBH})$ values correspond to the maximum level of transverse reinforcement (Φ8/7.5). On the contrary, with very few exceptions, the minimum differences correspond to the minimum level of transverse reinforcement (Φ8/20).

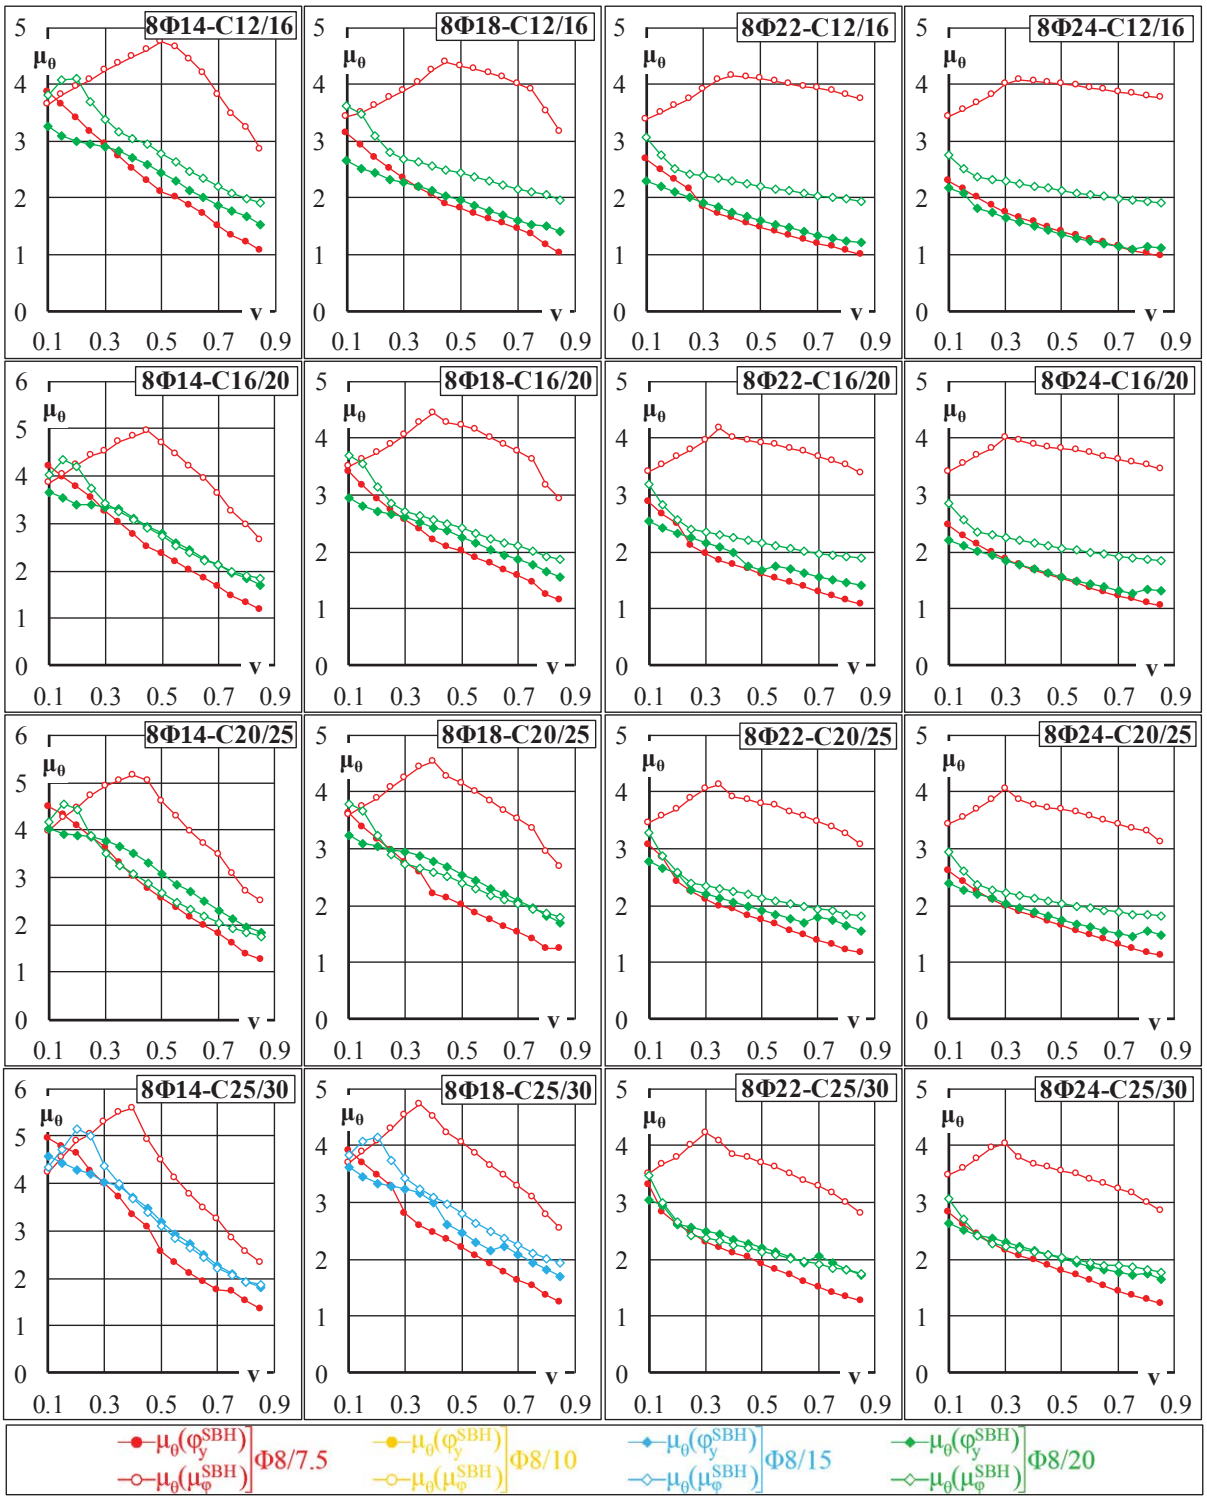

Figure 11: Max and min differences between the μ_θ values extracted by the equation proposed by KAN.EPE. for the relation μ_θ-μ_φ and the μ_θ values extracted by its theoretical definition and the bilinearization of M-μ_φ diagram

- In the vast majority of the studied cases the rate of variation between $\mu_\theta(\varphi_y^{SBH})$ and $\mu_\theta(\mu_\varphi^{SBH})$ values is greater for ν values less than 0.3-0.4.

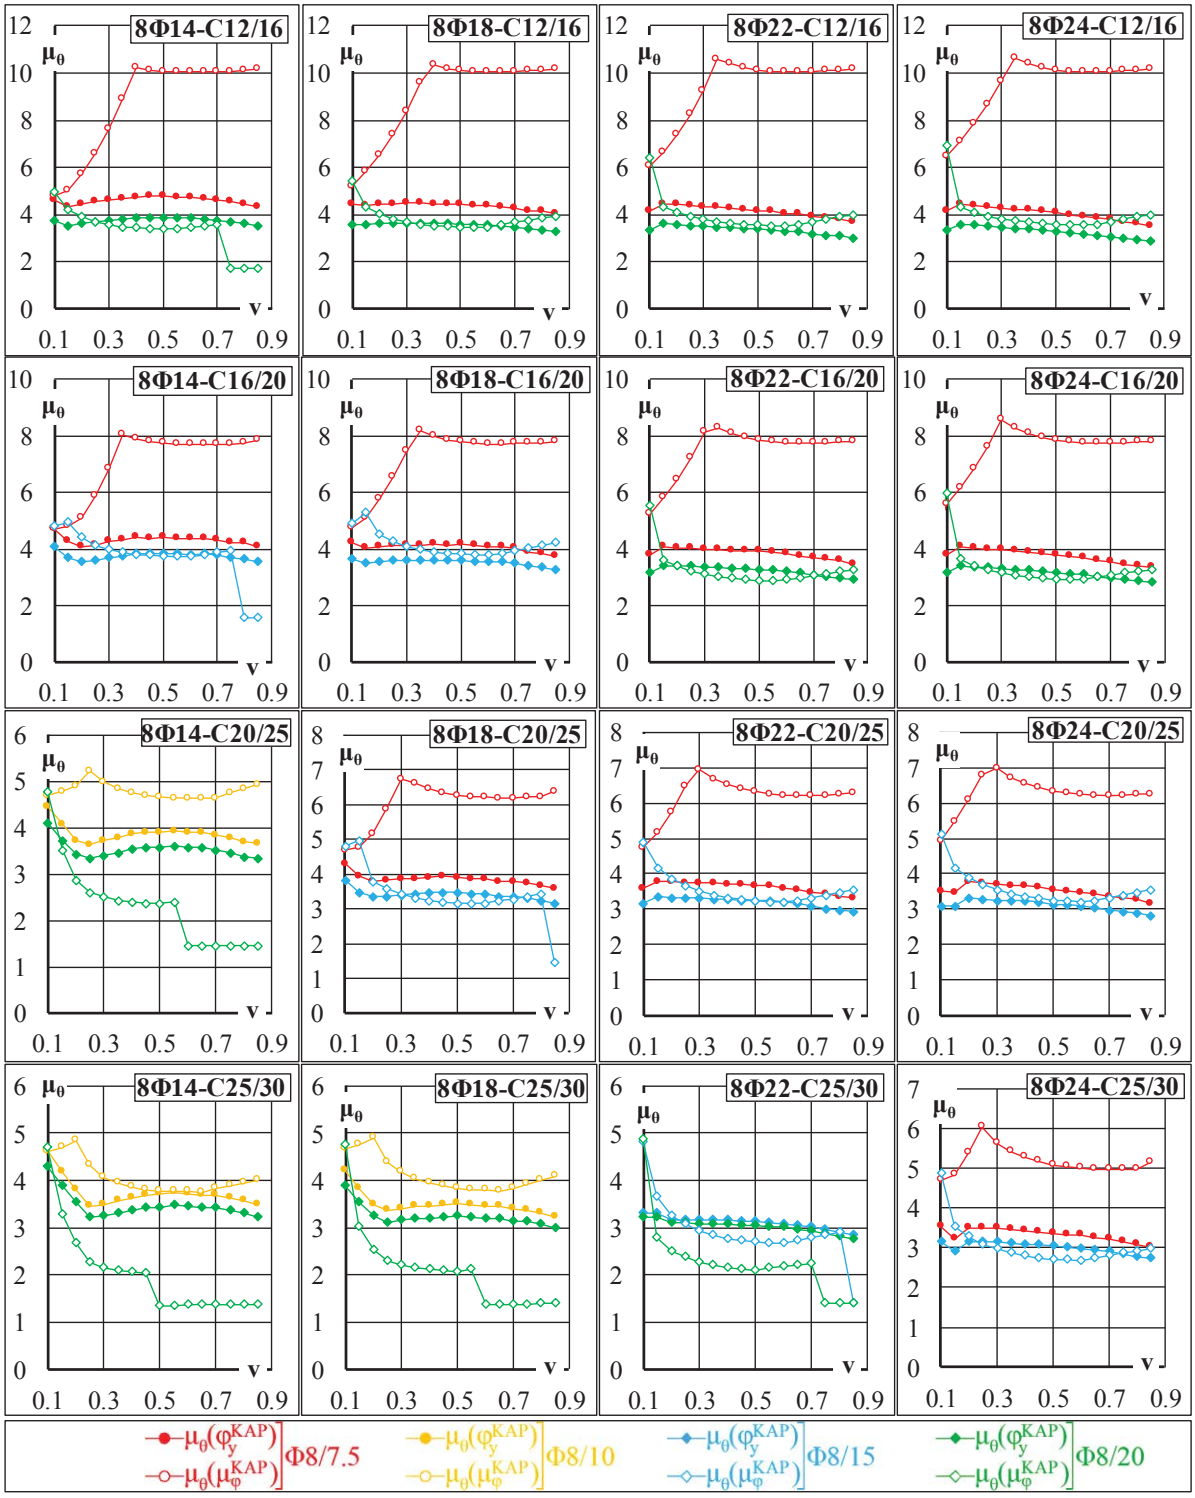

Figure 12: Max and min differences between the μ_θ values extracted by the equation proposed by KAN.EPE. for the relation μ_θ-μ_φ and the μ_θ values extracted by its theoretical definition and the procedure of Appendix 7A

The main conclusions which arise from the study of Fig. 12 are the following:

- The maximum differences between $\mu_\theta(\varphi_y^{KAP})$ and $\mu_\theta(\mu_\varphi^{KAP})$ values correspond to the maximum level of the transverse reinforcement (Φ8/7.5) mainly in cases of concrete grades

C12/16 and C16/20. In the cases of other two assumed concrete grades (mainly in case of C25/30) the maximum differences correspond to the minimum level of the transverse reinforcement (Φ8/20). The minimum differences generally correspond to low levels of transverse reinforcement (Φ8/15 or Φ8/20). Some exceptions are observed for concrete grades C20/25 and C25/30.

- The method which is based on the theoretical definition of μ_θ ($\mu_\theta(\varphi_y^{KAP})$) provides almost horizontal (slightly declining) μ_θ-ν curves for the entire range of ν values. As regards the $\mu_\theta(\mu_\varphi^{KAP})$-ν curves no general conclusion is extracted, since for the cases Φ8/7.5 and Φ8/10 the curves are ascending for low ν values whereas for the cases Φ8/15 and Φ8/20 the curves are mainly declining.
- In the vast majority of the studied cases the rate of variation between $\mu_\theta(\varphi_y^{KAP})$ and $\mu_\theta(\mu_\varphi^{KAP})$ values is greater for ν values less than 0.1-0.2.
- The approximative Eq. (4b) provides greater values for μ_θ ($\mu_\theta(\mu_\varphi^{KAP})$) than the application of its theoretical definition ($\mu_\theta(\varphi_y^{KAP})$) in the vast majority of cases where transverse reinforcements Φ8/7.5, Φ8/10 and Φ8/15 are applied. The opposite occurs in the vast majority of cases where transverse reinforcement Φ8/20 is applied.

Generally, from the combined study of the conclusions extracted from Figs. 11 and 12 the following basic remarks can be stressed:

(a) The Eq. (1) proposed by KAN.EPE. for the relation between μ_θ and μ_φ fails in many of the examined cases to approach effectively the μ_θ values which are calculated using the theoretical definition of $\mu_\theta(=\theta_y/\theta_u)$ in combination with the procedures proposed by KAN.EPE. for the estimation of θ_y and θ_u.

(b) The results provided by Eq. (1) approach more effectively the μ_θ values which are calculated using the theoretical definition of μ_θ only in cases where low levels of transverse reinforcement (Φ8/15 or Φ8/20) are applied.

4. CONCLUSIONS

In the present paper the methods which are proposed by the Greek code for structural intervention (KAN.EPE.) for the estimation of the ductility factors in terms of curvatures (μ_φ) and in terms of chord rotations at the ends of R/C members (μ_θ), as well as the relation between them were comparatively evaluated. The ductility factors μ_φ and μ_θ possess significant roles within the framework of KAN.EPE. Thus, several methods for their estimation as well as an equation for their relation are proposed. In order to achieve the goals of the present investigation, a R/C column with rectangular cross-section and different data regarding the concrete grade as well as the longitudinal and transverse reinforcement mechanical volumetric ratios was analytically investigated. The main conclusions extracted from the present study can be summarized to the following points:

- The methods proposed by KAN.EPE. for the estimation of the ductility in terms of curvatures ($\mu_{1/r}$ or μ_φ) provide in many of the examined cases values with significant differences between them. However, these differences generally decrease as the concrete grade increases.
- The methods which are based on the bilinearization of M-1/r diagrams for the estimation of the ductility in terms of chord rotations μ_θ, provide significantly different μ_θ values in comparison with the method based on the estimation of φ_y through the procedure of Appendix 7A of KAN.EPE. Generally, the latter provides higher μ_θ values. However, these differences decrease as the concrete grade increases.
- Equation (1) proposed by KAN.EPE. for the relation between μ_θ and μ_φ, approaches more effectively the μ_θ values which are calculated using the theoretical definition of μ_θ only in

cases where low levels of transverse reinforcement (Φ8/15 or Φ8/20) are applied. On the contrary, in cases of high level of transverse reinforcement (Φ8/7.5 or Φ8/10) the corresponding approach is not sufficient.

Finally, it must be stressed that the above-mentioned conclusions can only be considered as indicative for the range of the results which are provided by the various methods proposed by KAN.EPE. for the estimation of μ_φ and μ_θ. In any case, all these methods are well-documented and the differences between them can be simply considered as a result of the different assumptions on which are based. However, especially for the provision of KAN.EPE. pertaining to the relation between μ_φ and μ_θ the results of the present paper provide a motivation for further investigations (e.g. on the basis of their theoretic definition and/or extensive parametric analyses) for more efficient alternative approaches.

Abstract - This article presents a study on the seismic performance of reinforced concrete shear wall buildings with focus on shear strength of walls that are designed using the seismic design provisions of the National Building Code of Canada. A set of buildings, four, six and eight storeys with a simple configuration and different heights have been considered here. While the static and linear dynamic analyses indicate the robustness in the design but dynamic time history analysis indicates deficiency in the shear capacity in the plastic hinge region. It is observed that a dynamic amplification factor for shear on flexural walls governs the shear demand. Here, a simple method has been proposed to estimate the amplified shear demand and to enhance shear resistance of a structural wall economically to avoid unintended shear failure.

Keywords: Reinforced concrete, Shear wall, seismic demand, dynamic analysis.

1. Introduction

Failure of structural walls in shear has been identified as one of the reasons that can diminish the expected level of performance and lead to the big financial loss. For instance, the amount of America's financial losses in the 1990s' is estimated to be twenty times bigger than that of three earlier decades all together [1]. This is despite the fact that all the structural walls are designed according to the building code requirements, but these structural walls have still been a challenge and are failing with different reason including inadequate shear capacity. They should have adequate displacement capacity to ensure the satisfactory level of performance of the wall [2-3]. Building codes in various jurisdictions including Canada have moved towards performance-based design approaches. The National Building Code of Canada (NBCC 2005; has been provided in an objective based code format which provides under the "Alternative Solution"; category that a structure can be designed not only to have adequate strength, but also for the performance attributes, such as deformability. Although, the current seismic design approach of ductile RC shear wall provided by the NBCC 2005 and CSA A23.3-04 is more rational than the earlier editions; yet, despite all improvements made to them they do not specially address the higher mode effects on the base shear demand in the shear walls [4]. It also should be noted that even such improvements provided under "alternative solutions" that gives way for PBSD can still result in a major brittle shear failure. For instance, an increase in participation of higher modes of vibration can result in decrease of building drifts, and in a sense, a more desirable level of performance. But, on the other hand, such increase can also cause considerable increase in shear force demand at the base of the shear walls, particularly after formation of plastic hinge. If not taken into account, such magnification can result in a brittle shear failure, and turn the seeming desired level of

performance into a major loss. Hence, it is very inevitable that still it requires a lot of study and research on this field to mitigate these problems.

2. Literature review

Higher modes of vibration play an important role for enhanced shear demand. Blakeley et al. [5], were the first pioneer the idea that higher modes of vibration not only magnifies the elastic shear demand at the base of shear walls, but also increases the demand more appreciably after the structure enters inelastic phase and plastic hinge forms.

The recent work of Boivin and Paultre [6], shows that for the regular multi-storey ductile RC cantilever or coupled walls, the capacity design shear envelope determined from (CSA A23.3-04) to prevent shear failure can largely underestimate the shear force demand under design level ground motions, even when the wall response is slightly inelastic. This kind of underestimation results from a deficiency of the present codes to account for dynamic amplification effects, in the elastic and inelastic regimes, due to higher lateral modes. Boivin and Paultre [6], identified two sources of underestimation: (i) the 2005 NBCC spectral accelerations underestimate the elastic responses of higher lateral modes of the walls because their traditional 5% damping overestimate actual damping (about 2% on average) and that makes reducing the higher mode responses; and (ii) as per CSA standard A23.3-04, the capacity design method for shear strength design do not account for the dynamic amplification of shear forces due to inelastic effects of higher modes.

Boivin and Paultre [4], also noted that the capacity design method prescribed by CSA standard A23.3-04 to prevent unintended plastic hinges above the base plastic hinging region is not free from such a problem because it is formulated based on amplified elastic forces which is tributary of the analysis method, static or dynamic, used to derive these forces.

For New Zealand code and standard of the time, they recommended the shear force relative to the moment capacity (allowing for different sources of strength such as actual yield strength of steel greater than minimum specified) be calculated and then to be magnified based on their number of stories and class of importance. Their work then became the basis for modifying structural wall's base shear in many standards of the time.

Among many other countries, the earlier edition of Canadian Standard, CSA A23.3-94 (CSA 2001) also adapted New Zealand's approach (NZS 1995) in which was recommended as:

[1] $1 \leq J/1.25 * (0.9+N/10)$ $N \leq 6$

[2] $1 \leq J/1.25 * (1.3+N/30) \leq 1.8$ $N > 6$

In that J/1.25 is to adopt the original formulas into Canadian Standard; J is a reduction coefficient in NBCC that accounts for higher modes of vibration in the Equivalent static load method, and 1/1.25 is to account for the difference between probable and nominal values used in Canadian and New Zealand standard respectively. However, the New Zealand approach is not recommended in the current standard of practice A23.3-04 anymore.

Another approach that is compared with the results of this study are proposed by Filiatrault et al. [7], suggested that the shear demand to be calculated using the ESL method formula, $V = U * V_e / R$ (NBCC 1995), in which V is the design base shear, V_e is the equivalent lateral force at the base, U is a calibration factor equal to 0.6, and R is the force modification factor. But they suggested that the R to be replaced by a factor R_v equal to 1.0 in seismic zones $Z_a \geq Z_v$ and 1.5 when $Z_a < Z_v$. On the other hand, Ghosh and Markevicius [8], suggested that the base shear to be calculated using $0.25W \times a + M_y / (0.67h_n)$ equation in which W is the seismic weight, a is the design peak ground acceleration, and M_y is the yield moment of the wall, and hn is the building total height.

Currently, no method of analysis is capable of capturing the effect of higher modes of vibration but dynamic analysis. Yet, an elastic dynamic analysis is not sufficient if plastic hinge forms in the shear wall. That is because vibrating in the elastic range constitutes only a small portion of the effect of higher modes and the major portion of base shear magnification takes place after formation of plastic hinge that an elastic analysis is not capable of

capturing it. However, because of its complication, inelastic dynamic analysis of RC structures is not an approach of common practice. On the other hand, the initial approach for seismic design of RC shear walls used in most building codes is the equivalent lateral load method. Beside the fact that the Canadian code and standard do not implicitly address deficiency of such effects, the existing recommendations suggested for inclusion of the effects of higher modes of vibration still either underestimate or well overestimate the base shear demand in walls, or seems not to cover a large range of building heights.

3. Objectives

The objective of this research is to do a comparative study of different analyses methods like equivalent lateral force method, response spectrum analysis and dynamic time history analysis of reinforced concrete shear walls using Canadian National building Code and to check the design adequacy of reinforced concrete shear walls as per CSA A23.3-04, with seismic demand analyses from these Static, linear dynamic and dynamic time history analyses. And to propose any suitable solution, if any discrepancy arises between seismic demand and shear wall capacity as per Canadian design standards considering linear and non-linear dynamic analysis, which is usually not considered in standard practice.

4. Methodology

A set of buildings with a simple configurations and different heights have been modeled in ETABS. The seismic design parameters are considered for Vancouver locations. It has been utilized the real seismic database from PEER (Pacific Earthquake Research Institute). Fifteen ground motion records have used for this study. These 15 records have ratios of peak acceleration (A) to peak velocity (V) close to 1 which represents the seismicity of Vancouver, [9]. A comparative study has been performed between, ELF method, Response Spectrum analysis and Dynamic Time History analysis.

Three reinforced concrete RC office buildings with shear wall of 4, 8, and 16 storey heights and 3 bays by 3 bays in plan were modeled and performed analysis and design in ETABS. The buildings fall into the category of regular symmetric buildings according to NBCC 2015. The floors are designed as floor plates. The buildings are of heights equal to 15.8, 30.4, and 59.6 m, respectively covering limits of the applicability of the ESL methods as permitted by NBCC 2015. The range of heights considered here also cover both flexural and shear behaviour of walls. In low rise buildings the shear behaviour is dominant and in the high building the flexural behaviour is dominant.

The periods obtained from modal analysis are found to be more than the corresponding values of T_a by empirical formula in all the buildings. Therefore, the fundamental periods of the buildings are revised to maximum $2T_a$ as recommended in NBCC 2015.The design live load is equal to 2.4 kN/m^2 for all floors except for the first storey which is 4.8 kN/m^2. The snow load is calculated to be 2.3 kN/m^2. The dead load is 0.85 kPa for exterior walls, 1.0 kPa for partitions on floors, 0.5 kPa for ceiling and mechanical services for all floors and 0.5 kPa for roofing. It has been considered ductile shear walls, with R_d=3.5 and R_o=1.6 for the lateral force resisting system as stated in the code, where R_o and R_d are overstrength and ductility factors, respectively.

Located in Vancouver, location of high seismic activity region in Canada, the buildings are assumed to be founded on class “C” soil. The initial stiffness of the members is estimated based on the CSA-A23.3-04 provisions for seismic resisting buildings and is kept unchanged over every few floors. For instance, the eight storey walls are modelled with a flexural rigidity of $0.68EI_g$ for storey one to flour, and $0.64EI_g$ for stories five to eight.

The following two methods are used for scaling the 15 historical earthquake records (PEER database) to fit them into the response spectrum provided in the code. It has been used Seismosignal software to analyse these ground motion data. The scaling methods considered here are: (i) Partial Area Method (PAM) and (ii) Ordinate Methods (OM). For the ordinate method (OM), the accelerograms were scaled by a ratio of “design spectral

ordinate'', and "spectral ordinate of the accelerograms" both at the fundamental period T1; In the Partial Area Method (PAM), the accelerograms were scaled by a ratio of the area under the design spectrum of an accelerogram, both within the same period interval "T1' to "1.2T1"; The typical spectra from the 15 accelerograms and ETABS models are shown in below figures 4(a) and 4(b):

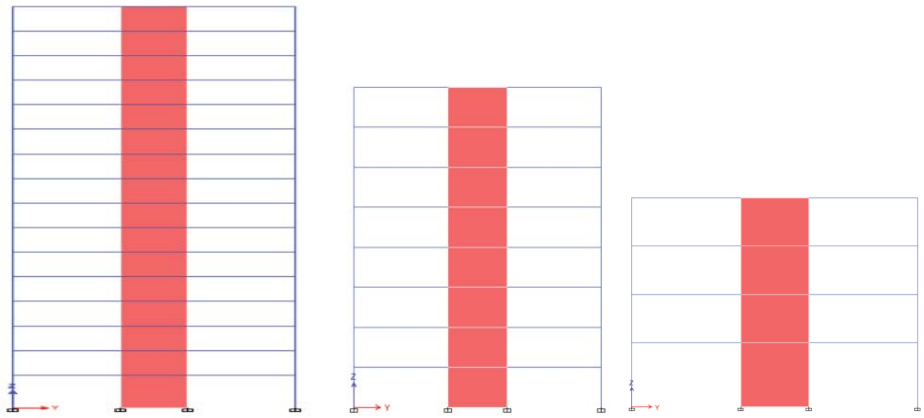

Fig.4(a) – ETABS Models (16, 8 and 4 Storey Building)

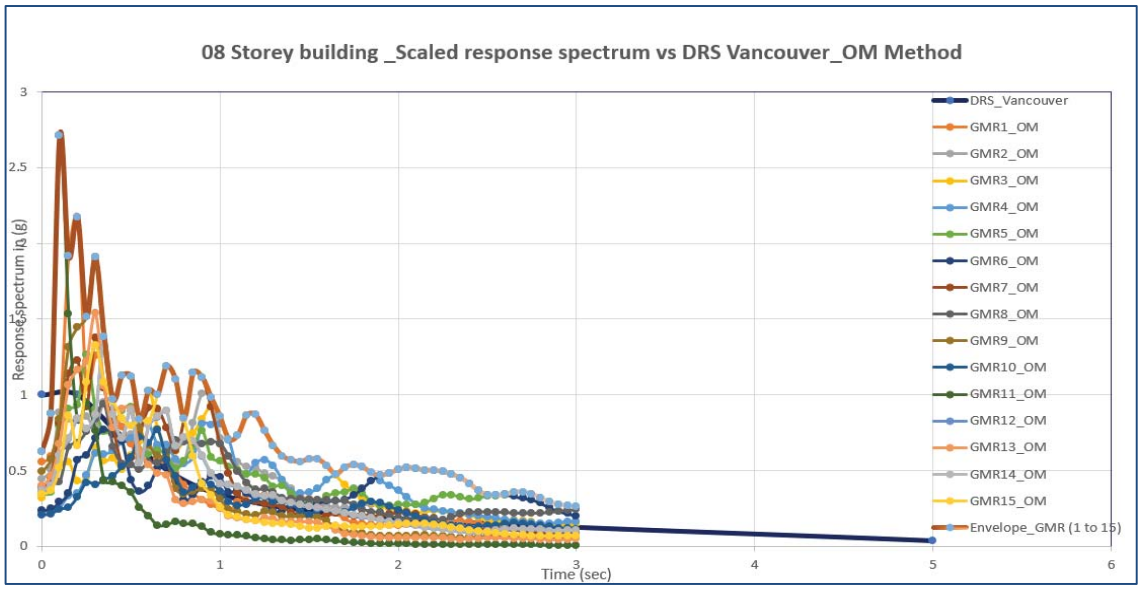

Fig. 4(b): Envelope scaled response spectrum vs design response spectrum, Vancouver, 8 Storey building

5. Assessments of Results

For comparison, the base shear demand and its distribution along the height of the critical wall for each building for different analysis methods are shown in below figures 5(a), 5(b) and 5(c); It has been observed that the base shear demand increases with the storey height with the same floor area. But this increase is not directly proportional to seismic weight of the buildings. Effect of time period and higher mode affect come into play in this scenario. In Fig 5(d), it has been plotted the factored base shear demand to factored shear capacity in static analysis. And the D/C ratio is less than one. And in Fig 5(e) it has been plotted the ratio of factored base shear demand to base shear capacity from detail time history analysis. And the D/C ratio is greater than one shows inadequacy in shear wall design that is usually not considered in standard practice.

Moreover, it can be observed the increase of higher mode effect with building height from this diagram, 5(d) and 5(e); It can be seen also that the ratio of factored base shear demand to factored shear capacity increases with the increase of building height but that increment is not proportional to the story height. This is because, with the increase of height the inelastic rotation requirement become the more dominant parameter in shear wall design. Therefore, it will be seen later in this paper that it seems more reasonable to dynamically amplify the shear capacity of the wall rather than using the common approach which is amplifying the factored or probable shear demand resulting from elastic analyses.

It has been observed from Fig 5(e) that difference of shear demand capacity ratio in 04 storey and 08 storey is not significant, but the ratio increases from 1.49 to 1.68 from 08 storey to 16 storey respectively. It needs to be noted that in below Figures, EMP-T, Revised-T, and DRS denote the base shear due to time period based on code empirical equation, code limit and ETABS calculation considering design response spectrum respectively.

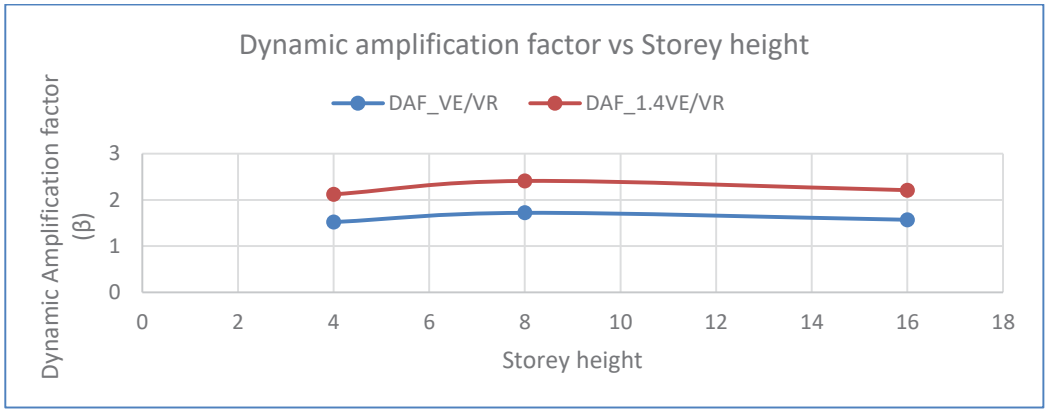

Fig.5(g) Variation of Dynamic amplification factor with Storey height

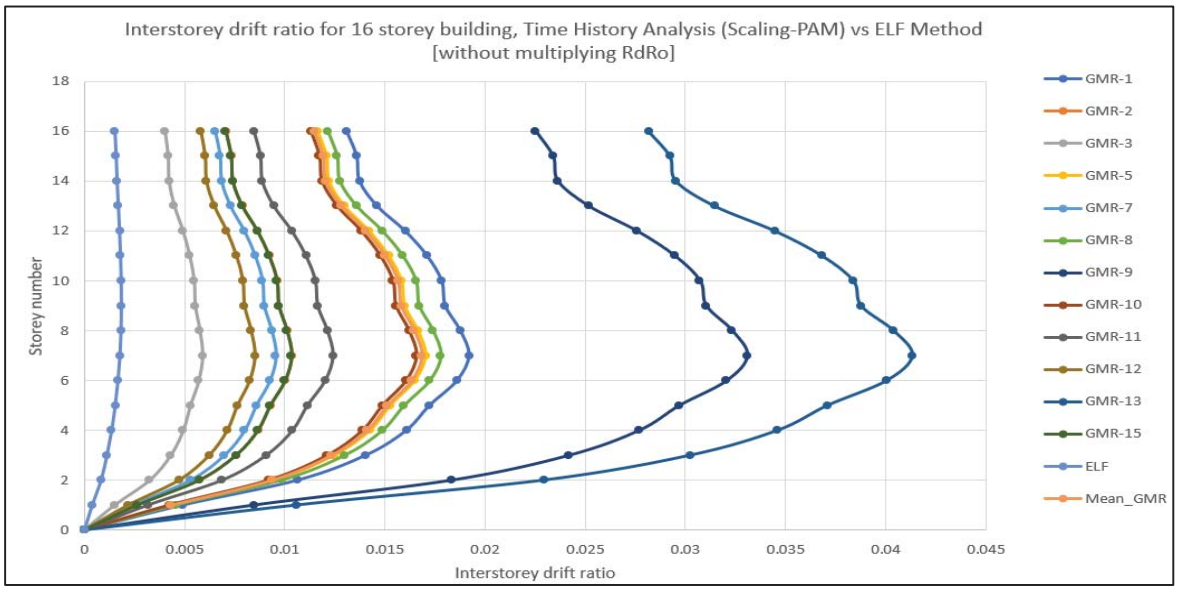

Fig. 5(h): Interstorey drift ratio for 16 storey building Time History Analysis (scaling PAM) vs ELF method

It has been plotted the variation of dynamic amplification factors in different proposed method vs storey height in Fig 5(g). The fundamental periods are increasing with increasing of storey height. In these calculations it has been considered minimum wall thickness as per Canadian standards. It has been observed that the interstorey drift ratio of 16 storey building Fig 5(h) as per 1.0DL+0.5LL+1.0Ex load combination is within the limit. ($0.002*R_d*R_o$)/IE=0.011<0.025), but as per load combination from time history analysis the interstorey drift is not within the code limit ($0.017*R_d*R_o$)/IE=0.095; This is because of higher base shear demand. It has been shown detailed discussions and conclusions in section 8.0;

6. Summary of cost to increase shear strength at critical regions: [RS Mean data-2009]

It has been designed the shear walls for all buildings in this study (4, 8 and 16 storey) as per Canadian standards and calculated additional reinforcement cost to provide additional shear capacity using the proposed approach mentioned in this study and summarized in below table. It has not been shown the detail design calculation in this paper due to page limitations.

It has been found that a very negligible effect on cost increase in this study, max (0.3%);

Table 6.1 – Modification factors for shear strength vs additional cost

Building height and cost	Modification Factors for Shear Strength in the critical Region [Proposed]		Additional reinforcements for increasing the critical Region Shear Strength (ton)	Additional Cost for increasing the critical Region's Shear Strength (CDN $)	Additional Cost Relative to the Total Cost (%)
16 Storey ($14 m)	VE/VR	1.58	5.0	16000	0.25
	1.4VE/VR	2.21	11.0	31000	0.3
08 Storey ($5.5m)	VE/VR	1.72	3.52	11000	0.20
	1.4VE/VR	2.42	5.72	18000	0.33
04 Storey ($2.5m)	VE/VR	1.52	1.1	3676	0.15
	1.4VE/VR	2.21	1.5	5000	0.2

Table 6.2 - D/C ratio due to Dynamic Time History Analysis

Storey	Partial Area Method (PAM)/Ordinate Method (OM)
04	1.46
08	1.49
16	1.69

7. Comparison of results

It has been compared the result of this study (proposed VE/VR or 1.4 VE/VR as a multiplication factor) with previous New Zealand code and study of Filiatrault et. Al. [7], and summarized in below table (Table-7.1). It has been observed that, the original New Zealand approach (NZS 1995) and that of adapted CSA A23.3-94 (the original New Zealand approach multiplied by J/1.25) results in shear values those are also comparable with the values from inelastic analysis of this study. From below table, it can be observed that both of the New Zealand and that of adapted to standard CSA A23.3-94 give close estimation of shear demand, they are at the lower bound that can be viewed as an underestimation of shear demand.

However, using VE/VR or 1.4VE/VR ratio as an amplifying multiplier gives a better estimate of shear demand that are comparable to results from the New Zealand approach. Moreover, the proposed approach gives even a better result compared to those of New Zealand approach even in case of using probable shear demand V_p as the multiplicand. Here V_p, V_r and V_n denote probable base shear demand, factored shear capacity and nominal shear capacity of wall respectively.

Table 7.1– Variation of shear demand (Proposed) from Dynamic Time History Analysis (%)

		Proposed						New Zealand						Filiatraul
		VE/VR			1.4VE/VR			βv			J/1.25 βv			
		Vr	Vn	Vp	Vr	Vn	Vp	Vr	Vn	Vp	Vr	Vn	Vp	
16 Storey	Mean	-6.5	3.8	14.1	30.7	45.3	59.8	8.2	20.2	32.27	-22.05	-13.3	-4.7	-93.5
08 Storey	Mean	15.3	28.12	12.37	61.9	79.36	57.32	4.31	15.9	1.66	-24.8	-16.5	-26	-92.8
04 Storey	Mean	35.27	50.3	14.5	89.3	110.4	60.3	15.6	28.4	-2.1	-16.7	-7.4	-29.5	-89.9

8. Discussions and Conclusion

The present study focuses on the evaluation of buildings based on National Building Code of Canada. Equivalent static load method, response spectrum analysis and dynamic time history analysis have been carried out in the design and evaluation process. The different findings from this study are summarized as follows:

The static and response spectrum analyses indicate the robustness in the design that the shear demands on the shear walls are below the shear capacities (D/C<1), while the dynamic time history analysis indicates deficiency in the shear capacity in the plastic hinge region. Based on the nonlinear dynamic analysis, it has been found that the shear demand in the walls is well above the capacity (D/C>1); It has been proposed dynamic amplification factors for modification of such deficiency. The ratio of probable base shear demand to factored shear capacity are found 1.46, 1.49 and 1.68 for 04, 08, and 16 storey buildings respectively. For calculation of probable base shear calculation, it has been considered flexural overstrength as per CSA A23.4-04.

It is determined that the shear capacity of a wall in the hinge region where the shear critical section is located, needs to be increased by a factor of VE/VR or1.4VE/VR in order to keep the shear demand lower than the capacity.

Here, VE represents the base shear due to time period from empirical equation and VR represents base shear due to revised time period as per Canadian code. The dynamic amplification factors for 4, 8, 16 storeys are determined 1.52, 1.72, 1.57 respectively for multiplication factor VE/VR and 2.12, 2.41, 2.21 respectively for multiplication factor 1.4VE/VR.

The dynamic amplification factor with respect to different storey are plotted in Fig. 5(g). It is not a straight-line variation. Since dynamic amplification factor depends on frequency ratio (β) and damping ratio. And the frequency depends on the stiffness and mass of the building. Here, β represents VE/VR or 1.4VE/VR.

It has been found a good agreement ratio of the engineering design parameters, moment, shear and deflection with respect to empirical time period and revised time periods (not shown in this paper) with this proposed multiplication factors, VE/VR and 1.4VE/VR. It has been observed also that the D/C ratio shown in Table-6.2 (D/C>1), which is failing due to considering detail time history analysis base shear has a good agreement with this multiplication factors (VE/VR or 1.4VE/VR) as well as the dynamic amplification factors.

The proposed factor has been proposed to apply to the shear capacity of the wall rather than shear demand from elastic analysis. And after applying these factors with shear capacity, it has been plotted D/C ratio in Fig 5(f), which is less than one.

It is shown in Table 7.1, the variation of proposed shear demand from dynamic time history analysis in percentage and VE/VR and 1.4VE/VR shows all positive values.

From Table 7.1, it has been observed also that using these factors (VE/VR or 1.4VE/VR as an amplifying multiplier factor gives a better estimate of shear demand that are comparable to results from the New-Zealand approach and Filiatraul et.al. [7].

It also can be observed from detail shear reinforcement calculation of these buildings as per CSA A23.4, that the proposed approach results in a better estimate of shear demand on wall in any case, whether magnifying the probable shear demand $[(M_p/M_f) * V_f]$ obtained from elastic analysis or magnifying shear capacity of the wall from capacity design approach. It needs to mention that to increase the shear capacity, it has been used CSA A23.4, ductility approach to apply those proposed multiplication factors. The probable base shear demand has been calculated from CSA A23.4 capacity design approach, that plotted in Fig. 5 (e) and can be commented that the Canadian capacity design for shear wall design is adequate for linear static and response spectrum analysis but it is inadequate for the shear demand from dynamic time history analysis. For probable shear demand calculation, it has been used γ_w equal to 3.49; It can be noted that the value of γ_w equal to 4 approximates the theoretical overstrength limit before shear strength design of ductile walls is controlled by elastic shear force, [4].

It has been studied also the effect of wall thickness on base shear demand and interstorey drift ratio. It has been observed that by increasing wall thickness from 450 mm to 500mm on 08 storey building, there is not significant base shear changed. Whereas, the interstorey drift can be reduced by 22 percent (not shown in this paper). It has been done detail cost analysis also due to increase of reinforcement for increasing section shear capacity considering ductile design and found that the shear strength of the walls can be modified at a relatively small expense; as compared with the whole buildings. It is estimated at 0.2, 0.33 and 0.3 percent of the building total cost for 4, 8 and 16 storeys building respectively; the shear capacity in walls can be increased such that D/C ratio is lower than one. The results are tabulated in Table 6.1; Hence, it can be commented that using the proposed scheme for shear capacity modification of shear walls, a well-defined level of performance for buildings can be achieved and it can be related to the design shear forces estimated using the equivalent static load method provided in the building code.

In this study for analysis process 5% damping is considered for all buildings, the effect of other damping is not considered. It has been considered Newmark method for time-history analysis base shear calculation in ETABS modelling. Since the configuration of the buildings studied here is simple and symmetric, the effect of accidental torsion is found to be negligible.

Keywords: Seismic Strengthening of RC Structures, Tension-Ties, Alternating Axial Forces, Multiple Earthquakes Simulation

Abstract. *The influence of varying and alternating axial forces, compressive or tensional ones, on the behavior of Reinforced Concrete (RC) framed structures, seismically strengthened by tension-tie elements, is investigated experimentally and computationally. The experimental investigation concerns the flexure-shear behavior of the structural elements (beam, columns) in a specimen of a two-columns one-story RC frame subjected to a recycling loading simulating seismic excitation. This frame has dimensions and reinforcement configurations that have been used commonly in older substandard RC structures, without anti-seismic design and with typical shear problems. Additional permanent vertical compressive axial loads on the two columns and gravity loads on the beam have not been applied, in order to investigate the influence of varying axial forces and vertical earthquake components. The specimen-frame is examined first as bare, and then as strengthened by X-ties. Next, the computational simulations of these two experiments are performed by a pseudo-dynamic relaxation approach simulating multiple earthquakes. Particular emphasis is given to the operation of tension-tie elements, which have a unilateral behavior. It is proved that ties-strengthening improves the structural seismic behavior and can prevent the flexure-shear failure. A very satisfactory coincidence of the computational with the experimental results has been found. Finally, the investigation shows that the effects of alternating axial forces can be very important for the seismic behavior of RC framed structures. This holds also for two-columns framed piers in bridges subjected to transverse horizontal or vertical seismic components, as is the case of near-field seismic excitations.*

1 INTRODUCTION

As well-known, see e.g. [1-10], variations in axial force can influence strength, stiffness, bending and shear behavior, and deformation capacity of reinforced concrete (RC) columns. In multi-floor RC buildings, the axial loads of the columns are continuously changing during a seismic excitation. This change is particularly significant in perimeter columns, affecting the seismic behavior of the entire structure [5].

Relevant experimental research work on seismic flexural behavior of columns under variable axial loads has already been successfully carried out, see e.g. [3-5]. In these investigations, the seismic behavior of column-specimens with constant axial load was compared with the seismic behavior of specimens similar to the first ones, but under variable axial load. However, the changing axial load was and remained in compressive values range. The same is holding for experiments concerning RC frames having additional vertical loads, see e.g. [5,13,18,20].

On the other hand, in low-rise RC buildings, that do not have additional vertical loads, the changing axial forces do not always remain as compressive ones during a seismic excitation. So, axial forces can be alternated from compressive to tensile ones, meaning that their sign switches from negative to positive ones. The same may hold for highway overcrossings under transverse horizontal seismic excitations, and especially for two-column framed-piers (two-column bents) of RC bridges, when the vertical earthquake component is important for near-field seismic excitations [7-11]. In the above mentioned research it is concluded that excessive tension or tensile strain of the column may lead to shear strength degradation, and therefore vertical excitation can be one of the causes of shear failure. Moreover, tension in the columns has the potential to degradate the shear capacity, which is mainly due to the degradation of the concrete contribution to this capacity.

The above shear capacity degradation and other degradation reasons (seismic, environmental, anti-seismic design according to old codes, etc.) can result to the necessity of seismic strengthening and rehabilitation of RC structures. As well-known, various traditional methods for such seismic strengthening are available [1,6,12,13-14, 47]. Among them, steel bracing systems can be used, and especially buckling resistant braces (BRB), [15-18]. So, the above appearance of alternating axial forces may also be the case for RC frames seismically strengthened with tie-tension (cable) elements [19-21]. Particularly for these cable elements, which are tension-only elements [52-53], their unilateral behavior must be strictly taken into account [22]. This leads to the problem formulation as an Inequality Problem of Structural Engineering, for which a numerical solution requires the use of optimization methods [23-25].

In the present work, the effects of alternating axial forces, compressive or tensile ones, on the recycling behavior of a single-span single-story RC specimen-frame, seismically strengthened with two diagonal tie-tension steel rods (X-bracing), is experimentally and computationally investigated. The investigation focuses on the effect of alternating axial force on the shear strength and on the active stiffness (rigidity) of the structural elements (beam, columns) of the frame. This specimen-frame has dimensions and reinforcement configurations that refer to older RC substandard structures, which have been constructed in Greece and in other seismically active regions without anti-seismic design provided by current Seismic Codes. So, this RC specimen-frame appears typical shear failure problems, such as insufficient concrete confinement and low shear ratio in the columns and beam.

Concerning the seismic strengthening with diagonal tie-tension rods, emphasis is given to the operation of tie-tension elements, which have unilateral behavior, i.e. they can undergo tensile stresses but do not get compressive ones. In both experimental and computational investigation, the frame response is examined first as bare, and then as strengthened by tension-

ties. The frames do not have additional vertical loads, so the changing axial force does not always remain compressive, but changes sign. This concerns the cases where the vertical component is important in near-field seismic excitations or spatial variability of ground motion has to be taken into account [26-27].

2 SUMMARY OF THE EXPERIMENTAL INVESTIGATION

The realized experimental investigation is extensively analyzed in the publications [28, 29]. The research concerns the shear-critical RC frame-specimen shown in Fig. 1., which has no additional vertical loads other than the dead weight. This frame-specimen was first tested without strengthening (bare test-specimen).

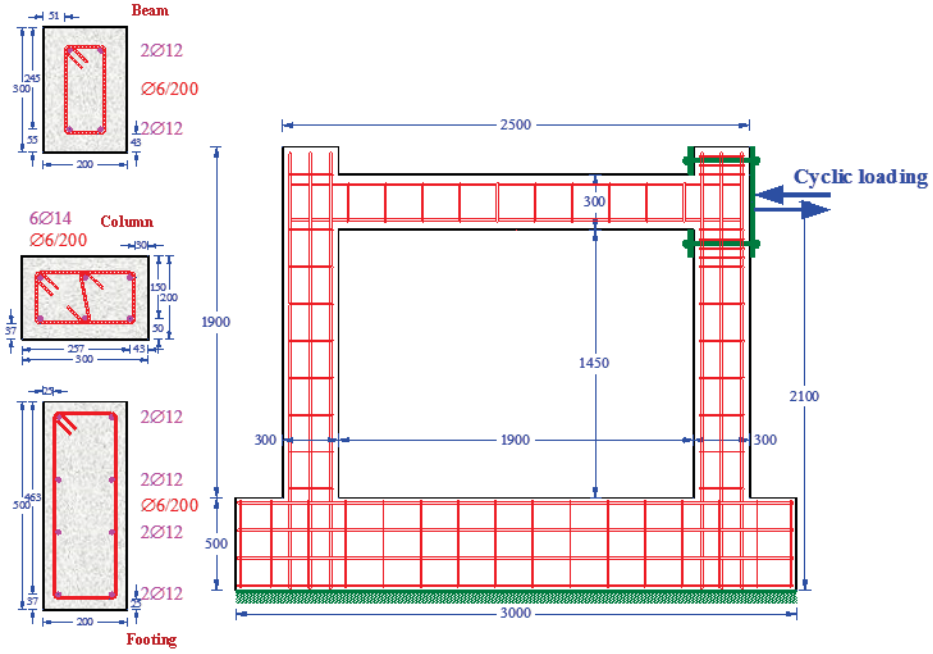

Figure 1: Dimensions and reinforcement configurations of the bare test-specimen [28, 29].

Subsequently, the same frame was tested after being strengthened with two diagonally mounted (X-bracing system) steel tie-tension rods of diameter 16 mm in cross-section, as shown in details in Fig. 2. The displacement-controlled loading history applied to both frames consists of five different and continuously increasing charging steps at ± 1.0, ± 3.6, ± 12.0, ± 22.5 and ± 45.5 mm and two equal charging cycles at each step, (as is further shown in Fig. 7 (d)).

The mode of failure of the control specimen (bare frame) of Fig. 1 is shown in Fig. 3. This is a flexure-shear mode of failure, not symmetric and much more pronounced at the left column, and it has been occurred for the imposed displacement of + 44.5 mm. As concerns the strengthened frame subjected to the same imposed displacement history, the cracking pattern at the end of the test is presented in Figure 4. There it is shown that critical flexure-shear failure of the left column has been prevented. Two distinctive flexural plastic hinges have been only formed in the beam extremities while both beam-column joints of the frame remained undamaged and practically elastic. Finally, the Figure 5 shows the comparative experimental load-displacement diagram for the bare and the strengthened frame. The load abrupt reductions (strength decay) are due to alternating axial forces.

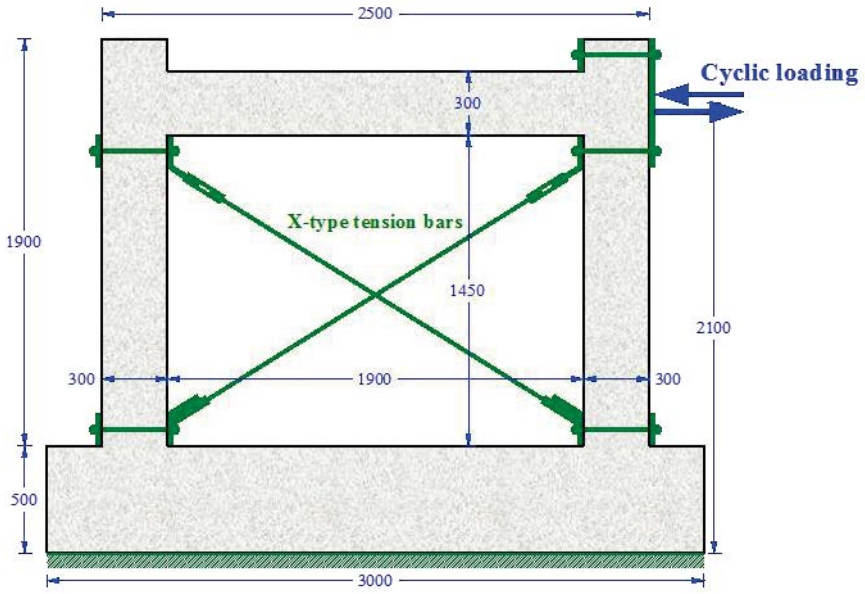

Figure 2: Dimensions and X-bracing of the strengthened test-specimen [28, 29].

Figure 3. Flexure-shear failure occurred at the left column of the bare test-frame [28, 29].

Figure 4. Cracking pattern of the steel X-braced RC frame at the end of the test [28, 29].

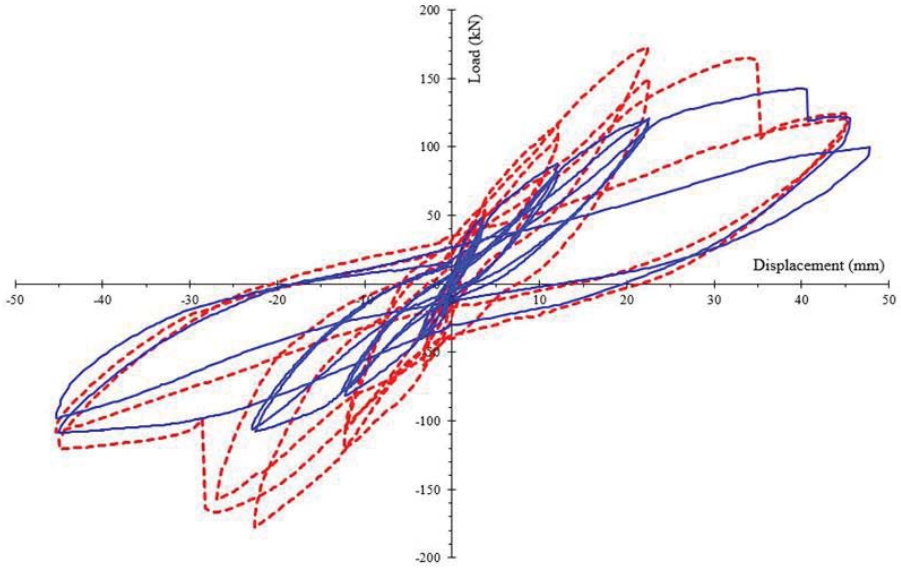

Figure 5: Experimental hysteresis load-displacement diagramme of the ties-strengthened frame (dashed red lines) in comparison to the diagramme of the bare frame without ties (continuous blue lines).

In general, the comparisons of the cyclic performance between the original bare and the X-bracing strengthened specimens indicate a significantly enhanced behavior: The load capacity in the bare frame is 120.82kN and in the strengthened frame is 178.18kN. So, an increase of 47.48% in the load capacity is recorded.

3 COMPUTATIONAL SIMULATION OF THE EXPERIMENTS TAKING INTO ACCOUNT ALTERNATING AXIAL FORCES

3.1 The computational method of analysis in general

The computational simulations of the above experiments concerns in general the dymamic response of RC framed-structures strengthened by tension-tie elements. In references [28, 30, 31] a developed methodology is presented, which concerns the dynamic analysis of RC structures strengthened by ties under multiple earthquakes. This methodology focuses on studying the seismic response of multistory RC frame structures in a practical and economic way according to suggestions of [1,6,32,33]. So, RC finite elements belonging to macroscopic models are used instead of microscopic fiber ones. For this purpose, the Ruaumoko computational code [34] is used for inelastic analysis in an appropriate way.

In order to simulate the imposed displacement-controlled loading, a pseudo - dynamic relaxation procedure [35] is applied simulating multiple earthquakes procedures [22,30,36,37]. Thus, the imposed displacements are considered as pseudo-events of a seismic sequence. These are adjusted to have a time-duration much bigger than the fundamental eigen-period of the investigated frame. Special attention and treatment is given herewith to the effects of alternating axial force on the behavior of the shear critical structural elements, in particular with

respect to the bending moment-curvature diagrams in sections, the active flexural stiffness and the cyclic shear strength, as discussed below.

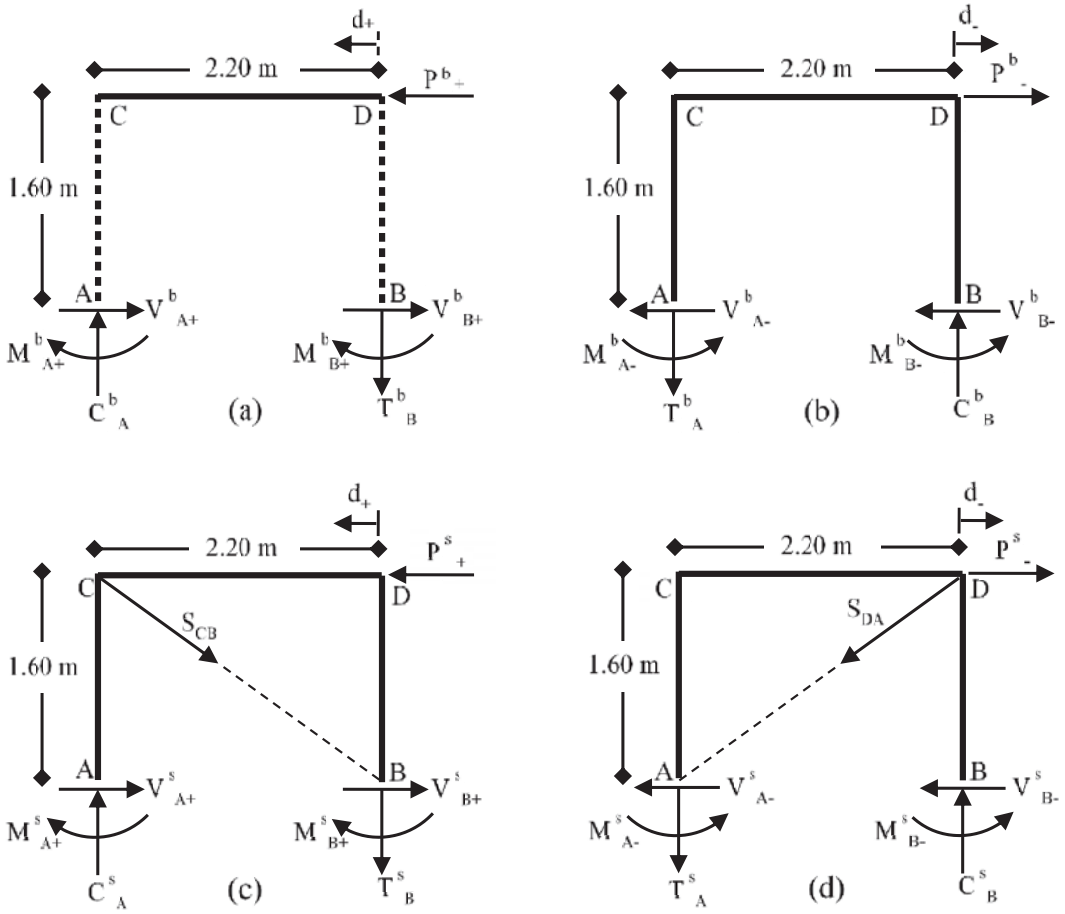

Figure 6. The alternating behaviour of the specimen-frames for the cyclic imposed displacements: (a), (b) bare frame, (c), (d) strengthened frame.

In Figure 6 the alternating behaviour of the specimen-frames of Fig. 1 and Fig. 2 due to the cyclic imposed displacements is shown. As has been reported in sections 2, the load was imposed to the right top corner joint (see Fig. 1 and Fig. 2) denoted as node D in Fig. 6. Taking into account the real axial deformation of the beam CD, this loading on node D has as result a non-symmetric behavior. This means e.g. that the shear-reactions V_A and V_B have no-equal value, but in any case, must satisfy the equilibrium condition $V_A + V_B = P$. So, equality for the shear-reactions V_A and V_B holds only under the theoretical linear-elastic assumption. Figure 6 shows the alternating frame behavior concerning the alternating axial forces, tensional or compressive ones, which are developed in the structural elements at each semi-cycle of imposed displacement, (d_{+}) ή (d_{-}), for the bare and the strengthened frame. As concerns the strengthened frame, for positive imposed displacement d_+ only the descending tie CB is activated- see Fig. 6 (c). Similarly, for the reversal negative imposed displacement d_-, only the ascending tie AD is activated- see Fig. 6(d).

Obviously, for positive (from right to left) imposed displacement d_+ on node D -see Fig. 6, (a)-the right column BD is under tension axial load T_B, whereas the left column AC and the

beam CD are under compression axial loads. On the contrary, for the reversal negative imposed displacement d- on node D, the left column AC and the beam CD appear tension, whereas the right column BD appears compression - see Fig. 7. (b). Thus, in every semi-cycle of the imposed displacements, an appropriate adaptive estimate for the effective flexural stiffness EI_{eff} of the structural members has to be realized, taking into account whether they are in compressive or in tensional state. This is in agreement with the already mentioned-see also [3,4,7,45-51]- well-known fact, that variable axial force affects, due to by it induced cracking, on the one hand the effective flexural stiffness EI_{eff}. and on the other hand the available cyclic shear strength V_R.

So, based on experimental research, they are known-see e.g. [3]- semi-empeirical relations of the form $EI_{eff} = (a_1 + a_2 P).EI_g$ for compressive axial force P, and $EI_{eff} = (a_3 - a_4 P).EI_g$ for tensional axial force P. Similarly, they are known semi-empeirical relations of the form $V_c = a(1+bP)^n$ for compressive axial force P, and $V_c = c(1-dP)^m$ for tensional axial force P, where V_c is the concrete shear strength and a,b,c,d,m,n are experimental parameters. Especially for the available cyclic shear strength V_R, the Eurocode EC8 [39] provides the formula

$$V_R = \frac{1}{\gamma_{el}} \cdot \left[\frac{(h-x)\lambda_1}{2L_s} + (1 - 0.05\lambda_2) \cdot \left[0.16\lambda_3 (1 - 0.16\lambda_4) A_c \sqrt{f_{cm}/\mathrm{CF}} + V_w \right] \right] \quad (1)$$

For the meaning of the various symbols, see [39,40]. Especially for the parameter λ_1, it depends on the variable axial force $N(t)$, i.e. $\lambda_1 = \lambda_1(N)$, and must be emphasized that $N(t)$ is positive when it is compressive, but it is taken zero when it is tensional.

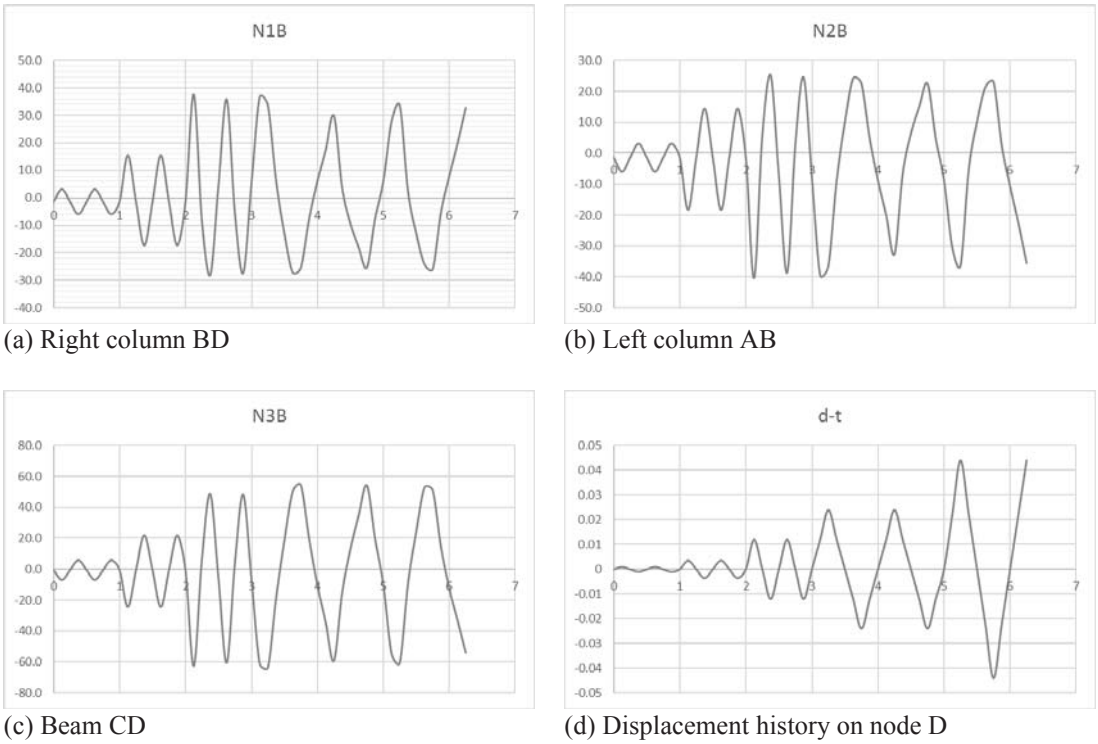
Finally, concerning the shear critical structural behavior, and especially the question, whether the flexural failure precedes the shear one or not, use of Moment versus Chord Rotation (M - θ) final elastic-plastic diagrams for the critical sections are constructed and used according to Makarios [40].

3.2 Some representative computational results

Next, some representative results by applying the above numerical simulation for the experimental process are reported. So, the alternating axial forces developed in the columns AC and BD and in the beam CD of the bare frame are shown in Fig. 7(a), 7(b) and 7(c), respectively, in dependence of the imposed displacement history on node D shown in Fig. 7(d).

As is already reported in section 2.1, the shear capacity and the stiffness of RC members is affected by the level of axial force. Compressive axial force increases and tensile axial force decreases the shear capacity and the stiffness of the columns. When the failure of the bare frame had occurred at imposed displacement of 44.5 mm, the left column AC was in compression, while the right column BD was in tension. The left column AB has appeared bigger compressive axion force than the right column BD-see Fig. 4. Note that although compressive axial force increases the shear capacity, it also increases the demand owing to the increase in the stiffness of the column. So, the left column AC "attracted" bigger portion of the horizontal load P than the right column BD, i.e. $V_A > V_B$, and when its shear resistance had been overcome by V_A, a shear failure had occurred in the left column AC.

Based on the above considerations, the mode of failure of the control specimen (bare frame) of Fig. 1 can be predicted numerically and explained. As the imposed displacement history is applied on the node D, the flexure-shear mode of failure is not symmetric and as shown in Fig. 3 it is much more pronounced at the left column.



(a) Right column BD (b) Left column AB

(c) Beam CD (d) Displacement history on node D

Figure 7. Alternating axial forces for the bare frame-specimen: (a) Right column BD, (b) Left column AB, (c) Beam CD, and (d): The history of the imposed displacement on node D.

The range-values of the alternating axial forces for the bare frame, as well as for the strengthened frame, are shown in the Table 1. These axial forces are due to both loading: on the one hand due to dead weight loading and on the other hand due to imposed displacement loading. The first ones, i.e. the compressive (negative, -) axial forces due to static dead weight loading, are: -2.89 kN for the columns AC and BD, and -0.46 kN for the beam CD.

As the total values in Table 1 show, the tensional (positive, +) axial forces in the strengthened frame are slightly reduced in comparison to the corresponding values of the bare frame. On the contrary, the compressive (negative, -) axial forces in the strengthened frame are significantly increased in comparison to the corresponding values of the bare frame. So, the shear capacity for the members of the strengthened frame is increased.

Structural Member	Bare Frame		Strengthened frame	
	max	min	max	min
Right column BD	+50.91	-35.97	+45.26	-91.17
Left column AC	+33.12	-48.11	+33.10	-109.08
Beam CD	+59.38	-68.47	+53.21	-147.48

Table 1: Extreme values [in kN] of the alternating axial forces in the structural members.

Next, for the strengthened with ties frame-specimen it is shown in Figure 8 the computational hysteresis load-displacement diagramme (continuous blue lines) in comparison to the corresponding experimental diagramme (dashed red lines). This comparison proves a good agreement between the computational results and the corresponding experimental ones. Moreover, the load abrupt reductions (strength decay) due to alternating axial forces are covered (captured) very satisfactorily.

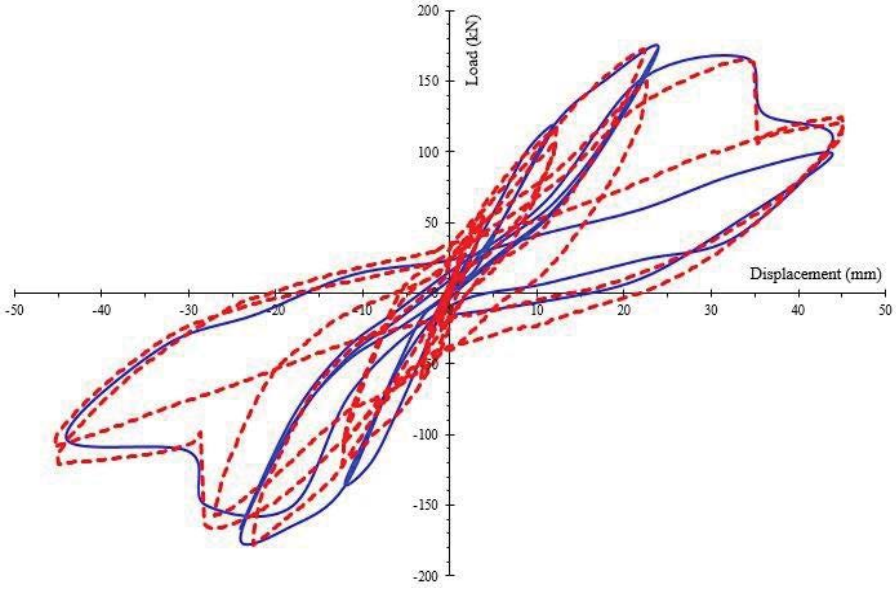


Figure 8: Strengthened with ties frame: Comparison of the computational hysteresis load-displacement diagramme (continuous blue lines) with the corresponding experimental diagramme (dashed red lines).

Finally, in Table 2 they are given indicative results, which prove the effectiveness of the strengthening by ties. The table values in columns (2) and (3) concern, respectively, the Total Damage Index DI_G and the Local Damage Index DI_L for the flexural bending moment in the base of the left column AC. These damage indices are computed according to Park & Ang formula [41,42]. In columns (4) they are given the maximum horizontal load P_{top}, which can be undertaken for both, the bare and the ties-strengthened test-frame of the experimental investigation.

FRAME	DI_G	DI_L	P_{top} [kN]
(1)	(2)	(3)	(4)
Bare	0.694	0.973	122.8 kN
Strengthened	0.001	0.001	181.9 kN

Table 2: Damage indices and maximum horizontal load P_{top}.

4 APPLICATION CONSIDERATIONS FOR FRAMED BENTS OF BRIDGES

The numerical approach presented in the previous section 3 and calibrated on the basis of the experimental results of section 2, can be effectively applied in various practical cases, which concern strengthening by tension-ties under alternating axial forces. Such cases are, e.g: (a) horizontal seismic excitation in low-rise RC framed buildings, that do not have additional

dead weight vertical loads, in coupled shear-walls systems [3], etc, (b) vertical seismic excitation due to near-field seismic excitations, especially for RC bridge systems, [7-10], (c) horizontal seismic excitation transverse to longitudinal axis of bridges having RC framed two-column bridge-bents, (d) horizontal seismic excitation of bridges with restrainer-cable systems [38]. Especially for the (c) case, where alternating axial forces have significant effects on the seismic behavior of framed bridge-bents, some typical examples are next considered.

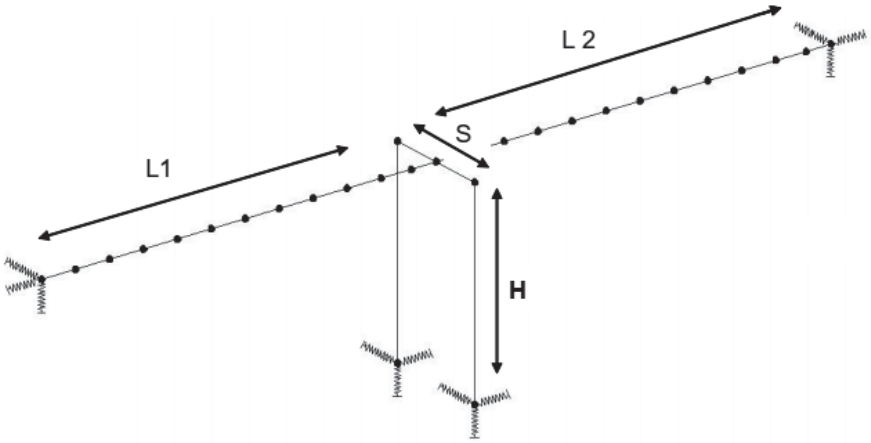

Figure 9: Simulation model of the typical two-span highway overcrossing bridge considered in [8].

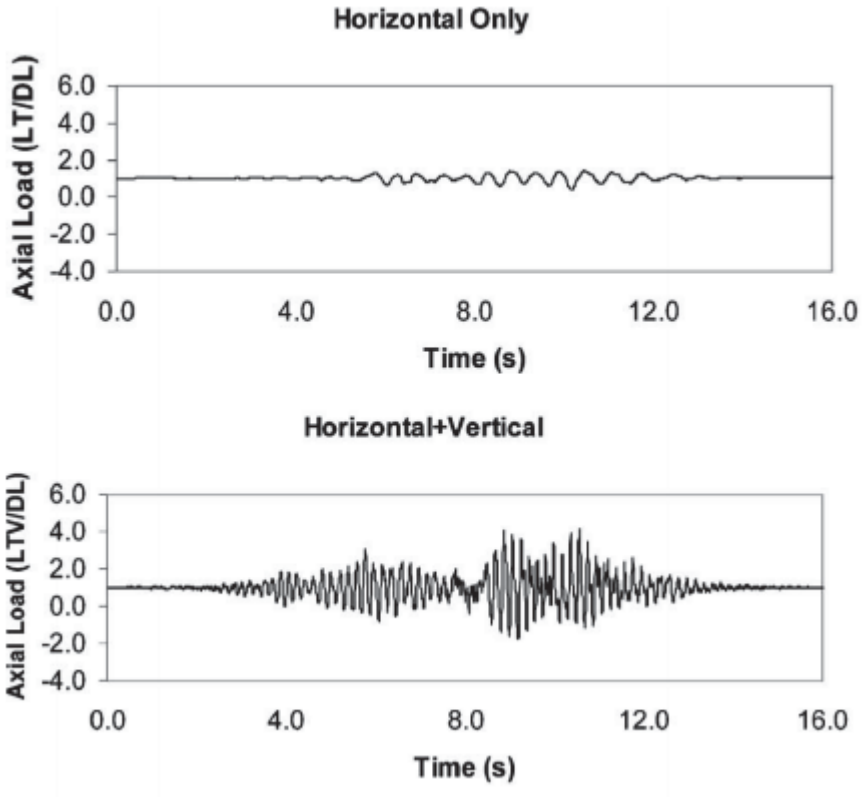

Figure 10. Time history response of axial force demand in the columns of the bridge considered in [8].

In above Fig. 9 it is shown a typical case for highway overcrossings [8] with one framed-pier. Figure 10 shows a typical response of the above bridge columns under horizontal longitudinal and vertical seismic actions. The computed axial force is considered as positive when it is compressive and is normalized by the dead axial load, which means that values below 0.0 indicate a state of axial tension in the column.

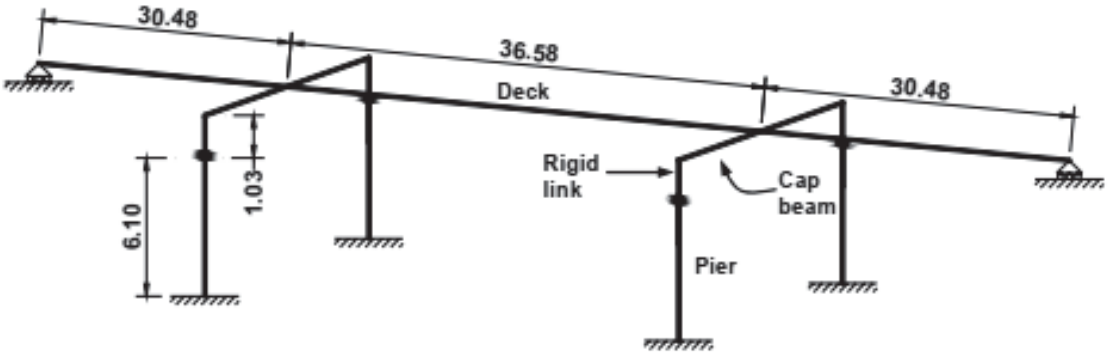

Figure 11: The FHWA Bridge #4 considered in [9] with two-colums framed piers.

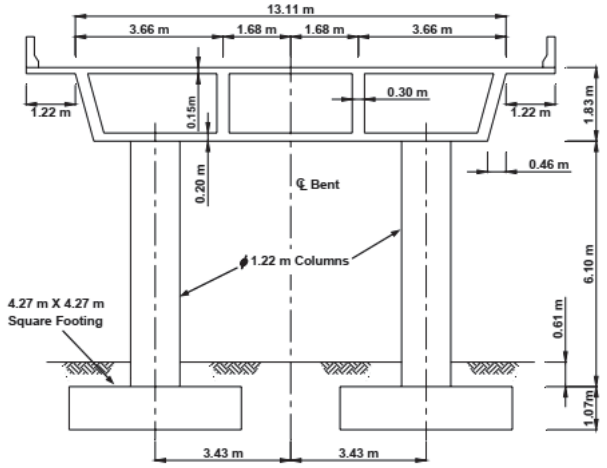

Figure 12: The cross section of the two-colums framed piers in FHWA Bridge #4 of [9].

Figures 11 and 12 show the case of a FHWA bridge considered in [9] with two framed-bent piers. Obviously, the above bents, i.e. two-column framed-piers, under transverse (to bridge axis) horizontal (along the bent) seismic excitations, may appear alternating axial forces on their columns. The same holds for the cases shown in Figure 13 and which are considered in [43,44]. The last case-(b) in Fig. 13- concerns the middle tall-pier of the high Evripos cable-stayed bridge in Chalkis, Evoia, Greece.

Concerning the seismic strengthening of above considered two-columns framed piers by bracing systems, the indicative case of using BRB (buckling resistant braces) diagonal "structural fuses" proposed in [17] is shown in Fig. 14.

In general, for strengthening by ties-bracing systems in bridges, the numerical treatment can be realized by using the herein proposed methodology.

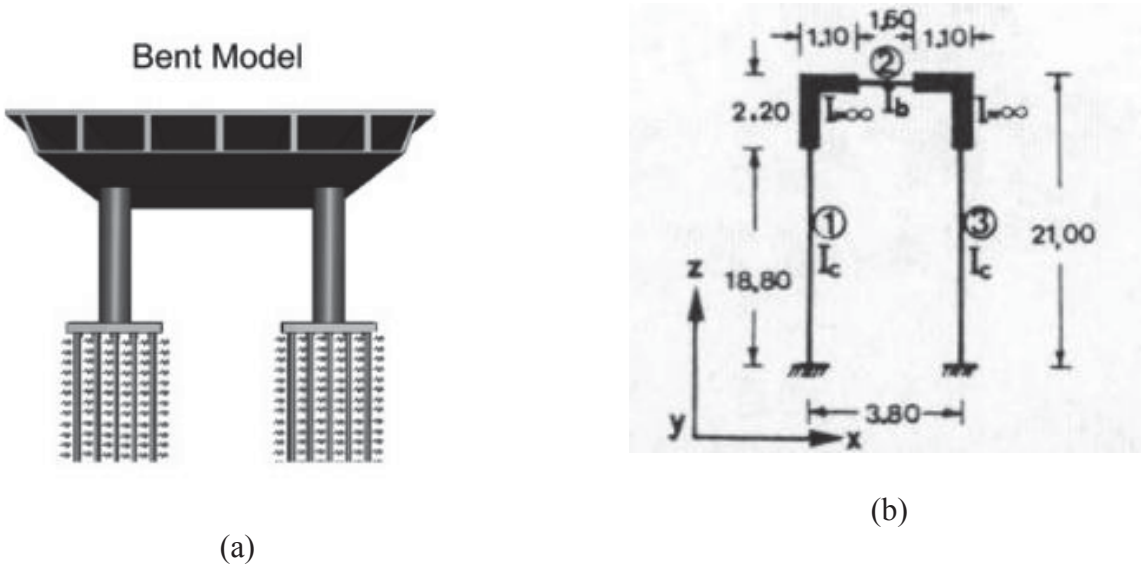

Figure 13: Two-columns framed bridge piers considered: (a) in [43], (b) in [44], Evripos bridge.

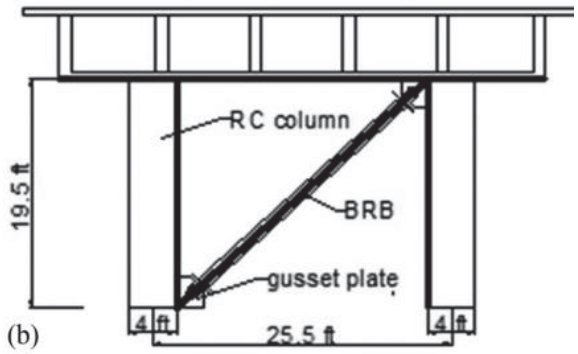

Figure 14: A two-columns framed pier strengthened by an BRB diagonal "structural fuse" proposed in [17].

5 CONCLUDING REMARKS

Based on available experimental results for shear-critical RC frame-specimens, a numerical approach has been presented and calibrated for the seismic strengthening by tension-ties under alternating axial forces. This approach can be used for the numerical treatment of the general problem concerning the tension-ties strengthening of framed-bents in existing bridges. Moreover, this approach can be used for the construction of fragility curves for the seismic vulnerability of bridges strengthened by ties. As well-known, see e.g. [54], fragility curves are very important for practical reasons concerning the evaluation of seismic risk in existing bridges. Thus, fragility curves for ties-strengthened bridges is an interesting research field. In

general must be taking into account that the numerical treatment of strengthening by bracing systems in existing bridges requires the estimation of various uncertain parameters. For this purpose, relevant results of significant recent research are now available and can be used [55-58].

Keywords: Vibration measurement; laser Doppler vibrometer; instrument vibration correction; time domain signal processing.

Abstract. *Despite widespread use in a variety of areas, in-field applications of laser Doppler vibrometers (LDVs) are still somewhat limited due to their inherent sensitivity to vibration of the instrument sensor head itself. Earlier work, briefly reviewed herein, has shown it to be possible to subtract the instrument vibration via a number of means, however, it has been difficult up to now to truly compare the performance of these. This is compounded by the constraint that a frequency domain based approach only holds for stationary vibration signals while, particularly for in-field applications, an approach that is also applicable to transient signals is necessary. This paper therefore describes the development of a novel time domain post-processing based approach for vibrating LDV measurement correction and compares it with the frequency domain counterpart. Results show that, while both techniques offer significant improvements in the corrected LDV signal when compared to a reference accelerometer measurement, the time domain based correction outperforms the frequency domain based method by a factor of eight.*

1 INTRODUCTION

Laser Doppler vibrometers (LDVs) have become indispensable tools both within industrial and research domains, especially where non-contact operation is advantageous [1]. Despite the considerable amount of published research, in-field applications of LDVs - which might include their incorporation into unmanned aerial vehicles for example - remains arguably limited, at least partly due to their sensitivity to vibration of the instrument itself. However, if this limitation was eliminated, it could enable remote vibration measurement campaigns in hazardous environments, for example facilitating the more accurate and rapid detection of remnant mines or structural health monitoring of remote infrastructure.

LDVs are based on an interferometric optical arrangement, meaning they measure target surface vibration *relative* to the instrument; conversely, more traditional contacting vibration transducers measure *absolute* surface vibration. In other words, instrument vibration, usually caused by the surrounding environment, is indistinguishable from that of the target in the resulting measurement. A common solution to this problem is to isolate the LDV using passive [2] or active anti-vibration mounting arrangements [3]. However, such solutions can be too heavy, ineffective or costly. The contemporary solution [4–6] is to independently measure the instrument vibration and use this information to correct the LDV measurement, thereby recovering the intended target vibration measurement.

Correction by measuring the instrument vibration has previously been carried out conveniently and effectively in the frequency domain [4–6], however, this is only appropriate for the statistically stationary signals that are typically encountered. Oftentimes, however, and in particular in field based measurement campaigns, vibration profiles may be transient in nature and an alternative, time domain based approach may, therefore, be more appropriate. Correction based in the time domain has previously been carried out using either an internal damper, which the reference beam is incident upon or an external accelerometer [7–9]. However, until now, no comparison has been been made of the two types of approach due to alternative experimental setups or effectiveness metrics. The development of a novel, post-processing, time domain based approach and its comparison with the frequency domain based alternative is, therefore, the focus of this article.

2 FREQUENCY DOMAIN BASED PROCESSING

It has been rigorously shown, both mathematically and experimentally, that correction of erroneous LDV measurements requires the subtraction of an independent simultaneous measurement of the instrument/optical element vibration [4, 5]. In the case of a single beam LDV, this measurement is conveniently achieved in practice using a single, ‘correction accelerometer’ mounted somewhere along the laser beam axis, generally on the back of the housing. To experimentally confirm the validity of the correction, a second ‘reference accelerometer’ is typically mounted to the target at the measurement location to offer a ‘true’ target vibration measurement. For statistically stationary velocity signals, frequency domain processing is a convenient means by which subtraction of the correction accelerometer signal can be realised while simultaneously performing the required integration and temporal alignment. The framework for this frequency domain based processing approach for the correction of erroneous LDV measurement is already well-established and the description is therefore intentionally kept brief in what follows.

2.1 Sensitivity adjustment and time delay correction

Accelerometer sensitivities are adjusted, with reference to the LDV, using a broadband frequency domain based relative calibration procedure. By necessity, this includes integration, readily achieved in the frequency domain, of the accelerometer signals. Ratios of the vibration levels over the frequency range of interest are used to revise the accelerometer sensitivities. Furthermore, due to inevitable differences between accelerometer and LDV signal conditioning electronics, finite time delays, independent of the sensitivity adjustment, exist between the digitised signals. Again, taking the LDV as the reference, these can be similarly readily estimated in the frequency domain from the signal phase differences [4, 5].

2.2 Instrument vibration correction

Among other typical practical measurement factors, including the accuracy of the positioning of the correction transducer to accurately determine the instrument vibration in the laser beam direction, the mean error reduction achieved depends upon the relative levels of instrument and target vibration. For vibration levels and frequency ranges of relevance to 'real-world' measurement campaigns, that is an RMS of 1 $\mathrm{mm\,s^{-1}}$ to 10 $\mathrm{mm\,s^{-1}}$ over the frequency range 2.5 Hz to 100 Hz, comparison of the LDV signal to the reference accelerometer typically yields a significant mean error reduction between 15 and 30 dB [4–6]. As previously derived [6], the mean error reduction, R, is calculated using:

$$R = -10 \log_{10} \left(\frac{\mathrm{MSE_{corr}}}{\mathrm{MSE_{m}}} \right) \ \mathrm{dB} \tag{1}$$

where $\mathrm{MSE_m}$ and $\mathrm{MSE_{corr}}$ are the mean square error of the LDV signal before and after correction, respectively, when taking the reference accelerometer signal as the 'true' vibration signal. For N spectral lines, the general formulation is:

$$\mathrm{MSE_{signal}} = \frac{1}{2} \sum_{n=1}^{N} (A_{\mathrm{signal}}(n) - A_{\mathrm{true}}(n))^2 + (B_{\mathrm{signal}}(n) - B_{\mathrm{true}}(n))^2 \tag{2}$$

where $A_{\mathrm{signal}}(n)$ and $B_{\mathrm{signal}}(n)$ are the real and imaginary parts, respectively, of either the measured or corrected LDV signal at the nth spectral line. Similarly, $A_{\mathrm{true}}(n)$ and $B_{\mathrm{true}}(n)$ are the equivalents for the reference accelerometer signal.

3 TIME DOMAIN BASED PROCESSING

While there are some earlier studies in which erroneous measurements from LDVs subject to instrument vibration are resolved in real time or using time domain based techniques [7–9], they are few in number and diverse in approach with each employing a different metric to gauge the efficacy of the correction. This makes it somewhat difficult to contextualise the relative performances as well as to compare each with the established frequency domain based approach previously described. An early approach used a purely mechanical means to perform the compensation, incorporating an internal damper into the optical arrangement, upon which the reference beam was incident [7]. However, this system performance is unlikely to be consistent over a sufficiently wide frequency range as a result of damper resonances. Other known solutions employ a correction accelerometer, with the compensation being performed either in real-time [8] or in post-processing [9]. In the former, it is unclear where the accelerometer was mounted geometrically, only that it was mounted to the probe laser beam optics. Recent work

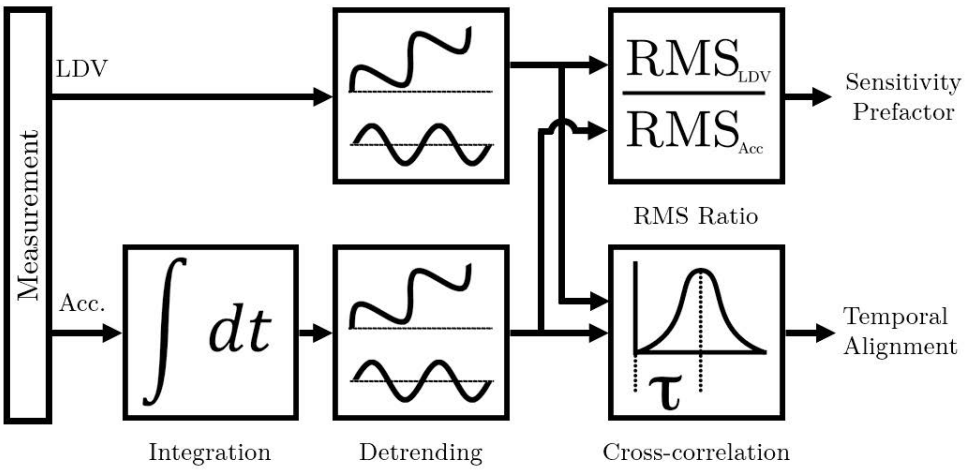

Figure 1: The time domain based accelerometer calibration procedure with "Acc." representing either the correction or the reference accelerometer signal.

has shown that the accelerometer must be on the laser beam axis for complete correction in the presence of arbitrary six degree-of-freedom instrument vibration [5]. In the latter, some useful enhancements to the preceding frequency domain based approach are introduced, in particular the means to undertake signal time delay compensation using time series data.

Offering complementarity to the earlier approaches, the method proposed herein is entirely based in the time domain and, for the moment, is performed in post-processing on recorded signals. In this respect, it does not differ to the frequency domain based approach, previously summarised, and, as such, the required experimental arrangement is common. While the motivation for the novel approach is to extend current capability to processing of *non-stationary* signals, in order to directly compare with the frequency domain equivalent, using the same previously defined metric, R, *stationary* vibration signals only are considered herein.

3.1 Sensitivity adjustment and time delay correction

As for the corresponding stage in the frequency domain based processing approach, accelerometer sensitivities and signal finite time delays are determined with the LDV taken as the reference. Figure 1 schematically depicts the time domain based processing calibration procedure for a single accelerometer; this can be replicated for as many accelerometers as are required. Again, the accelerometer signals must first be integrated and this is straightforwardly achieved here using the cumulative trapezoidal method. However, the integration of accelerometer signals commonly leads to the introduction of errors such as a DC offset and drift. Detrending is intended to remedy this and is achieved by subtracting a least squares fit of a first order polynomial from the integrated signal. Since this might remove genuine as well as spurious signal content, the LDV signal is subjected to the same for consistency.

With the accelerometer and LDV signals both represented as velocities, an RMS ratio can then be used to revise the accelerometer sensitivities; all subsequent measurements acquire signals accordingly adjusted. Meanwhile, the finite time delays between the LDV and accelerometer signals which occur as a result of differences between the signal processing electronics in the measurement chain, are estimated using a cross-correlation function as follows [9]:

$$r_{xy}(\tau) = \frac{1}{T}\int_0^\infty x(t)y(t+\tau)dt \tag{3}$$

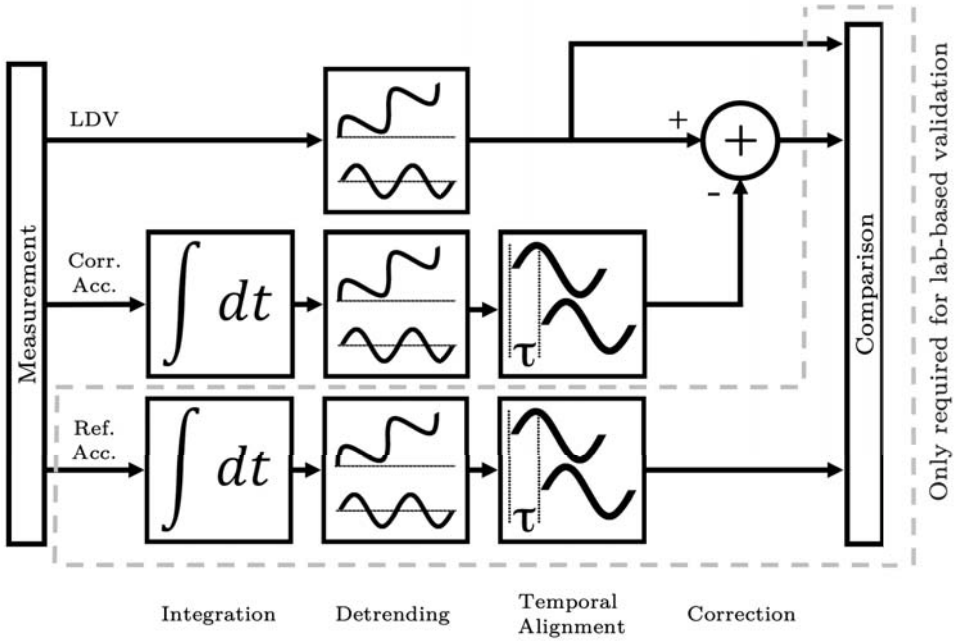

Figure 2: The time domain processing correction procedure with "Corr. Acc." and "Ref. Acc." representing the correction and reference accelerometer signals, respectively.

where τ is the time delay between the signals, x and y are the two signals, t is time and $r_{xy}(\tau)$ the cross-correlation function in which the peak will occur at the time delay between the signals.

3.2 Instrument vibration correction

Figure 2 schematically depicts the time domain based processing correction procedure. The first, "Integration", and second, "Detrending", steps are consistent with those previously described. The third, "Temporal alignment", step incorporates the finite time delay in the accelerometer signals. This is achieved by time-shifting each accelerometer signal relative to the LDV signal by the amount previously determined, τ. Since this is only possible in integer units of the time step, a high sample frequency is required to maximise the accuracy of the temporal alignment between the signals. This time-shifting results in regions at the start and at the end of the measurement duration where samples for all three signals are not present and these regions are therefore truncated. The total original measurement duration may therefore need to be slightly longer than that which is ultimately required.

The final signal processing step in Figure 2, "Correction", refers to the LDV signal correction and is given mathematically by [4]:

$$U_{\text{corr}}(t) = U_{\text{m}}(t) - U_0(t) \tag{4}$$

where $U_{\text{m}}(t)$ is the measured LDV signal, $U_0(t)$ is the integrated correction accelerometer signal and $U_{\text{corr}}(t)$ is the fully corrected LDV signal.

Ultimately, and only possible in the lab-based experimental validation approach described herein, the "Comparison" step in Figure 2 determines the efficacy of the correction procedure. This is achieved by comparing the corrected LDV signal with the final reference accelerometer signal. The performance metric used here is the previously described mean error reduction, R, given by (1). To calculate this in the time domain, an appropriate formulation of the MSE

should be used, given by [6]:

$$\mathrm{MSE}_{\mathrm{signal}} = \overline{\big(U_{\mathrm{signal}}(t) - U_{\mathrm{true}}(t)\big)^2} \tag{5}$$

where $U_{\mathrm{true}}(t)$ is the reference accelerometer, $U_{\mathrm{signal}}(t)$ is either the measured or corrected LDV signal and $\overline{(\cdot)}$ signifies the time average. Direct comparison can now be made between processing techniques in both the time and frequency domains.

4 EXPERIMENTAL VALIDATION

4.1 Setup

An experimental setup, common with that implemented in earlier work [4–6], depicted in Figure 3 was arranged, whereby independent control of the target vibration and of the LDV vibration was possible. The target vibration is the measurement of interest while the base vibration simulates the effect of a vibrating platform on the LDV measurement. Both target and base vibrations were created using electrodynamic shakers independently powered and driven using uncorrelated broadband white noise signals up to 200 Hz, generated by a Siemens PLM Simcenter SCADAS Mobile data acquisition system.

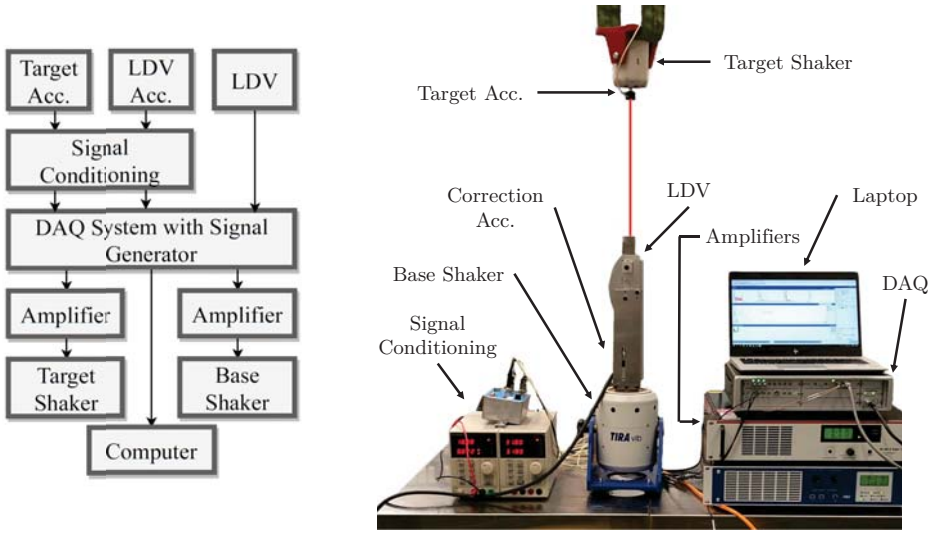
Mounted to the base vibration shaker, using a custom-made aluminium mounting bracket such that the LDV sensitive direction was aligned with the shaker vibration direction, was a Polytec Compact Laser Vibrometer NLV-2500-5. The bracket also contained an Endevco 770-10-U-120 (200 $\mathrm{mV/g}$ nominal) DC-response accelerometer, rigidly mounted with synthetic beeswax. This correction accelerometer was aligned with the probe laser beam axis to be optimally effective [4]. The target shaker was suspended from above using an overhead crane, providing isolation from the large base motion shaker. Mounted to the shaker spigot was a second similar Endevco accelerometer providing the 'true' vibration measurement.

4.2 Data collection and processing

The Siemens acquisition system was used to record the various time data throughput vibration signals at the maximum sampling frequency of 204.8 kHz for a duration of 8 s. This extremely high oversampling factor assists in the accurate temporal alignment of the three signals in the time domain, as previously mentioned. The acquired data were processed as five separate 1.6 s segments for both processing methods. In the frequency domain, these acquisition parameters lead to a spectral resolution of 0.625 Hz and a bandwidth of 102.4 kHz. The DC component was excluded from the calculation of R in frequency domain processing. The mean error reduction for both the time and frequency domain based approaches was averaged over the five segments with the standard error of the mean taken as the uncertainty in each result.

4.3 Results comparison

Frequency domain based accelerometer calibration for the model and conditioning used yielded a time delay of -138.5 ± 13.2 µs with the corresponding time domain based method value of -125.0 ± 1.1 µs in agreement. Since the estimation using the time domain based method yielded a lower uncertainty, a time delay of -125.0 µs was subsequently used for both correction procedures. It should be noted that, due to the necessary signal truncation following time domain based temporal alignment, comparisons between time and frequency domain approaches are not of *exactly* identical signal content. In this case, however, the difference is only 26 out of over 300,000 samples and it is therefore unlikely this will significantly affect the

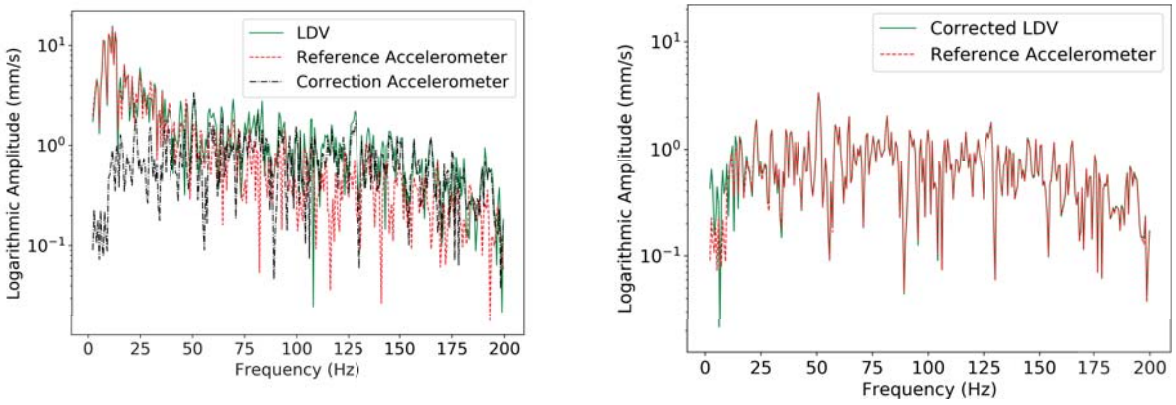


(a) (b)

Figure 3: Experimental setup used to simulate a LDV target vibration measurement during base motion vibration: (a) block diagram representation and (b) physical setup.

results.

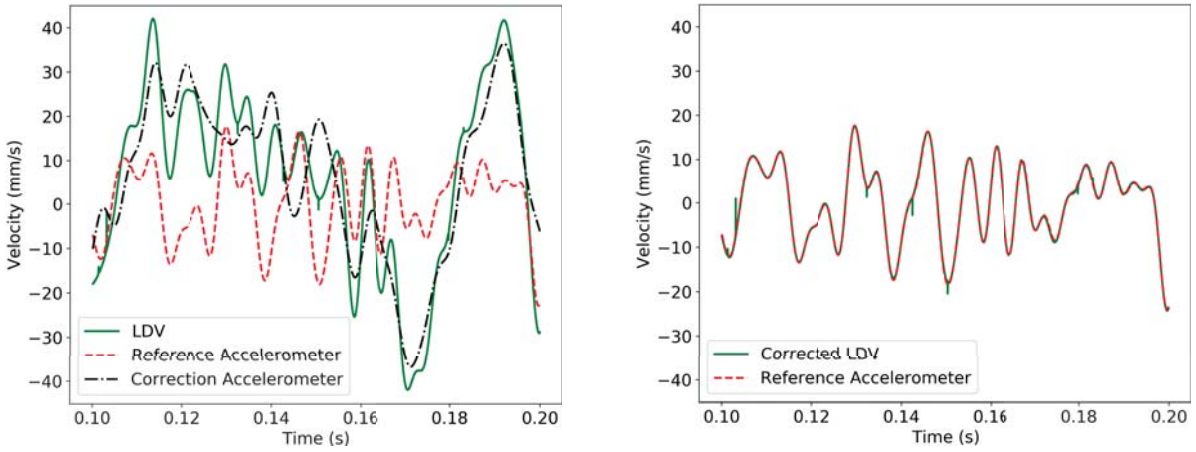
As can be seen qualitatively by comparing Figure 4 (a) and Figure 4 (b), this frequency domain based processing method yields significant improvements in the corrected versus the uncorrected LDV signal over the range 25 Hz to 200 Hz. However, the performance below 25 Hz is relatively poor, likely due to the lower signal level in this range owed to the shaker-amplifier dynamic characteristics.



(a) (b)

Figure 4: Frequency domain processing spectra for a 1.6 s segment in the range 0.625 Hz - 200 Hz: (a) all signals before correction and (b) corrected LDV and reference accelerometer signals.

As can be seen in Figure 5 for a 100 ms segment of data, the time domain based processing method proposed here also offers significant improvement in the corrected versus the uncorrected LDV signal. However, in the time domain, the effect of speckle noise [1] is apparent, manifested as instantaneous spikes not present in the reference accelerometer signal.



(a) (b)

Figure 5: A 100 ms segment of data from time domain processing: (a) all signals before correction and (b) corrected LDV and reference accelerometer signals.

The quality of the correction for the two alternative methods can be compared quantitatively using the mean error reduction, R, which can be seen in Table 1. Here it is shown that the time domain processing method outperforms the established frequency domain based processing method by a factor of eight.

Table 1: The mean error reduction for the five 1.6 s segments along with their logarithmic uncertainties calculated as the standard error of the mean.

	R	
Frequency Domain	$25.3^{+1.8}_{-1.3}$	dB
Time Domain	$34.5^{+2.1}_{-1.4}$	dB

5 CONCLUSIONS

While correction of LDV measurements in the presence of instrument vibration has typically been carried out in the frequency domain and for *stationary* vibration signals only, extension to vibration signals that are *transient* in nature requires an alternative, time domain based approach. Furthermore, the direct comparison of existing time domain based approaches with the established, frequency domain approach is challenging. In this paper, therefore, the totally general theoretical basis for complete measurement correction was extended to include a completely time domain based approach.

Validation using a conventional experimental arrangement consisting of a vibrating LDV instrumented with a correction accelerometer and a vibrating target similarly instrumented to provide a true vibration reference measurement, has been shown. Throughput time data for statistically stationary vibration signals have been acquired and processed in both frequency and time domain processing. It has been shown that, while both approaches lead to significant improvements in the quality of the corrected LDV measurement, the time domain based approach described here yields a mean error reduction value, R, eight times higher than the previously described frequency domain based approach.

This improvement is a significant finding and offers a viable alternative to the established frequency domain equivalent for *stationary* vibration signals, provided time data signals can be acquired with a high oversampling factor. Moreover, it now extends the capability to perform complete correction of LDV measurements in the presence of *transient* instrument vibration, such vibrations being more likely to occur in real-world in-field applications for example in measurement campaigns from unmanned aerial vehicles.

Future investigations will explore the sensitivity of the time domain based approach to reduced sample frequency signals and identify the sources of the performance gap. Improved frequency domain approach performance, including the estimate of accelerometer signal time delays, will be realised. Ultimately, however, deployment of the time domain based approach for transient signal processing will be the most significant follow-up to the work presented here.

Keywords: granular damping, friction, impact, irregular particle, sphericity, circularity, discrete element method.

Abstract. *In numerical models for granular dampers, particles are generally considered to be perfect spheres. However, in practical engineering applications these particles can slightly deviate from being true spheres. It has been observed experimentally that sphericity, which defines the proximity degree of a shape to a sphere, plays an important role in the amplitude dependent behaviour of granular dampers. This paper mainly examines the significance of the sphericity level for slightly oblate particles in a granular damper that are subjected to sinusoidal vibrations in the same direction as standard gravity. This investigation is carried out by evaluating the dissipated power from the granular medium by utilizing three-dimensional discrete element method simulations. Apart from the effect of amplitude of vibrations in the dissipated power, the relative contributions of frictional and inelastic collisional damping mechanisms in the overall power dissipation, are also investigated for varying sphericity levels of the oblate particles.*

1 INTRODUCTION

Granular (or particle) damping is an effective passive damping approach that involves many small spherical particles (typically 0.05 mm – 5 mm in diameter) located inside an enclosure that is fixed to a vibrating structure. The kinetic energy from vibration is transmitted to the particles by collisional momentum exchanges between the particles and the boundaries of the enclosure. Granular dampers dissipate the transmitted kinetic energy through inter-particle and particle-enclosure boundary interactions. This is unlike common viscoelastic dampers which generally dissipate the stored elastic energy.

Interest in granular damping is rapidly increasing in engineering fields because such dampers are robust, cost-effective, easy to retro-fit and relatively insensitive to the environment and excitation frequency. [1–4]. As a result, granular dampers have been successfully applied in numerous mechanical systems to solve noise and vibration problems, such as a desk-top banknote processing machine [5], the exterior panel of a launch vehicle [6], a gear transmission system [7], and an automotive oil pan [8].

Despite their conceptual simplicity, granular dampers have quite complex and distinctive behaviour. Since the particles are generally hard, made from materials such as metal and ceramic, surface friction plays an important role in energy dissipation, which leads to significant non-linearity in the form of amplitude dependent behaviour [9,10]. Granular damping has been studied extensively and this non-linearity is the likely reason for the existence of many contradictory findings in the literature. To improve understanding, studies have been undertaken to investigate the sensitivity of granular damping against damper parameters, such as coefficient of restitution between impacting bodies, coefficient of friction in contacting surfaces, particle number and individual stiffness of particles and enclosure walls [11–13]. More recently, it has also been shown that an approximated granular damper model in Discrete Element Method (DEM) simulations can adequately represent the essential properties of a real granular damper without matching parameters exactly provided the total mass is represented accurately [14]. This presumably arises from the compensation feature of multiple particles against the small variations of parameters from exact ones. It should be noted that this 'universal response' approach is only valid when using relatively large numbers of particles.

Previous studies have reported that granular dampers exhibit the characteristic properties of both friction dampers and single impact dampers since the main damping mechanisms of granular dampers are surface friction and inelastic collision within the granular media [15]. Furthermore, it has been also emphasized before that understanding of the damping mechanisms would provide an efficient way to increase the performance of such dampers [1]. Accordingly, a few attempts have been made to identify relative contributions of damping mechanisms in granular damping [15–18]. However, much uncertainty still exists and the literature on this topic is very scarce.

Although the hard particles used in granular dampers typically have a high level of durability, over time their shape may deviate from a true sphere due to harsh working conditions or intense collisional events. Moreover, non-spherically shaped particles may be deliberately used either for cost reasons or to avoid practical design issues such as the packing problem in small voids or because of manufacturing tolerances. Therefore, the investigation of irregular particles has grown in importance [19–21]. However, there is no notable study that focuses upon slightly oblate particles in granular dampers.

The aim of this study is to provide a numerical investigation on slightly oblate hard particles in a granular damper undergoing harmonic vibrations in the same direction as gravity. Several three dimensional DEM simulations are carried out to find the effects of particle sphericity levels on the dissipative behaviour. Steady-state cumulative power loss calculations are

utilized to characterize the amplitude dependent granular damper in every simulation. The contributions of frictional and collisional energy dissipation mechanisms on the total dissipation are computed.

2 DEM MODEL FOR OBLATE PARTICLES

DEM is a numerical scheme for analyzing granular matter, in which the motion of every particle is tracked in time. The full time history of interest is broken into a series of very short time steps over which the equations of motion for each particle are solved. Where particles interact with one another, or with the physical boundaries of the system being studied, appropriate force-displacement and force-velocity relations for the contact are employed. The fundamental theory of DEM was originally presented by Cundall and Strack [22] and was first applied to granular dampers more than 20 years ago [23]. The use of DEM is attractive in the study of granular damping because it provides a way to control and observe the contact parameters and their effect on overall damping achieved.

2.1 Oblate particle generation

Although several algorithms have been developed recently that allow irregular particles to be defined and used directly within the DEM field, the most common method is the multi-sphere approach. In this approach, two or more overlapping spherical particles are rigidly joined together. Relatively complex shapes can be produced as the spheres are allowed to intersect each other. The use of the sphere as the building block provides computational benefits including the existence of advanced contact detection algorithms and contact models. Thus, the oblate particles used in this study are formed by employing the multi-sphere approach in the EDEM 2020 software [24].

Shape is an important indicator which defines a particle in numeric computational fields – especially for rock-like irregular particles [25]. If a large number of spheres is used in the multi-sphere approach, non-spherical shapes can be represented more precisely. However, it also causes significant increases in computational times. Hence, irregular shapes should be modeled conducting a balance between computational efficiency and closeness of representation. In this study, oblate particles are generated considering these criteria and are shown in Figure 1.

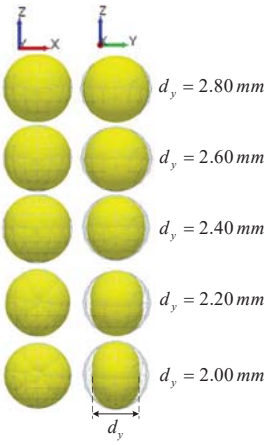

Figure 1: Created particle types for simulations with respect to a $3\,mm$ diameter perfect sphere mesh template.

It should be noted that the reference perfect sphere diameter used in this study is 3 mm and particle resizing occurs along the local y-axis (i.e. d_y changes) as can be seen in Figure 1,

whilst the other lengths (d_x , d_z) are kept constant. In this investigation, the lower limit for d_y was set at 2 mm, which represents a moderate change in particle shape.

The relative similarity of oblate particles to the reference sphere can be described using the sphericity index [25] which can be written as,

$$\psi = \sqrt[3]{\frac{c^2}{ab}} \tag{1}$$

Here, a , b and c are the corresponding lengths (largest to smallest, respectively) along the three local axes. In this paper, only the smallest length of the oblate particles is adjusted and therefore, $c = d_y$, $a = b = d_x = d_z = 3\,\text{mm}$.

Since oblate particles are created by deforming a sphere along one axis, a two dimensional parameter called the circularity index can also be used to define the shape. Circularity is defined in the local YZ axis as shown below [20].

$$C = \sqrt{\frac{4\pi A_{YZ}}{P_{YZ}{}^2}} \tag{2}$$

where A_{YZ} and P_{YZ} are respectively the projection area of a particle on the YZ axis and the perimeter of the particle. Sphericity and circularity values for the oblate particles used in this work, are presented in Table 1.

Particle minor axis length, d_y [mm]	Sphericity, ψ [-]	Circularity, C [-]
2.00	0.763	0.970
2.20	0.813	0.980
2.40	0.862	0.989
2.60	0.909	0.995
2.80	0.955	0.999
3.00	1.000	1.000

Table 1: Shape parameters of oblate particles.

2.2 Contact force model

In DEM, although particles are created as completely rigid bodies, contacts between them are deformable. Contacts are traditionally modeled using spring and dashpot elements as shown in Figure 2a, which allow relatively rapid calculations to be performed. For perfect spheres, force-displacement relationships have already been defined and tested for suitability [26–28]. As the multi-sphere is employed, these validated models can be applied to address the load-deformation behaviour of oblate particles. The contact model used in EDEM 2020 for this study is briefly summarized below considering the spheres shown in Figure 2a.

Normal elastic force between the spheres is determined using the well-known non-linear Hertzian contact model.

$$\boldsymbol{F}_{N_e} = -\underbrace{\frac{4}{3} E^{eq} \sqrt{R^{eq}}}_{k_N} \delta_N{}^{3/2} \boldsymbol{e}_N \tag{3}$$

Here, $\boldsymbol{e}_N$ is the unit vector from the centre point of sphere under consideration to the contact point and δ_N is the normal overlap of sphere. In this expression, the equivalent elastic modulus (E^{eq}) and the equivalent radius (R^{eq}) can be found by $1/E^{eq} = \left(1-\nu_1^2\right)/E_1 + \left(1-\nu_2^2\right)/E_2$ and $1/R^{eq} = 1/\mathrm{R}_1 + 1/\mathrm{R}_2$, where E, R and ν are elastic modulus, radius and Poisson's ratio of relevant spheres, respectively. In order to define inelastic (i.e. dissipative) part of normal force between the spheres, a coefficient of restitution (e) based approach is employed [29]:

$$\boldsymbol{F}_{N_d} = -\underbrace{2\sqrt{\frac{5}{6}}\frac{\ln(e)}{\sqrt{\ln^2(e)+\pi^2}}\left(2m^{eq}E^{eq}\sqrt{R^{eq}\delta_N}\right)^{1/2}}_{c_N}\frac{d\boldsymbol{r}_{\boldsymbol{rel}_N}(t)}{dt} \tag{4}$$

where equivalent mass (m^{eq}) is defined using the individual masses of spheres $1/m^{eq} = 1/m_1 + 1/m_2$ and $d\boldsymbol{r}_{\boldsymbol{rel}_N}(t)/dt$ denotes the normal relative velocity between the spheres in contact.

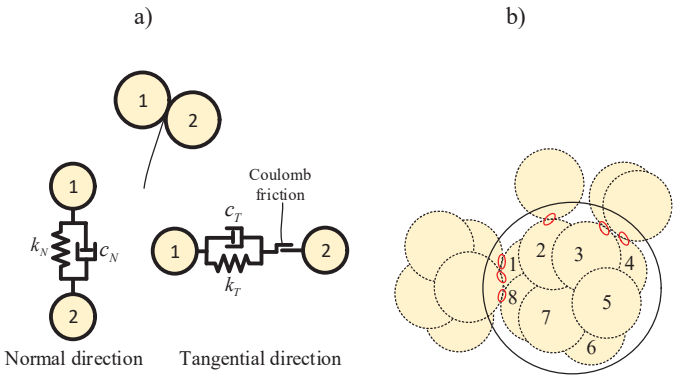

Figure 2: a) Modelling at the contact point of two contacting spheres, b) contacts of an irregular particle constructed with many spheres.

On the other hand, tangential elastic force is determined according to normal overlap defined as Mindlin and Deresiewicz method [16]. Unlike the original method in which many incremental elastic-plastic loading and unloading steps exist [30], a simplified version of this method is used to define tangential elastic force-displacement relation as given below.

$$\boldsymbol{F}_{T_e} = -(1-\vartheta)\underbrace{8G^{eq}\sqrt{R^{eq}\delta_N}}_{k_T}\delta_T\boldsymbol{e}_{\boldsymbol{T}} \tag{5}$$

While equivalent shear modulus (G^{eq}) is defined by $1/G^{eq} = \left(1-\nu_1^2\right)/G_1 + \left(1-\nu_2^2\right)/G_2$ with shear modulus of spheres (G), δ_T and $\boldsymbol{e}_{\boldsymbol{T}}$ stands for the tangential overlap and the unit vector along tangential overlap, respectively. Additionally, tangential inelastic force can be also formed using the similar approach as for normal direction. However, shear friction should be also taken into consideration in tangential direction. Thus, the widely used Coulomb friction model is added to tangential contact model:

$$\boldsymbol{F}_{T_d} = -(1-\vartheta)\underbrace{2\sqrt{\frac{5}{6}}\frac{\ln(e)}{\sqrt{\ln^2(e)+\pi^2}}\left(8m^{eq}G^{eq}\sqrt{R^{eq}\delta_N}\right)^{1/2}}_{c_N}\frac{d\boldsymbol{r}_{\boldsymbol{rel}_T}(t)}{dt} - \vartheta\gamma_f\left|\boldsymbol{F}_N\right|\boldsymbol{e}_{\boldsymbol{T}} \tag{6}$$

where $d\boldsymbol{r}_{rel_T}(t)/dt$ is the tangential relative velocity between the spheres and γ_f is coefficient of friction. ϑ is for indicating whether slipping occurs or not as seen in Equation 7.

$$\vartheta = \begin{cases} 1 & |\boldsymbol{F}_T| > \gamma_f |\boldsymbol{F}_N| \\ 0 & otherwise \end{cases} \tag{7}$$

It should be also noted that although the contact model is presented considering sphere – sphere contacts, it would be also valid for sphere – cylindrical enclosure contacts if one assumes $R_{enclosure} \to \infty$ and $m_{enclosure} \to \infty$ in above expressions.

For an irregularly shaped particle modelled using multi-sphere approach, contact force calculation procedure should be performed accounting all existing contacts of all individual spheres which constitute the particle. For example; as can be seen in Figure 2b, 8 perfect spheres which form the irregular particle have different number of contacts with other particles (e.g. number 1 has 2 contacts while number 8 has 1 contact) and the effects of the total 6 contacts can be only obtained by looking all 8 spheres. Thus, the resultant force acting on the particle can be computed as follows for a particle:

$$\boldsymbol{R}_F = \sum_i \left\{ \sum_{j(i)} \left(\boldsymbol{F}_{N_e} + \boldsymbol{F}_{N_d} + \boldsymbol{F}_{T_e} + \boldsymbol{F}_{T_d} + \boldsymbol{F}_g \right) \right\} \tag{8}$$

where i and $j(i)$ are the indices which count the total spheres forming the particle and the total contacts involved by sphere i, respectively. $\boldsymbol{F}_g$ is the gravitational force acting on the corresponding sphere. The resultant moment acting on the particle can be also determined by vectorial product of the resultant force and the position vector of particle mass center ($\boldsymbol{r}_c$).

$$\boldsymbol{R}_M = \boldsymbol{r}_c \times \boldsymbol{R}_F \tag{9}$$

2.3 DEM simulation procedures

In three dimensional DEM simulations, detected contacts of particle – particle and particle – enclosure pairs are considered to perform the given contact force computation procedure at a solution time step. After the calculation of resultant forces and moments, Euler-Newton equations of motions are numerically solved to find updated translational and rotational kinematics (i.e. positions, velocities and accelerations) of every particle by utilizing central-difference formulae.

The time step needs to be set small enough to capture particle overlaps, avoid propagating disturbances of a particle far from away and decrease numerical inaccuracies in simulations. Although several other approaches have been available to estimate a time step for realistic simulations in DEM, the Rayleigh time step criterion is used in the present study [31]. The time interval used in the simulations is chosen to be approximately %50 – %35 of the Rayleigh time step according to the particle type to ensure the reliability of simulations.

Even though there have been studies which investigate the characteristics of granular damping considering the dynamics of host structure [12,32], it is useful to carry out investigations on the damper alone to determine energy dissipation behaviour independently from the host structure [33,34], so that the damper can be adopted to any structure. This study involves a cylindrical enclosure filled with oblate particles subjected to vertical sinusoidal vibrations.

Particles are given the properties of stainless steel while the material of enclosure is chosen as polymethylmethacrylate (PMMA). The properties of these materials and the dimensions of

the enclosure are given in Table 2. The contact properties used in the simulations (i.e. friction and restitution coefficients) are determined as presented in this table. These parameters are selected according to a comprehensive study in which stainless steel – stainless steel and PMMA – stainless steel interactions were experimentally examined to extract the contact properties between those for DEM simulations [35].

Enclosure parameters		**Particle parameters**	
Material	PMMA	Material	Steel
Elastic modulus	3.3 GPa	Elastic modulus	206 GPa
Poisson's ratio	0.37	Poisson's ratio	0.30
Diameter	0.02 m	Density	7800 kg/m^3
Height	0.04 m	Nominal total mass	0.04 kg
Other simulation parameters			
Particle-enclosure friction coefficient	0.4		
Particle-particle friction coefficient	0.4		
Particle-enclosure restitution coefficient	0.92		
Particle-particle restitution coefficient	0.92		
Time step	~5x10^{-7} s		

Table 2: Parameters and properties of numerical simulations.

To allow a comparative study to be undertaken, it was considered desirable that the total mass of particles remained the same for different particle types. In order to achieve a suitable clearance level (75% – 80% filling ratio or 20% – 25% clearance ratio) for practical damping in every simulation configuration [11], the total particle mass was set to 0.04 kg. However, because particles are discrete but had different sizes, the total mass varied by up to the mass of half a particle, as shown in Figure 3a. Figure 3a also shows that a greater deviation in shape from a perfect sphere results in an increase in the number of particles required to achieve the target mass. Before any vibrational loading was applied, all particles were allowed to settle in the enclosure by the gravitational effect (see Figure 4).

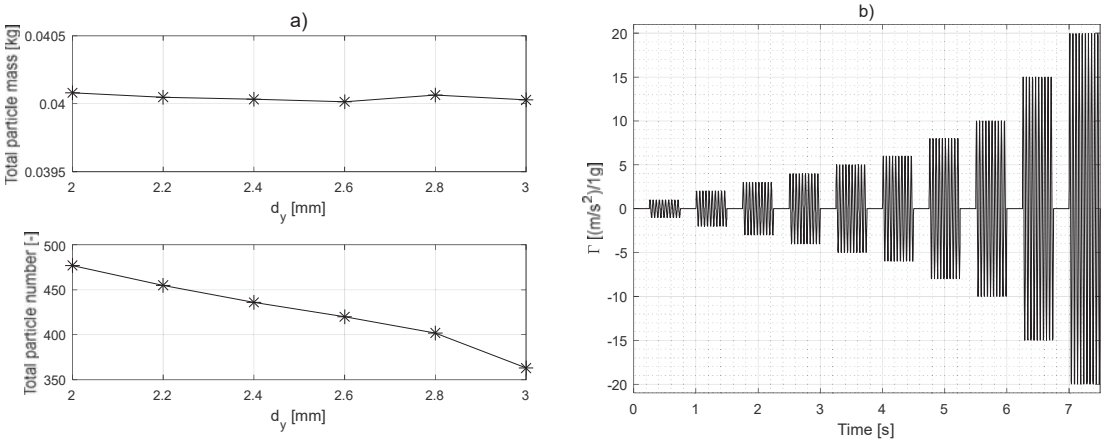

Figure 3: a) Changes in total particle mass and total particle number in terms of particle type, b) given vibration signal.

Behaviour of the granular medium under steady-state vibration was studied by prescribing sinusoidal motion for the enclosure at a frequency of 20 Hz. The effect of vibration intensity

was investigated by increasing the amplitude in steps, with the response being calculated for ten cycles at each level, as shown in Figure 3b. These vibrational levels are represented by commonly used non-dimensional acceleration (Γ).

$$\Gamma = \frac{A\omega^2}{g} \tag{10}$$

where A and ω are displacement magnitude and angular frequency of vibrations, respectively. In the vibration signal, time gaps are provided between each vibrational level to let the particles become stationary before the next excitation.

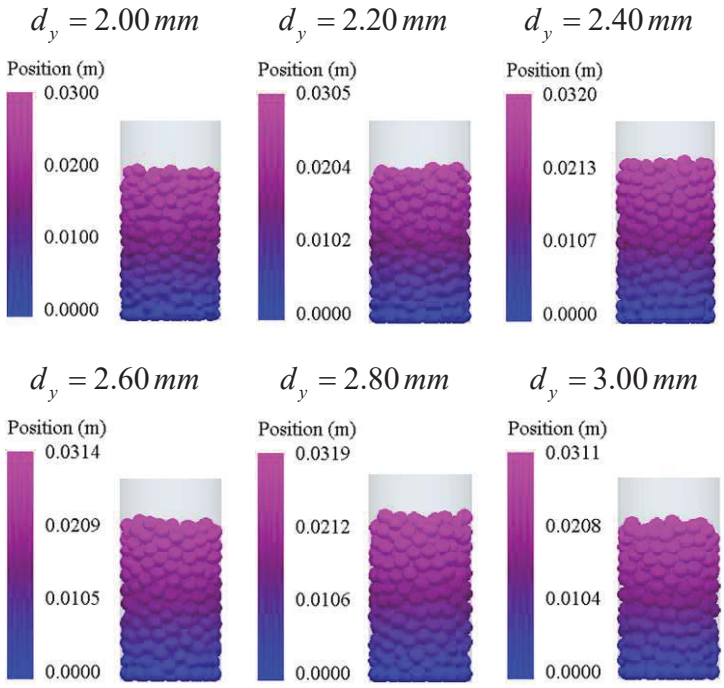

Figure 4: Views of granular oblate particles in the enclosure after settling process (i.e. stationary positions).

3 DISSIPATED ENERGY CALCULATION

Total cumulative dissipated energy in the simulations can be obtained by utilizing an incremental numeric computation scheme. For a single contact, total dissipated energy increments (ΔE_C) are computed integrating the scalar product of dissipative forces (i.e. in normal direction, $\boldsymbol{F}_{N_d}$ and in tangential direction, $\boldsymbol{F}_{T_d}$) and corresponding relative velocities between the contacting bodies through the contact time, T_c. In order to account all N number of contacts in the current computation step, this calculation is repeated for every contact, and then the effects of every contact is summed accordingly as following.

$$\Delta E_C = \sum_{k=1}^{N} \int_{T_c^{(k)}} \left\{ \left| \boldsymbol{F}_{N_d}^{(k)}(t) \cdot \frac{d\boldsymbol{r}_{rel_N}^{(k)}(t)}{dt} \right| + \left| \boldsymbol{F}_{T_d}^{(k)}(t) \cdot \frac{d\boldsymbol{r}_{rel_T}^{(k)}(t)}{dt} \right| \right\} dt \tag{11}$$

where $\boldsymbol{r}_{rel_N}$ and $\boldsymbol{r}_{rel_T}$ represent the relative positions of contacting bodies with respect to each other in normal and tangential directions, respectively, while t stands for time. In addition, the computation time step of the energy dissipation calculation scheme should be sufficiently larger than the contact durations to account all contacts within a single step.

The tangential dissipation can arise from either friction between the bodies in contact or restitution of the bodies unlike the normal dissipation where whole dissipation is caused by only collisional restitution. Frictional dissipation is solely employed if slipping, in which the tangential force is higher than the maximum static friction force between the contacting bodies, is occurred. The frictional cumulative dissipation steps can be separately determined as given in below.

$$\Delta E_C^f = \gamma_f \sum_{k=1}^{N} \int_{T_c^{(k)}} \left| \boldsymbol{F}_N^{(k)}(t) \cdot \frac{d\boldsymbol{r}_{rel_T}^{(k)}(t)}{dt} \right| dt \tag{12}$$

Collisional dissipation can then be obtained by subtracting the frictional loss from the total dissipation energy.

$$\Delta E_C^c = \Delta E_C - \Delta E_C^f \tag{13}$$

4 RESULTS

4.1 Overall dissipative behaviour of oblate particles

To assess the general damping behaviours of oblate particles against different vibrational amplitudes and the relationship between the dissipation and the granular motional behaviour, cumulative total dissipated energies were extracted separately for every vibrational case in all simulations. Figure 5 presents some of those dissipated energy results. In these results, the last five vibration periods at each vibration level are considered. Simulations were repeated to determine the effects of packing on the results. The results verified that packing effects stay very small except at the amplitude $\Gamma = 1$.

The first set of analyses belongs to very small oscillations (i.e. $\Gamma = 1.0$). Under such small vibrations, the particles inside the enclosure have almost no relative motions with respect to each other, they only follow the enclosure motion (i.e. solid-like behaviour) since the particles do not overcome the gravitational and the static frictional forces within the granular media. Thus, the dissipated energies are extremely small, and they do not exhibit obvious steady-state behaviors since a few individual particle movements that induce energy dissipation can be instantly observed due to wave propagation through the granular media from the bottom boundary of the enclosure. These instantaneous dissipation increases can be more likely seen for perfect spheres owing to their smooth circular surfaces. In addition, numerical errors in computational operations and initial packing may also considerably affect these small outcomes.

It is apparent from Figure 5 that huge differences surprisingly emerge between the particle types at several vibration amplitudes. Further investigation into granular media indicates that this is mainly connected with the dissimilarities of granular motional states which the particles are in. For instance; in Figure 5d, there are two groups of result: one is high dissipation group, and the other is low dissipation. At this vibration level, the high energy dissipation group is at the onset of two-sided bouncing bed behaviour in which the granular particle cluster impacts the bottom and the top boundaries of enclosure during a period of vibration (i.e. 2 collective impacts with the enclosure in a period), thereby transferring the momentum effectively to the granular media. On the other hand, the granular media in low dissipation group generally collides with only the bottom boundary in a vibration period (one-sided bouncing bed), while it slightly touches to the top boundary in this period (mild collision).

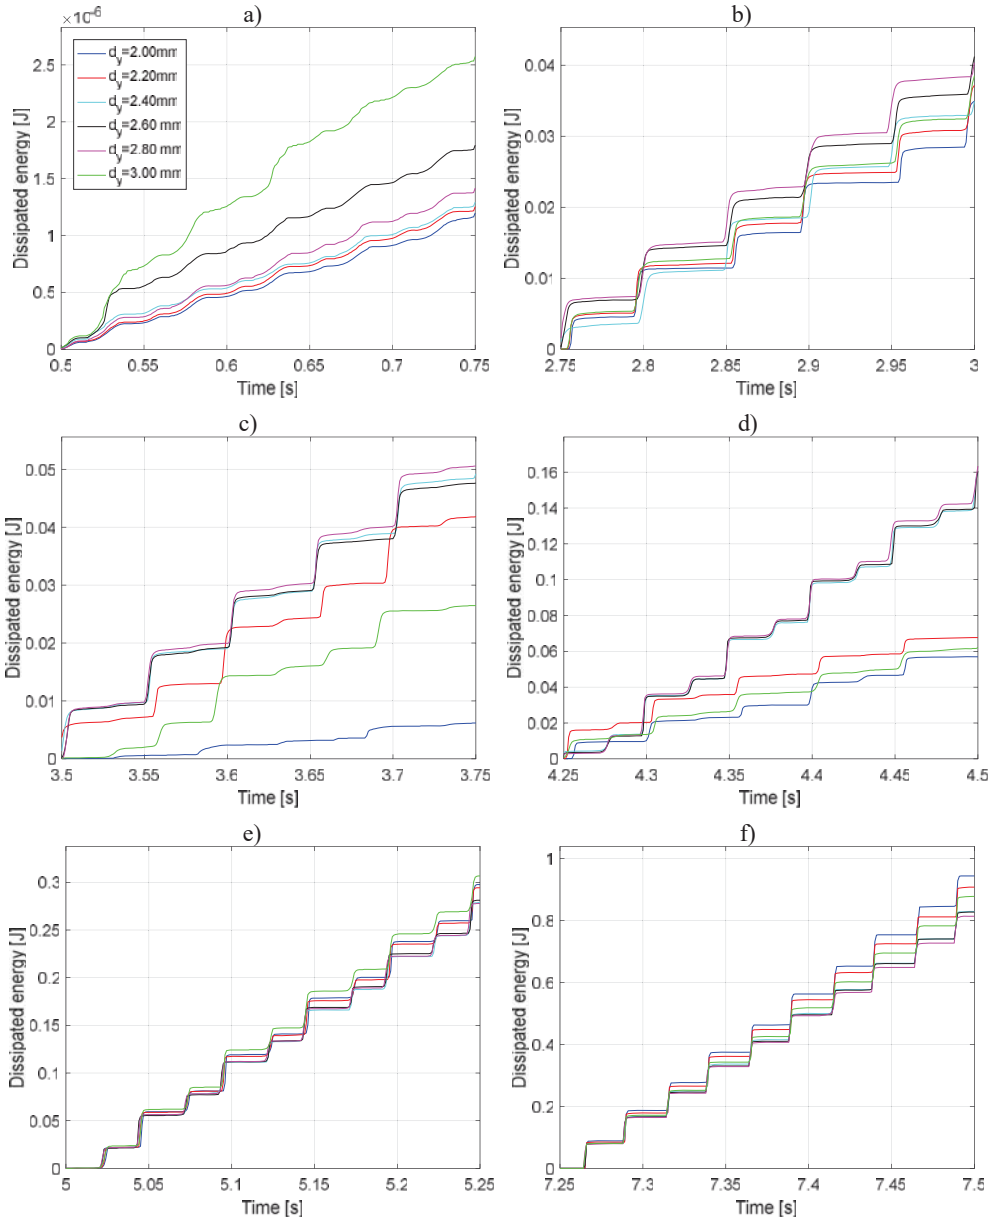

Figure 5: Total cumulative dissipated energy characteristics for 5 vibrational periods of a) $\Gamma = 1$, b) $\Gamma = 4$, c) $\Gamma = 5$, d) $\Gamma = 6$, e) $\Gamma = 8$, f) $\Gamma = 10$.

The defined dissipation groups in Figure 5d are also valid at $\Gamma = 5$ as can be seen in Figure 5c. At this vibration level, the high dissipation group members exhibit similar behaviour to that seen previously except that the granular cluster impacts the top boundary once in every two periods. Although the members of low dissipation group have similar motion, the most squashed particle type somehow executes impacts with quite less intensive than the other members as can be clearly seen in Figure 5c.

Figure 6 shows the total potential energy in the particles throughout the simulation. Observed motional behaviours of granular media at various vibrational sequences are marked with different colors. Purple represents solid-like behaviour, while magenta and cyan stand for one-sided bouncing bed with fluidization of a few of the particles on the top layer and one-sided bouncing bed with fluidization of the uppermost layers of particles, respectively. As one can see in this figure, red marked potential energy regions are clearly more uneven and scat-

tered than other vibrational cases. This result may be explained by the fact that the granular media shows relatively higher level of fluidization in which a reasonable amount of particle indistinctly floats in these loading ranges. Another possible reason for this is that the collective motion of granular media is not symmetric at every vibrational period in these cases as it is in other vibration scenarios. The motions within these red marked ranges are described as following: dotted red is one-sided complete bouncing bed with few individual top particles-top wall impacts in every period, dot-dashed red is one-sided complete bouncing bed with few individual top particles-top wall impacts once in every two periods, dashed red is one-sided complete bouncing bed and mild collective collision with the top wall once in every two periods and flat red is one-sided complete bouncing bed and mild collective collision with the top wall in every period. The last phenomena observed in the simulations is two-sided complete bouncing bed that is marked with blue in total potential energy plots.

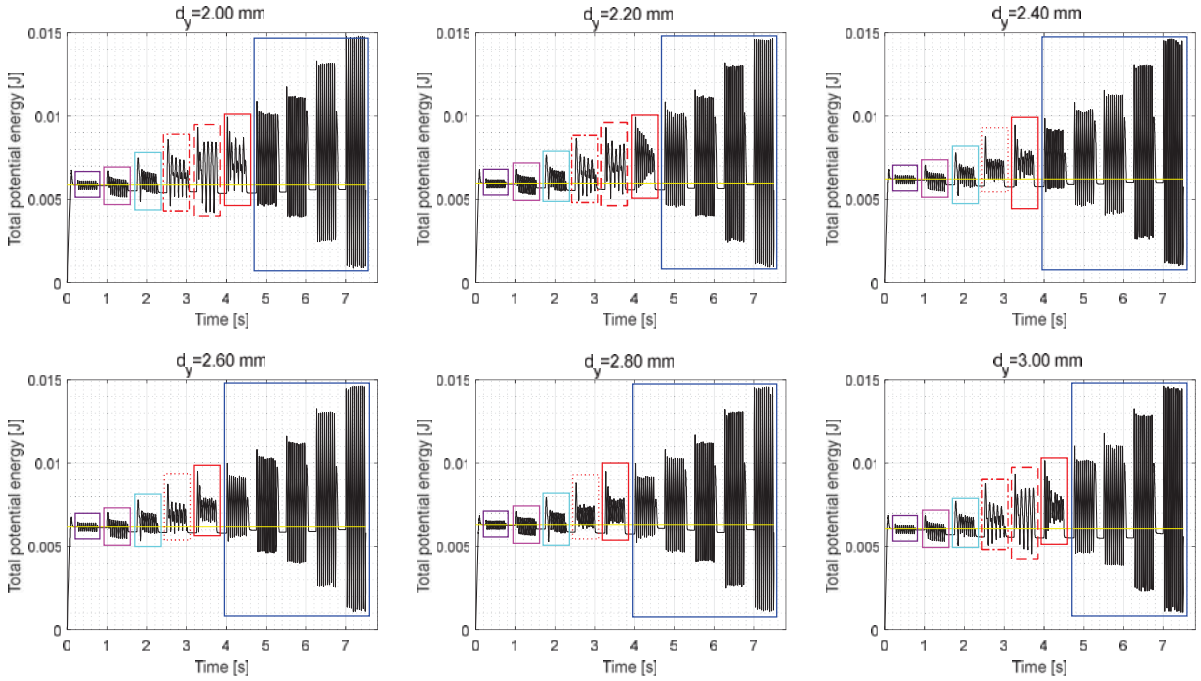

Figure 6: Total potential energy changes of simulated particles in time, yellow flat line indicates the total potential energy at the stationary positon of particles.

4.2 Damping characterization of oblate particles

In order to compare the damping behaviour of oblate particle types, the energy dissipation rates in a steady-state vibration period (i.e. power loss) were determined by integrating the cumulative dissipated energies through this period.

$$Power\,loss = \frac{1}{T}\int_{T} E_C(t)\,dt \tag{14}$$

The power losses are illustrated with respect to either sphericity or circularity for every simulated vibrational level in Figure 7 and Figure 8, respectively. The perfect sphere results are also included in these figures as a reference of default particle type used in most typical granular damper applications. In these graphs, the contribution of damping mechanisms of granular damping (i.e. friction and impact) on overall power loss are also shown to illustrate the macroscale damping behaviour of oblate particles. In addition to this, particle-particle and

particle-enclosure frictional losses are separately depicted in these plots to show dominance of interaction type.

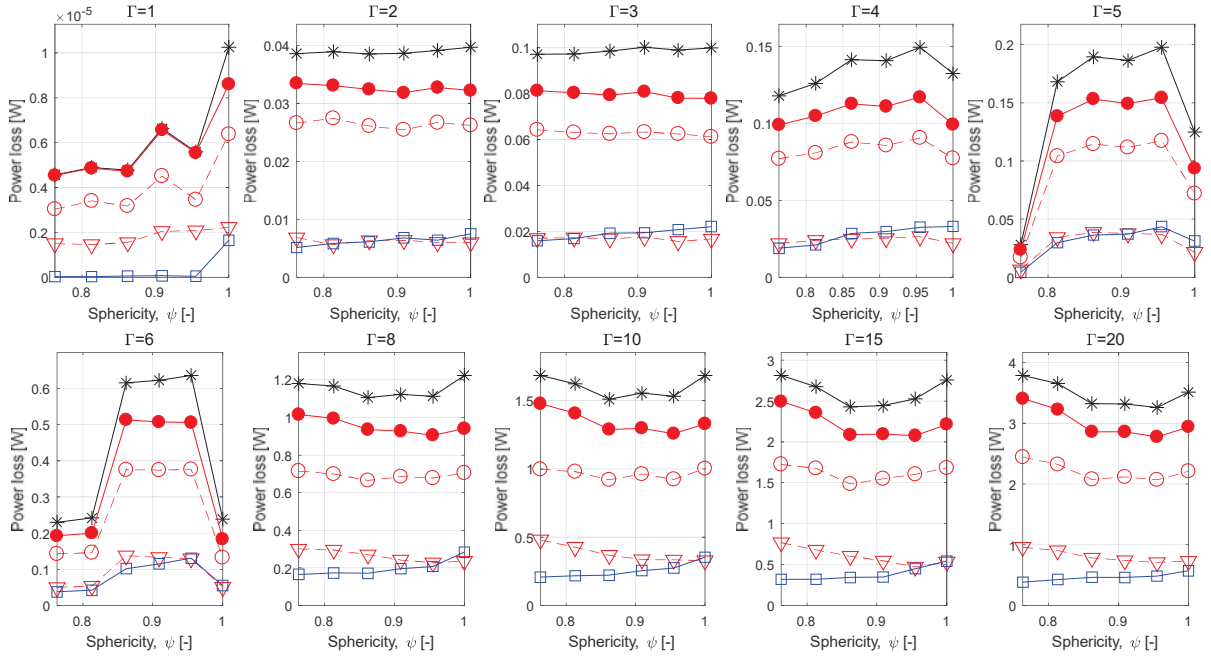

Figure 7: Power loss changes in terms of sphericity at different vibration levels: total loss (—✳—), frictional loss (—●—), inter-particle frictional loss (—⊖—), particle-enclosure frictional loss (—▽—), collisional loss (—□—).

If one looks into the total power loss results omitting the reference particle (i.e. the perfect sphere: $\psi = 1$ and $C = 1$) in both charts, it can be found that there are three damping regimes according to the vibrational intensity in which the total loss is affected by particle shape. The first one is 'inclining' regime where the total power loss generally increases with increasing sphericity or circularity level before $\Gamma \approx 5$. This increasing behaviour becomes moderate at higher amplitudes, whilst it is very slight for small vibrations. Afterwards, there is 'transition' regime up to $\Gamma \approx 8$. Although increasing tendency in total power loss continues in this regime, a dramatic jump is also observed because of impacts with the upper surface of the cavity, as discussed in the previous section. The last damping regime is 'declining' in which the power loss is decreasing with increasing sphericity or circularity unlike the other regimes and this falling behaviour is more apparent at higher vibration amplitudes. Together, these findings suggest that damping is optimised at different amplitudes, depending on particle shape. The results also indicate that there is an oblate particle type which provides more damping than the perfect sphere for almost all vibrational levels. Thus, it can be preferable in granular applications to use very slight oblate particle if the vibrations ensure working before two-sided complete bouncing bed. Otherwise, in two-sided complete bouncing bed state, it is more appropriate to employ highly flattened particles. However, it should be noticed that these results need to be supported by quantitative data from experimental works.

For a given non-dimensional acceleration level, it can be highlighted from the power loss plots that the most dominant damping mechanism is friction for every particle type. Besides, particle-particle frictional interactions are responsible for most of frictional dissipation. In fact, it is reported that particle-particle contacts contribute most of overall dissipation (i.e. particle-enclosure boundary interactions have minor effects on dissipation) as similarly mentioned before [18]. The dominancy of frictional loss leads that the overall damping behaviour stated in the previous paragraph completely reflects the frictional energy dissipation.

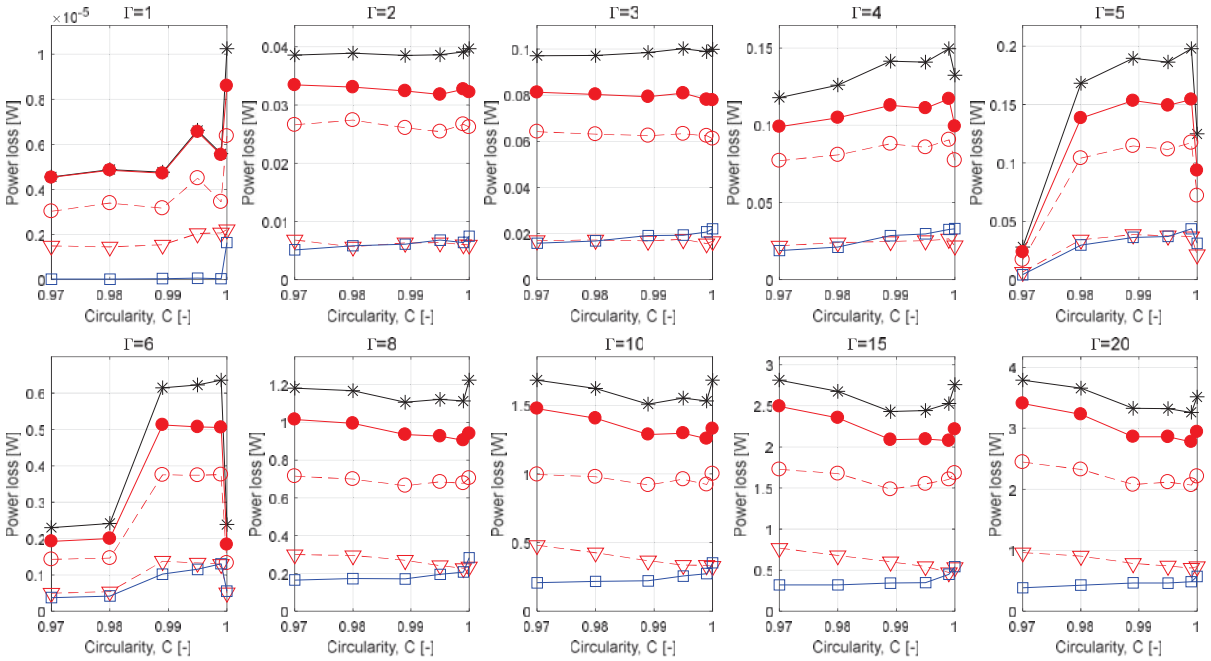

Figure 8: Power loss changes in terms of circularity at different vibration levels: total loss (—✳—), frictional loss (—●—), inter-particle frictional loss (–⊖–), particle-enclosure frictional loss (–▽–), collisional loss (—□—).

One unanticipated result is that collisional loss always increases with sphericity or circularity whatever the damping regime. It is believed that this occurs because flatter (i.e. low sphericity or low circularity) particles have fewer intense collisions (i.e. high overlap, high impact velocity). Additionally, an interesting correlation is found between collisional and particle-enclosure frictional loss characteristics along sphericity or circularity. As can be seen in Figure 7 and Figure 8, they generally have the same tendency before two-sided bouncing bed behaviour (i.e. $\Gamma < 8$) while the power loss trends of those seem opposite after this threshold vibration intensity.

5 CONCLUSIONS

This study set out to assess the effect of oblate particle usage in granular dampers undergoing vertical harmonic excitations by conducting numerical studies. The investigation has shown that the damping performance and the motional behaviour is sensitive to the sphericity level of the particles as well as the vibration amplitude. The power loss results in this study indicate that three damping regimes exist, each depends on vibration level and sphericity of the particles. Additionally, there is generally an oblate particle type which can be chosen rather than the typical perfect sphere to provide higher damping to main structures according to the motional state. Also, it has been shown that the general damping characteristics of particles follow the frictional dissipation behaviour which is the dominant mechanism in granular damping. This research extends the existing literature on damping from irregular particles. However, experimental investigations should be also conducted to confirm these numerical outcomes.

Keywords: Cable-Beam System, FRF-based Decoupling, Finite Element Model Updating.

Abstract.

Interactions between cable and structure affect the modal properties of cabled structures such as overhead electricity transmission and distribution line systems. Modal properties of an in-service pole, without the effects of conductors, are potentially useful for condition monitoring, but are difficult to determine. This paper presents a frequency-based decoupling method to extract modal properties of a beam with the effects of cable filtered out. A scalable experimental lab-scale pole-line for a cable-beam system consisting of a cantilever beam and stranded cable is used to validate the method. A finite element model for the stranded cable is developed and optimized using FRF-based nonlinear optimization based on experimentally obtained FRF and the FRFs of the assembled system are measured. The (unknown) FRF of the cantilever beam is predicted by substructural decoupling of the numerical cable dynamic model (known FRF matrix) from the measured assembled cable-beam dynamic model (known FRF matrix). Comparison of the estimated and directly-measured beam FRF's show good agreement, demonstrating that the method can be used to filter out the effects of cable on the modal properties of the structure in cabled structures.

1 INTRODUCTION

Dynamic interaction between cables and the main structure in cabled structures such as cable-stayed bridges, guyed towers, cable-stayed wind turbines, and power transmission lines has been a topic of interest of researchers for many years. The focus of this study is power transmission lines and dynamic interaction between the conductor (cable) and the pole. The authors are developing a global NDE (Non-destructive Evaluation) method to detect damage at any location, based on vibration response from modal impact testing at a single arbitrary location [1]–[5]. Since power lines (conductors) are attached to the poles, vibrations of the conductors affect the modal properties of the pole. Removing the effect of the conductors to reveal pole properties requires a structural dynamic method to decouple the cable dynamic model from the assembled cable-pole dynamic model.

There are many studies in the literature about the interaction between cables and structures as a coupled system. Gattulli et. al. [6] investigated linear coupled vibration of two masonry walls connected by a cable. The system was modeled as two cantilever beams connected by a cable and the effect of different parameters on coupled vibration behavior was investigated. Potenza et. al. [7] and Gattulli et. al. [8] studied the same system using nonlinear analysis. Jalali et. al. [3] developed an analytical model to study the effect of cable sag and bending stiffness on coupled vibration behavior of a cable-beam system. Cable bending stiffness and sag had significant effects. The analytical results were verified by experiments on a lab-scale cable-beam system. Li et. al. [9] presented a simplified computational model for a high-voltage transmission tower-line system to study the coupling behavior of adjacent tower spans and cables due to seismic excitations. Reviewing the literature in cable-beam system dynamic analysis reveals that all the published papers studied the dynamic interaction of cable and beam in linear or nonlinear analysis and there is no research dealing with extraction of dynamic properties of the beam as an independent substructure.

Dynamic substructuring methods and the reverse problem (inverse dynamic substructuring) are well established [10]–[14]. Inverse dynamic substructuring or decoupling is a relevant issue for subsystems that cannot be measured separately, since they are coupled to their neighboring substructure(s) in operational conditions [15]. In this paper, a frequency-based or FRF-based decoupling technique is used to extract beam dynamics in a cable-beam system with the effects of connected cable filtered out. An experimental reduced-scale cable-beam set up of a cantilever beam connected to a stranded cable was built to measure the assembled system FRFs and a finite element model for the cable was developed and optimized using FRF-based optimization. The cable numerical model was then decoupled from the assembled (measured) system through experimental-numerical FRF-based decoupling.

The paper is outlined as follows. A summary of theory behind FRF-based decoupling is presented in Section 2 and FRF-based finite element model updating is described briefly in Section 3. Section 4 describes the cable-beam system and finite element model updating of the cable. Decoupling results and discussion are presented in Section 5 and conclusion and future work are presented in Section 6.

2 SUBSTRUCTURE DECOUPLING

In a cable-beam system (Figure 1), the cable and the beam are "substructures" of the assembled system and the purpose of substructure decoupling is to find the dynamics of beam subsystem (*B*) as a "standalone" component that is completely decoupled from subsystem cable (*C*).

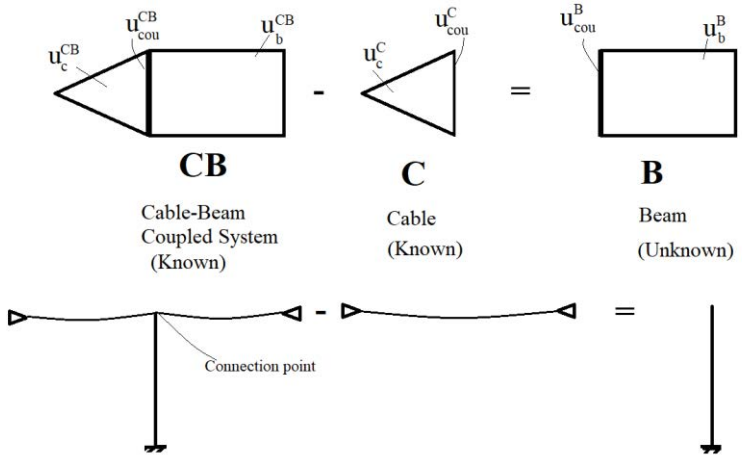

Figure 1. Substructure decoupling schematic

Assuming the dynamics of system *CB* and *C* are known, a dynamic stiffness representation of the assembled system *CB* in compact form is [15]:

$$\boldsymbol{Z}^{CB}\boldsymbol{u}^{CB} = \boldsymbol{f}^{CB} + \boldsymbol{g}^{CB}$$

$$\begin{bmatrix} \boldsymbol{Z}_{cc}^{CB} & \boldsymbol{Z}_{ccou}^{CB} & \boldsymbol{0} \\ \boldsymbol{Z}_{couc}^{CB} & \boldsymbol{Z}_{coucou}^{CB} & \boldsymbol{Z}_{coub}^{CB} \\ \boldsymbol{0} & \boldsymbol{Z}_{bcou}^{CB} & \boldsymbol{Z}_{bb}^{CB} \end{bmatrix} \begin{bmatrix} \boldsymbol{u}_c \\ \boldsymbol{u}_{cou} \\ \boldsymbol{u}_b \end{bmatrix} = \begin{bmatrix} \boldsymbol{f}_c \\ \boldsymbol{f}_{cou} \\ \boldsymbol{f}_b \end{bmatrix} + \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{g}_{cou} \\ \boldsymbol{0} \end{bmatrix} \tag{1}$$

And subsystem *C*:

$$\boldsymbol{Z}^{C}\boldsymbol{u}^{C} = \boldsymbol{f}^{C} - \boldsymbol{g}^{C}$$

$$\begin{bmatrix} \boldsymbol{Z}_{cc}^{C} & \boldsymbol{Z}_{ccou}^{C} \\ \boldsymbol{Z}_{couc}^{C} & \boldsymbol{Z}_{coucou}^{C} \end{bmatrix} \begin{bmatrix} \boldsymbol{u}_c^{C} \\ \boldsymbol{u}_{cou}^{C} \end{bmatrix} = \begin{bmatrix} \boldsymbol{f}_c \\ \boldsymbol{f}_{cou} \end{bmatrix} - \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{g}_{cou}^{C} \end{bmatrix} \tag{2}$$

where $\boldsymbol{u}^{CB} = \begin{bmatrix} \boldsymbol{u}_c \\ \boldsymbol{u}_{cou} \\ \boldsymbol{u}_b \end{bmatrix}$ is the vector of DOF of system *CB* (**Error! Reference source not found.**) (the superscripts are omitted for brevity), $\boldsymbol{u}^{C} = \begin{bmatrix} \boldsymbol{u}_c^{C} \\ \boldsymbol{u}_{cou}^{C} \end{bmatrix}$ is the vector of DOF of substructure *C*, $\boldsymbol{Z}^{CB}$ and $\boldsymbol{Z}^{C}$ are the stiffness matrices of system *CB* and *C*, respectively (stiffness matrix is the inverse of FRF matrix ($\boldsymbol{Z} = \boldsymbol{H}^{-1}$)). Vectors $\boldsymbol{f}^{*}$ are the external force vectors and vectors $\boldsymbol{g}^{*}$ represent the additional disconnection forces (with non-zero entries only at the interface DOF) felt from the decoupling of the neighboring components [15]. When two substructures are in contact and (de)coupling is carried out, compatibility and equilibrium conditions at the connected interface DOFs must always be satisfied. The compatibility condition ($\boldsymbol{u}_{cou}^{C} = \boldsymbol{u}_{cou}$) states that the displacements of connected interface DOF must be compatible and the equilibrium condition ($\boldsymbol{g}_{cou} + \boldsymbol{g}_{cou}^{C} = \boldsymbol{0}$) states that the connection forces between the substructures should be in equilibrium. A more systematic description of the problem can be written by introducing the Boolean matrices $\boldsymbol{B}$ and $\boldsymbol{L}$ and writing the compatibility and equilibrium in a compact from: [15]

$$\boldsymbol{B}\boldsymbol{u} = \begin{bmatrix} \boldsymbol{B}^{CB} & \boldsymbol{B}^{C} \end{bmatrix} \begin{bmatrix} \boldsymbol{u}^{CB} \\ \boldsymbol{u}^{C} \end{bmatrix} = \boldsymbol{u}_{cou}^{C} - \boldsymbol{u}_{cou} = \boldsymbol{0} \tag{3}$$

$$\boldsymbol{L^T g} = [\boldsymbol{L}^{CB^T} \quad \boldsymbol{L}^{C^T}] \begin{bmatrix} \boldsymbol{g}^{CB} \\ \boldsymbol{g}^{C} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \boldsymbol{g}_{cou} + \boldsymbol{g}_{cou}^{C} \end{bmatrix} = \mathbf{0} \tag{4}$$

Eq. (3) presents the compatibility equation and Eq. (4) presents the equilibrium equation. Therefore, the decoupling problem can be described in the following equations:

$$\begin{bmatrix} \boldsymbol{Z}^{CB} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{Z}^{C} \end{bmatrix} \begin{bmatrix} \boldsymbol{u}^{CB} \\ \boldsymbol{u}^{C} \end{bmatrix} = \begin{bmatrix} \boldsymbol{f}^{CB} \\ \boldsymbol{f}^{C} \end{bmatrix} + \begin{bmatrix} \boldsymbol{g}^{CB} \\ -\boldsymbol{g}^{C} \end{bmatrix}$$

$$[\boldsymbol{B}^{CB} \quad \boldsymbol{B}^{C}] \begin{bmatrix} \boldsymbol{u}^{CB} \\ \boldsymbol{u}^{C} \end{bmatrix} = \mathbf{0} \tag{5}$$

$$[\boldsymbol{L}^{CB^T} \quad \boldsymbol{L}^{C^T}] \begin{bmatrix} \boldsymbol{g}^{CB} \\ \boldsymbol{g}^{C} \end{bmatrix} = \mathbf{0}$$

Employing the dual formulation for decoupling [16], the interface forces are satisfied a priori by choosing interface forces of the form of:

$$\boldsymbol{g} = -\boldsymbol{B}^T \boldsymbol{\lambda} \tag{6}$$

where $\boldsymbol{\lambda}$ are Lagrange multipliers, corresponding physically to the interface force intensities. The equilibrium condition in Eq. (4) thus becomes:

$$\boldsymbol{L^T g} = -\boldsymbol{L^T B^T \lambda} = \mathbf{0} \tag{7}$$

But by considering the fact that $\boldsymbol{L^T}$ is the null space of $\boldsymbol{B^T}$ [10], this condition is always satisfied. The decoupling methods can be categorized as collocated methods when both the compatibility and equilibrium are imposed at the same sets of DOFs ($\boldsymbol{C}^* = \boldsymbol{E}^*$) or non-collocated methods when different sets of DOFs ($\boldsymbol{C}^* \neq \boldsymbol{E}^*$) are used for imposing the compatibility and equilibrium conditions. The decoupling problem can therefore be formulated in a dual way as [15]:

$$\begin{bmatrix} \boldsymbol{Z}^{CB} & \mathbf{0} & \boldsymbol{E}^{CB^T} \\ \mathbf{0} & -\boldsymbol{Z}^{C} & \boldsymbol{E}^{C^T} \\ \boldsymbol{C}^{CB} & \boldsymbol{C}^{C} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \boldsymbol{u}^{CB} \\ \boldsymbol{u}^{C} \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \boldsymbol{f}^{CB} \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix} \tag{8}$$

By eliminating Lagrange multipliers $\boldsymbol{\lambda}$ in Eq. (8) and solving for decoupled DOF:

$$\begin{bmatrix} \boldsymbol{u}^{CB} \\ \boldsymbol{u}^{C} \end{bmatrix} = \left(\begin{bmatrix} \boldsymbol{H^{CB}} & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{H^{C}} \end{bmatrix} - \begin{bmatrix} \boldsymbol{H^{CB}} & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{H^{C}} \end{bmatrix} \begin{bmatrix} \boldsymbol{E^{CB^T}} \\ \boldsymbol{E^{C^T}} \end{bmatrix} \left([\boldsymbol{C^{CB}} \quad \boldsymbol{C^{C}}] \begin{bmatrix} \boldsymbol{H^{CB}} & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{H^{C}} \end{bmatrix} \begin{bmatrix} \boldsymbol{E^{CB^T}} \\ \boldsymbol{E^{C^T}} \end{bmatrix} \right)^{+} [\boldsymbol{C^{CB}} \quad \boldsymbol{C^{C}}] \begin{bmatrix} \boldsymbol{H^{CB}} & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{H^{C}} \end{bmatrix} \right) \boldsymbol{f} \tag{9}$$

which is the form of $\boldsymbol{u} = \boldsymbol{Hf}$, so that the decoupled FRF of substructure B in a general form can be found:

$$\boldsymbol{H^B} = \begin{bmatrix} \boldsymbol{H^{CB}} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{-H^C} \end{bmatrix} - \begin{bmatrix} \boldsymbol{H^{CB}} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{-H^C} \end{bmatrix} \begin{bmatrix} \boldsymbol{E^{CB^T}} \\ \boldsymbol{E^{C^T}} \end{bmatrix} \left(\begin{bmatrix} \boldsymbol{C^{CB}} & \boldsymbol{C^C} \end{bmatrix} \begin{bmatrix} \boldsymbol{H^{CB}} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{-H^C} \end{bmatrix} \begin{bmatrix} \boldsymbol{E^{CB^T}} \\ \boldsymbol{E^{C^T}} \end{bmatrix} \right)^{+} \begin{bmatrix} \boldsymbol{C^{CB}} & \boldsymbol{C^C} \end{bmatrix} \begin{bmatrix} \boldsymbol{H^{CB}} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{-H^C} \end{bmatrix} \tag{10}$$

where + denotes the (Moore–Penrose) pseudo-inverse, since the matrix in parentheses is not necessarily a square matrix. Eq. (10) is used throughout the paper for decoupling analysis.

3 FRF-BASED FINITE ELEMENT MODEL UPDATING

The form of the frequency response function (FRF) used in this study is accelerance which means acceleration response over force in the frequency domain. Accelerance FRF, $H_{a,b}(\omega)$, is the acceleration response at node a, $A_a(\omega)$, divided by the force at node b, $F_b(\omega)$, both in the frequency domain [17]:

$$H_{a,b}(\omega) = \frac{A_a(\omega)}{F_b(\omega)} \cong \sum_{i=1}^{m} \frac{-\omega^2 \hat{\phi}_{ai} \hat{\phi}_{bi}}{-\omega^2 + 2i\omega\Omega_i\xi_i + \Omega^2{}_i} \tag{11}$$

where m is the number of modes, ω is frequency, Ω_i is i^{th} natural frequency of the system, ξ_i is i^{th} damping ratio corresponding to i^{th} mode and $\hat{\phi}_{ai}$ and $\hat{\phi}_{bi}$ are the scalar values of mode shape i at response node a and excitation node b, respectively. The maximum number of modes, m, that can be used to construct the response is equal to the total number of degrees of freedom of the system. However, it is not feasible to measure all degrees of freedom and the entire range of natural frequencies during structural testing. Therefore, a reduced number of mode shapes can be used. Special care must be taken to include enough mode shapes in the formulation, typically more than measured [18]-[19]. For a rule of thumb, at least double the number of modes that are measured should be used for analytical FRF calculation [17].

From of FRF used for model updating is as follows and the values of the FRF magnitude is in dB scale:

$$\bar{H}_{a,b}(\omega) = 20\log_{10}\left(\left|H_{a,b}(\omega)\right|\right) \tag{12}$$

The goal of the FE model updating is to change the properties of a FEM such that the analytical response of the model matches that of measured data. The goal is to obtain an analytical FRF as close as possible to the experimental FRF in a desired frequency range. After developing the FE model, Eq. (12) and Eq. (11) are used to obtain the FRF at the response and excitation nodes corresponding to the response and excitation locations considered in the experiment. The problem then is a least squares problem where the difference between analytical and measured FRFs, the error or residual, is found and a scalar objective error function value is calculated [18]. With the scalar objective error function value, numerical optimization techniques are used to minimize the difference between the analytical and measured FRFs by modifying the parameters of the FEM such that the analytical FRF best matches the measured FRF [18].

Since all of the structural properties in the finite element can be modified, any combination of stiffness, mass, and damping updating may be performed. Stiffness, mass and damping parameter updating can also occur simultaneously. Substituting Eq. (11) into Eq. (12) and using modal responses as functions of the unknown updating parameters p results in Eq. **(13)** [18]:

$$\bar{H}_{a,b}(\omega, p) = 20\log_{10}\left(\left|\sum_{i=1}^{m} \frac{-\omega^2 \hat{\phi}_{ai}(p) \hat{\phi}_{bi}(p)}{-\omega^2 + 2i\omega\Omega_i(p)\xi_i(p) + \Omega^2{}_i(p)}\right|\right) \tag{13}$$

The error function, or residual e, is defined as:

$$e(\omega, p) = \bar{H}^{a}{}_{a,b}(\omega, p) - \bar{H}^{m}{}_{a,b}(\omega, p) \tag{14}$$

where $\bar{H}^{a}{}_{a,b}(\omega, p)$ and $\bar{H}^{m}{}_{a,b}(\omega, p)$ are analytical and measured FRF, respectively. Then, a scalar objective error function J is created and is the quantity that is minimized through bounded numerical optimization:

$$J(p) = e^{T}(\omega, p)e(\omega, p) \tag{15}$$

The purpose of optimization is to minimize $J(\omega, p)$ by considering the upper and lower bounds for p [18]. The scalar objective error function is normalized by the initial value of the scalar objective error function $J(p)_1$ so that the optimization starts at a value of 1 and the perfect match would be a value of 0.

$$J(p)_i = \frac{J(p)_i}{J(p)_1} \tag{16}$$

The parameter p is a unitless modifier that modifies any structural parameter.

4 CABLE-BEAM SYSTEM

The schematic of assembled cable-beam system (*CB*) and the cable substructure (*C*) is shown in Figure 2. The geometry of the (sub) structures is illustrated. The cantilever is a steel rectangular beam with cross section area of 46.67 mm^2 and the cable is a 7×19 steel stranded cable with a nominal diameter of 1/4 inch and linear density of 0.16667 kg/m. Three measurement points are considered for decoupling. In Figure 2-a, point 1 is a coupling DOF ($\boldsymbol{u}_{cou}^{CB}$ in Figure 1) and points 2 and 3 are the beam internal DOFs ($\boldsymbol{u}_{b}^{CB}$ in Figure 1) within the assembled system. There is no cable internal DOF ($\boldsymbol{u}_{a}^{CB}$ in Figure 1) since it was intended to need the least number of DOF from the numerical cable model. In Figure 2-b, the coupling point 1 ($\boldsymbol{u}_{cou}^{C}$ in Figure 1) is shown. All the degrees of freedom are along the *z* direction. The cable tension is 150 N when the cable is connected to the beam (in system *CB*) and when the cable-only system is considered.

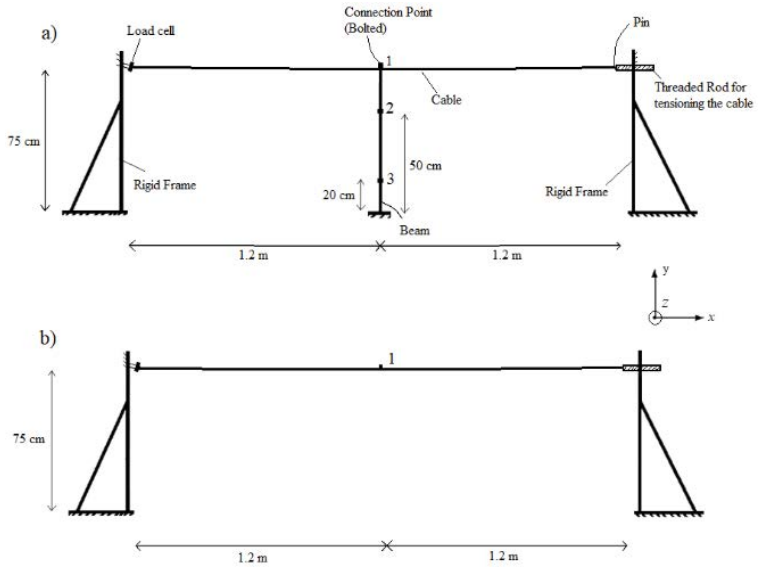

Figure 2. Schematic of a) Assembled cable-beam system (*CB*) b) Cable substructure (*C*)

FRFs of the assembled system ($\boldsymbol{H}^{CB}$ in Eq. (10)) are measured using modal testing and FRF of the cable at the coupling point ($\boldsymbol{H}^{C}$ in Eq. (10)) is obtained using a finite element model. Eq. (10) is then used to obtain the decoupled beam FRF, $\boldsymbol{H}^{B}$. The assembled system set up (*CB*) is shown in Figure 3. Two rigid frames were secured to the floor on the right and left sides. The natural frequencies of the frames were verified to be far away from the natural frequencies of the system. The right end of the cable was attached to a threaded rod to adjust the tension of the cable and an in-line load cell at the left end of the cable measured the longitudinal tension of the cable. Two U-bolts were used in the connection point of the cable and beam. Both ends of the cable are pinned and the beam is cantilevered. More details of the set up can be found in [3].

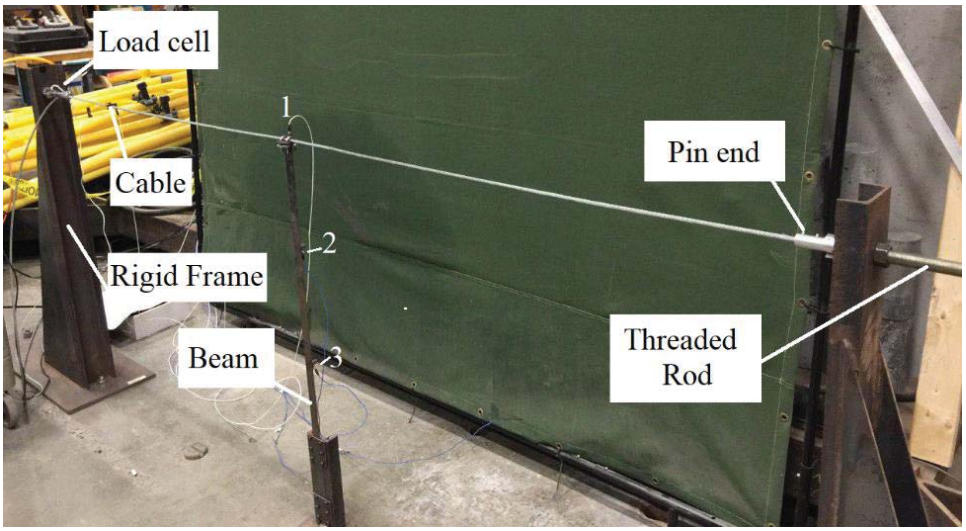

Figure 3. Experimental set up for cable-beam system

FRFs were obtained using a B&K 8205-002 impact hammer, a NI c-DAQ 9172 chassis and the software ModalView [20] was used to analyze the data.

4.1 Finite element model updating of the cable

In order to obtain the substructure *C* FRF matrix, $\boldsymbol{H}^{C}$ in Eq. (10), a finite element model for the cable is developed. The cable is modeled as pinned-pinned Euler beam with 100 finite elements. The bending stiffness (EI) of the cable was measured in the previous work of the authors [3] in different tensions and the measured value of 0.525 $Nm^2$is used in the FE model. The beam cross section area is 31.66 mm^2 and the linear density is 0.16667 kg/m.

Figure 4. Finite element model of the cable

The FRF matrix $\boldsymbol{H}^{C}$ has only one array, ${H_{11}}^{C}$, since point 1 in Figure 2 is the only DOF on the cable substructure (*C*) that is being considered in the analysis. Therefore, in the FE model updating process, direct FRF of point 1 (excitation and response at the same place), ${H_{11}}^{C}$, that is obtained using Eq. (13) is updated based on the measured FRF. In the updating process, all the stiffness and mass elements are directly modified using the multipliers p in Eq. (13). Therefore, there are 100 multipliers (number of finite elements is 100) for the stiffness matrices and

100 multipliers for the mass matrices that need to be updated in each iteration. The nonlinear constrained optimization technique in MATLAB software is used. The lower and upper bounds for all the variables are considered to be 0.5 and 1.5, respectively. Figure 5 shows the updated and initial FRF compared to the FRF obtained from experiment. The magnitude of the updated FRF matches more with the experimental one and the sharpness of the peaks is closer to the experimental FRF in the updated FRF. There is still a slight discrepancy between the updated and experiment FRFs but the decoupling result in Section 5 shows that this discrepancy does not cause any unacceptable error in the final decoupling results.

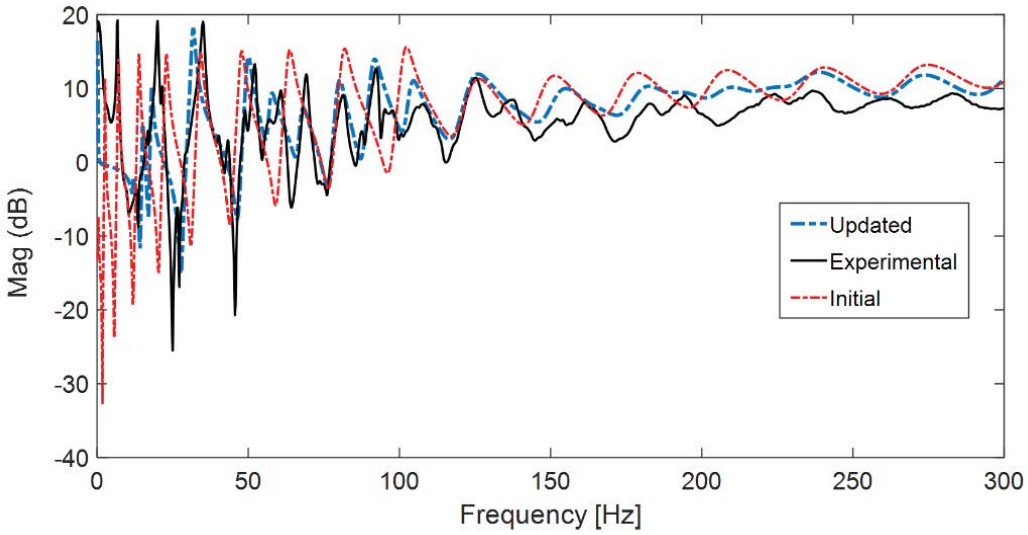

Figure 5. Comparison of updated and initial cable FRF with experimental FRF

5 DECOUPLING RESULTS

The measured FRFs from the assembled system and the calculated FRF from the finite element model are used in Eq. (10) to predict the decoupled beam FRF. Figure 6 shows the predicted FRF ${H_{33}}^{B}$ and ${H_{23}}^{B}$ compared to the directly-measured FRF. Decoupled FRFs show a good agreement with the measured FRFs. There is a spurious peak around 140 Hz which is probably due to numerical singularity that is common in dynamic substructuring [21]. A non-collocated approach [15] is used to obtain the results which means all the internal DOFs of the beam substructure were used for equilibrium condition.

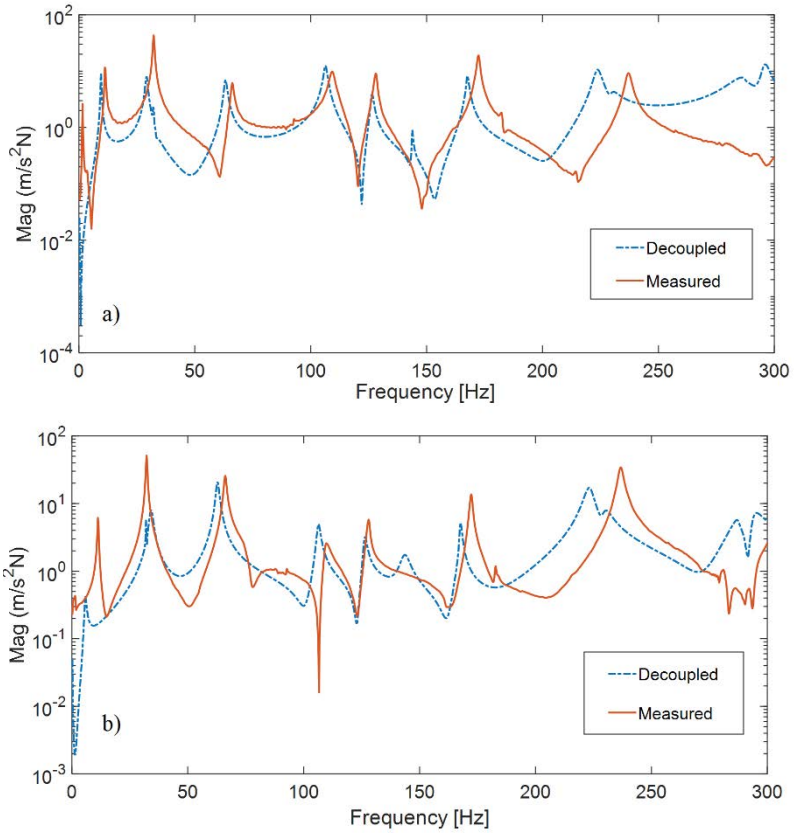

Figure 6. Comparison of decoupled beam FRF with measured FRF a) ${H_{23}}^B$ b) ${H_{33}}^B$

From the obtained FRFs, the modal properties of the beam can be extracted. Natural frequencies and damping ratios of the beam extracted from the predicted FRFs and measured FRFs are compared in Table 1. The 3 dB method [22] was used to extract the damping ratios from the FRF peaks. There is an acceptable agreement between the modal properties of the beam extracted from measured FRF and predicted FRF which shows that frequency based decoupling can be used to extract the modal properties of the beam in a cable-beam system with the cable effects filtered out. In some modes, the predicted and measured damping ratios differ which could be attributed to measurement error and difficulty in exciting the coupling point in the assembled and substructure at the same location. Damping ratio of the first mode was predicated with high error and it is not presented in the table.

Table 1. Natural frequencies (Hz) and damping ratios (%) of beam: predicted (decoupled) and measured

Mode	1		2		3		4		5		6		7		8	
	Hz	%	Hz	%	Hz	%	Hz	%	Hz	%	Hz	%	Hz	%	Hz	%
Measured	1.6	2.03	11.2	1.42	32.2	0.52	66.2	0.52	92.8	0.19	109.4	0.68	128	0.35	172.4	0.23
Decoupled	1.4	-	9.6	1.37	32	0.37	63.2	0.59	--	--	106.2	0.57	126.4	0.31	167.6	0.21

6 CONCLUSIONS

In this study, a cable-beam system was studied through the application of experimental-numerical FRF-based decoupling and the beam FRF was predicted. A finite element model for the cable was developed and updated using FRF-based nonlinear optimization and then was decoupled from the measured assembled system. It was shown that frequency-based decoupling can be applied in cable structures to extract the dynamics of a structure with the effects of cable filtered out. In the field, some parts of the system such as connection point of the conductors and electricity pole are inaccessible. In future, reliable simulation models should be developed for the assembled system so that FRFs of such inaccessible points be replaced by simulation results.

Keywords: ambient vibrations, induced seismicity, non-structural components, masonry

Abstract. *Since the 1990s, the recordings of ambient vibrations in structures have gained interest in the civil engineering community due to technological improvements of portable sensors, allowing the recordings of small amplitude vibrations, and the possibility of processing a large amount of data even in real time. Many applications, based on the analysis of seismic noise, exist in the literature for checking the serviceability limit state of existing construction in the case of earthquakes. These applications can be extended to the case of occurrence of induced and triggered seismicity and its potential impact on the built environment. The latter impact has heightened both public concern and regulatory scrutiny, emphasizing the need for an integrated risk management framework. Considering the case of induced seismicity, the vulnerability assessment requires the expected damage to refer to non-structural components. In this study, some historical masonry buildings located in Alsace France are considered and the dynamic characteristics of these structures were estimated by the analysis of seismic noise recordings by sensors installed at each floor of the buildings under study. The estimated dynamic properties for small amplitude vibrations of these historical structures were used to derive simplified vulnerability models. Moreover, the Eurocode 8 defines the interstory drift limit of a building for non-structural damage, by looking at its displacement-sensitive non-structural components at the serviceability limit state. Therefore, by adopting these limits and the developed simplified vulnerability models, new fragility curves for typical historical masonry building types dominant in the region under study are proposed. The fragility curves have been calculated using incremental dynamic analysis for the seismic demands generally imposed upon linear and slightly non-linear models of single and multiple degrees of freedom, which is the case for the effects of induced seismicity. These results will prove useful for both local end-users and industrial stakeholders, with a clear perspective for a better understanding of the risk related to induced and triggered seismicity and its sound management.*

1 INTRODUCTION

Since the 1990s, the recordings of ambient vibrations in structures have gained interest in the civil engineering community due to technological improvements of portable sensors, allowing the recordings of small amplitude vibrations, and the possibility of processing a large amount of data even in real time. Many applications, based on the analysis of seismic noise, exist in the literature for checking the serviceability limit state of existing construction in the case of earthquakes. These applications can be extended to the case of occurrence of induced and triggered seismicity and its potential impact on the built environment. The latter impact has heightened both public concern and regulatory scrutiny, emphasizing the need for an integrated risk management framework. Considering the case of induced seismicity, the vulnerability assessment requires the expected damage to refer to non-structural components.

The ultimate goal of seismic design of a structure is to prevent structural collapse and human losses in case of an earthquake event. Over time, advances in earthquake engineering have led to a wide range of methodologies for earthquake resistant structural design. As a result, structures built with current methods are generally able to resist expected seismic activity and preserve their structural integrity. However, although a building remains structurally sound, it can be rendered unusable due to damage to its non-structural components. Additionally, the majority of the value of some specific buildings lies in their non-structural components. For instance, it has been shown that non-structural components account for 82%, 87% and 92% of building costs for offices, hotels and hospital buildings, respectively [1]. Therefore, building owners may still be burdened with high expenses due to the need to repair and replace non-structural components, despite applying the current seismic design standards.

The Eurocode 8 (Cl.4.4.3.2) [2] defines the maximum interstory drift (IDR) limit of a building for non-structural damage of its displacement-sensitive non-structural components for the serviceability limit state. The latter relates to structural performance for normal service conditions, under which the function of a building, its appearance, maintainability, durability and comfort for its occupants must be preserved. In that case, the IDR obtained from elastic analyses should be limited to the following values, set as a function of the non-structural typology/detailing and represented by θ_{ns}, which is the limiting story drift ratio, equal to the relative inter-story displacement divided by the story height:

- for buildings having non-structural components fixed in a way so as not to interfere with structural deformations: $\theta_{ns} \leq 1.0\%$;
- for buildings having ductile non-structural components: $\theta_{ns} \leq 0.75\%$;
- for buildings having non-structural components, realized with brittle materials, attached to the structure: $\theta_{ns} \leq 0.5\%$.

It is not clear from the above definitions in Eurocode 8 how ductile non-structural components are distinguished from the other mentioned types. In addition, a minimum required ductility capacity is not provided in these guidelines. Moreover, the drift limit of 1.0% for non-structural components fixed in a way not to interfere with structural deformations appears to be very high for masonry structures and there are not clear indications of how it is set to this value also for this case. However, the above criteria provide a test-bed for drift sensitive non-structural damage to be considered as damage thresholds in the analytical definition of fragility curves.

In this paper the focus will be on the rapid and efficient modeling of an urban area from the vulnerability point of view (considering only the possible damage to non-structural components), which is the key component for the efficient and reliable implementation of risk monitoring applications.

2 CASE STUDIES

In this study, some historical masonry buildings located in Alsace France are considered and the dynamic characteristics of these structures were estimated by the analysis of seismic noise recordings by sensors installed at each floor of the buildings under study (Fig. 1).

In the considered test site, the analysis of the collected exposure information indicates that traditional or historical masonry structures occur in large numbers near in the mostly rural areas close to the geothermal platforms in Alsace region in France [3]. Two general classes of structures, namely unreinforced masonry (URM) and timber-framed masonry (TFM) buildings have been considered, and the simple performance assessment models ([4], [5]) have been adopted in order to carry out a preliminary vulnerability assessment for these classes of structures. The objective is to rapidly identify buildings and their non-structural components that are at greater risk in the event of an induced earthquake, and to model their non-structural fragility.

The vulnerability modelling focused on buildings constructed of masonry, which may be more susceptible to the range of ground motion expected in the event of induced seismicity in the area. The measurements have been carried out using the MPwise (Multi-Parameter Wireless Sensing System) smart device [6], which has been designed to carry out rapid measurement activities by exploiting the computing and advanced networking capacities embedded in individual units. Based on measurements of environmental seismic noise, the fundamental frequency of vibration of the inspected buildings has been estimated and used to calibrate the respective fragility curves.

In collaboration with GFZ and ES-Géothermie a three-day acquisition campaign was organized which involved the installation of four sets of sensors in private houses located in villages located around the Soultz and Rittershoffen geothermal sites. The fundamental period of these structures was verified by analyzing the ambient noise measured using the MPwise sensors [6], with one sensor installed outside of the buildings, and the three others installed on each floor of the houses (basement, ground floor and first floor). The sensors were installed to record the ambient noise and to draw a vulnerability mode that allows the issuing of damage forecasts (Table 1, [7]). Finally, the main geometry required as input for the simplified vulnerability models was taken through field inspection of these buildings.

No	Building Type	Building Latitude	Building Longitude	Fundamental ESDOF Model Period (s)	Fundamental Frequency Sensor (Hz)
1	URM	48.964946	7.881095	0.17	5.5
2	URM	48.902075	7.874917	0.37	2.7
3	URM	48.905270	7.950266	0.11	9
4	TFM	48.914307	7.882233	0.15	6.7
5	URM	48.932865	7.874377	0.32	3.1

3 VALIDATION OF THE NUMERICAL MODEL

The estimated dynamic properties for small amplitude vibrations of these historical structures were used to derive simplified vulnerability models.

While steel or concrete frames are mostly lumped systems with stiff diaphragms, URM buildings have distributed mass and stiffness commonly in combination with flexible diaphragms. This fact obstructs the adoption of the established methodologies to URM buildings. Specifically, the fundamental mode shape of the latter buildings involves a low percentage of the total mass of the building below the 75% limit required for the good performance of ESDOF-based methods. In order to solve this issue, the simplified procedure of Vamvatsikos et al. (2015) [4] was adopted. In their procedure the dynamic URM building response is repre-

sented. Global response indices are transformed to local deformation measures in closed-form seismic assessment solution both for demand and supply in the critical structural locations. The solution involves the definition of the fundamental vibration mode, approximated by 3D shape function consistent with the building's boundary conditions. Strength and deformation indices are adopted for the evaluation of the acceptance criteria. Typical local failures are estimated through a local shape of deformation while the model captures the global dynamic characteristics. The adopted method allows the automation of the necessary calculations through closed-form expressions. The application of the methodology presented in this work to produce the analytical fragility curves for URM buildings is demonstrated here (Table 2) on a box-shaped unreinforced masonry structure of the townhall of Keffenach (URM building No.1 in Table 1) in Alsace region in France near the geothermal platforms of this region (Soultz-sous-Forêts and Rittershoffen).

Longitudinal wall length	9.14 m
Transverse wall length	12.04 m

Shear Strength	0.93 MPa
Wall mass	75.57 tn
Story mass	2.1 tn
Roof mass	3.27 tn
Total mass	80.94 tb
Horizontal "gravity" load	226.85 kN/m
Wall total area	10.59 m^2
Wall box moment of inertia	157.64 m^4
Resistance of wall plan	33.58 m^3
Wall plate stiffness factor	8470 kNm
Total crest acceleration at flexural cracking	2.7 g
Shear deformation	0.141 mm
In-plane flexural deformation	0.0044 mm
1st floor windows shear deformation	0.0006 mm
2nd floor doors shear deformation	0.002 mm
2nd floor windows shear deformation	0.01 mm
Out-of-plane flexural deformation	8.48 mm
In-plane deformation participation	0.025
Out-of-plane deformation participation	0.975
ESDOF generalized mass	7.98 tn
ESDOF generalized stiffness	10398.56 kN/m
ESDOF period	0.17 sec
ESDOF earthquake excitation factor	15.03 tn
ESDOF effective mass ratio	0.35
ESDOF participation factor	1.88

Table 2: Simplified model parameters for URM building (No.1 in Table 1) under transverse/short/weak building plan direction loading. Values are calculated based on Vamvatsikos et al. (2015) [4].

TFM walls are reinforced with timber elements, both horizontal and vertical but also X-type diagonal braces. It is evident historically, since the Bronze Age that the timber reinforcement into masonry walls is strongly related to seismic resistance in earthquake-prone areas. In TFM walls there is also recent experimental and numerical evidence [5] that the contribution of the diagonal braces is vital for walls' lateral behavior in the nonlinear range due to early detachment of the masonry infill from the surrounding timber frame in the event of an earthquake. In addition, it is observed that for very low horizontal displacement the diagonals in tension detach from the surrounding frame. Therefore, it is suggested [5] that the diagonals should contribute to the lateral behavior only in compression and moreover the infill masonry walls of the timber frame should not be considered in the analytical model. Based on these considerations, a macro-model was proposed ([5], [8]) where its input can be easily determined since it involves only the key geometric characteristics of the timber panels and the timber strength. The latter model facilitates the seismic assessment of TFM walls resulting in a valuable tool for simplified seismic vulnerability and risk analyses [9]. Based on the resulting pushover curves produced by pushover analysis [10] of the TFM walls' macro-model, a shape-function is defined for the derivation of the ESDOF properties which is similar to the methodology already described for URM buildings [4]. An example (TFM building No.4 in Table 1) of the resulting pushover curve [10] is given in Fig. 2 and the overall analysis results are tabulated below (Table 3).

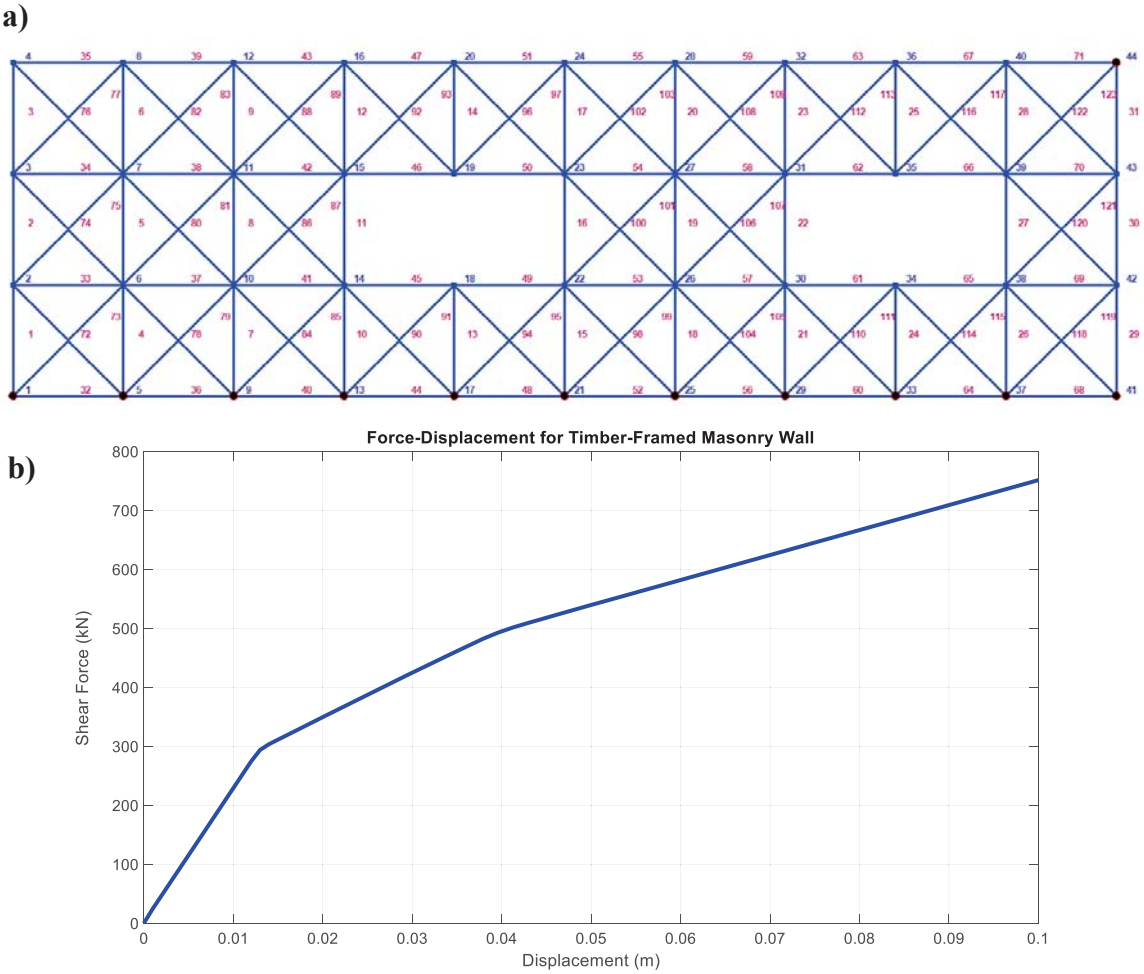

Figure 2: a) TFM wall model with panels incorporating X-type diagonal braces (No.4 in Table 1). b) Pushover curve from the methodology adopted by Kouris et al. (2014) [5].

Longitudinal wall length	7.7 m

4 ESTIMATION OF THE NON-STRUCTURAL DAMAGE LEVEL

Considering these real TFM and URM building cases in Alsace France (Table 1) the corresponding fragility curves are derived in terms of peak ground acceleration (PGA) with the aid of structural analysis for a gradually increasing intensity (incremental dynamic analysis - IDA) [11]. The latter analysis of ESDOF of the building cases under study was performed with the MATLAB [12] toolbox FEDEAS Lab [13]. The correlation of the PGA values of the recordings used in the IDA analysis with the corresponding PGV values follows the rule that for very flexible structures (very high fundamental periods) the relative velocity response spectrum of the used record tends to the peak ground velocity (PGV). The induced ground motions obtained from the PEER database were employed and applied in the transverse/short/weak building plan direction ([7], [14]). The fundamental periods of these structures as already mentioned were verified with ambient noise vibration measurements using sensors [5] located at each floor of the buildings under study (Table 1). Moreover, the main geometry required as input for the simplified vulnerability models was taken through field inspection of these buildings. The results are shown in Fig. 3. It can be seen that the fragilities for URM buildings have more or less the same range of probability of damage while the more earthquake resistant TFM building is less fragile for low and medium intensities.

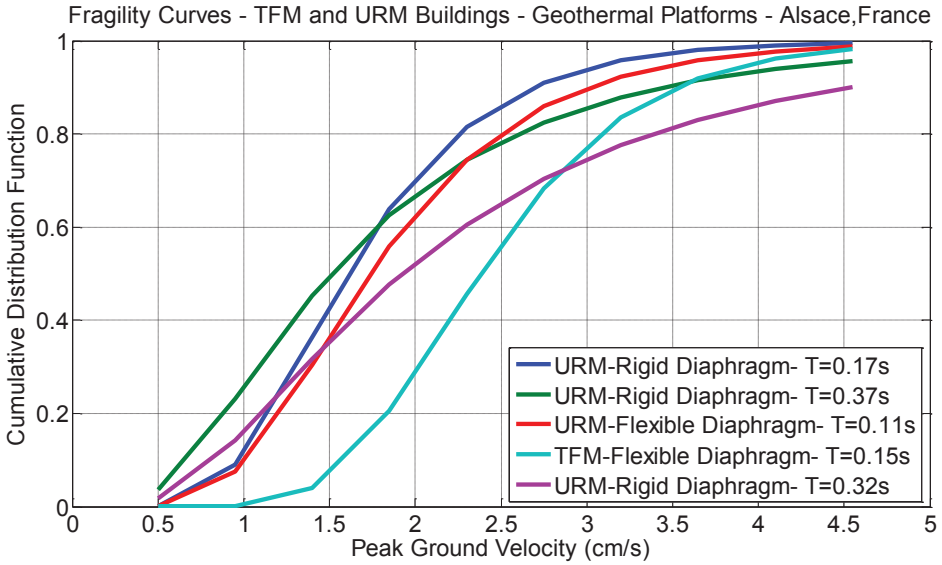

Figure 3: Proposed analytical fragility curves for first damage state (pre-yielding damage state –DS1-0.1% drift limit for non-structural damage) for Unreinforced Masonry Buildings (URM) and Timber-Framed Masonry Buildings (TFM). The buildings are located near the geothermal platforms in Alsace France and are loaded in the weak/short plan view direction of shaking. The fundamental period of these structures was verified with ambient noise measurements through applied sensors [7].

5 CONCLUSIONS

- The estimated dynamic properties for small amplitude vibrations of the historical structures near the geothermal platforms in Alsace, France considered in this work were used to derive simplified vulnerability models.
- Moreover, the Eurocode 8 defines the interstory drift limit of a building for non-structural damage, by looking at its displacement-sensitive non-structural components at the serviceability limit state.
- Therefore, by adopting these limits and the developed simplified vulnerability models, new non-structural fragility curves for typical historical masonry building types dominant in the region under study are proposed.
- The fragility curves have been calculated using incremental dynamic analysis for the seismic demands generally imposed upon linear and slightly non-linear models of single and multiple degrees of freedom, which is the case for the effects of induced seismicity.
- These results will prove useful for both local end-users and industrial stakeholders, with a clear perspective for a better understanding of the risk related to induced and triggered seismicity and its sound management.

Keywords: Structural health monitoring, Observation of strong motion, Primary natural frequency, Control of vibration structures, Secular change

Abstract. *Structural health monitoring, the observation of strong earthquake motions, is carried out at Kanagawa University, a low-rise steel structure. In this paper, a transfer function obtained from these observation records was examined. The results of microtremor and shaker experiments to determine the primary natural frequency, which we always conduct on the completion of a building, were almost the same. The natural frequency in the x-direction was 2.4–2.5 Hz. The natural frequency in the y-direction was 2.6–2.7 Hz. From the five years of monitoring data, we focused on 17 earthquakes, which had the greatest levels of vibration. For these earthquakes, where the maximum acceleration was large in the x-direction, the natural frequency tended to be slightly lower. However, such a trend could not be confirmed in the y-direction. We will continue observing and proceed with further analysis in the future.*

1 INTRODUCTION

After the 1995 South Hyogo Prefecture Earthquake, the number of strong earthquake ground motion observation sites in Japan rapidly increased, and today, this type of observation is conducted at a density unmatched worldwide, for example, at the National Research Institute for Earth Science and Disaster Prevention [1] and in Yokohama City [2]. Moreover, although not matching the extent of ground observations, there has been a steady increase in strong earthquake motion observations focusing on buildings, especially high-rise buildings. Although limited in scope, as part of business continuity planning, corporations use the results of building motion observation records for structural health monitoring by diagnosing the actual performance and soundness of their buildings [3].

The Kanagawa University Yokohama Campus Building 3 (Building 3) was completed in March 2014. Structural monitoring of Building 3 occurs through displacement meters installed on accelerometers and buckling-restrained braces. In addition, to determine the vibration characteristics of the building, microtremor measurements and shaker experiments were conducted in January 2015 [4–6].

In this paper, we outline the observation system, summarize the results of the analysis of the microtremor and shaker experiments, and, with special attention to the primary natural frequency of the building, compile a list of the results of the strong earthquake ground motion observations made during the 2015 to 2019 fiscal years.

2 TOPOGRAPHIC OUTLINE OF THE TARGET AREA

Kanagawa University Yokohama campus is located in Yokohama City in the northeastern part of Kanagawa prefecture (Figure 1). Yokohama City, an economic and industrial center, has a population of 3.7 million and is the second-largest city in Japan. It contains many historically valuable buildings because it has prospered as a port city since ancient times.

Figure 2 shows the topography of Kanagawa University and its surroundings [7]. The Yokohama campus is located on the Shimosueyoshi Plateau, which extends across the east side of the prefecture. The Shimosueyoshi Plateau is composed of Kazusa Group sediments overlain by a gravel layer and a Kanto Loam layer. Dendritic-shaped river valley lowlands have been cut into the plateau. A small valley is located to the north of the Yokohama campus, but the campus is located entirely on the plateau.

The northeastern part of Kanagawa prefecture, where the study area is located, suffered heavy damage from the 1923 Kanto Earthquake. Figure 3 shows the distribution of the destruction rate of wooden houses during the Kanto Earthquake. The destruction rate was high on the coast and extended to the south, and it was extremely high in the west (40%–50%). As shown by the administrative divisions of the time, the Yokohama campus is located near the border between the village of Shirosato and the former location of Yokohama City (Figure 3). In the former location of Yokohama City, relatively detailed damage investigations were conducted, and the destruction rate of wooden houses was as high as 20%–30%. However, the destruction rate of Shirosato is unknown.

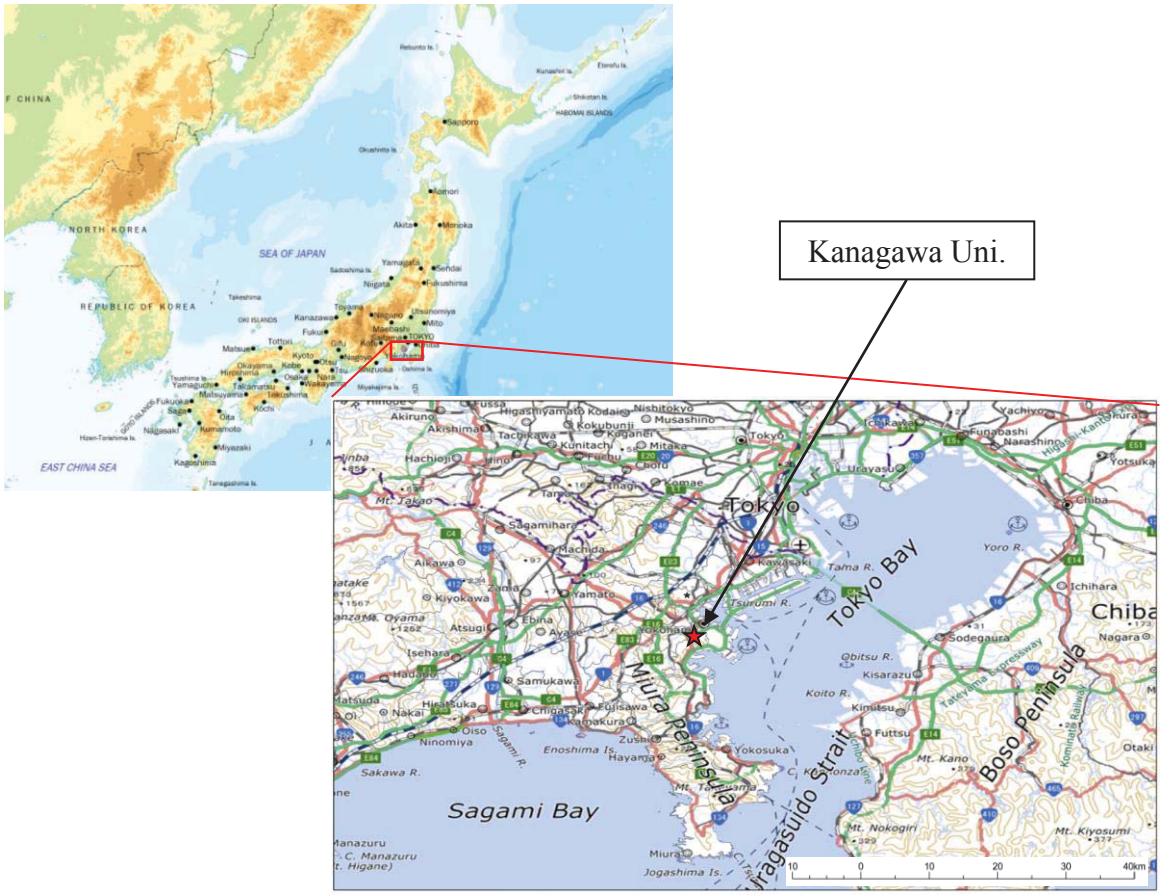

Figure 1: Location of Kanagawa University

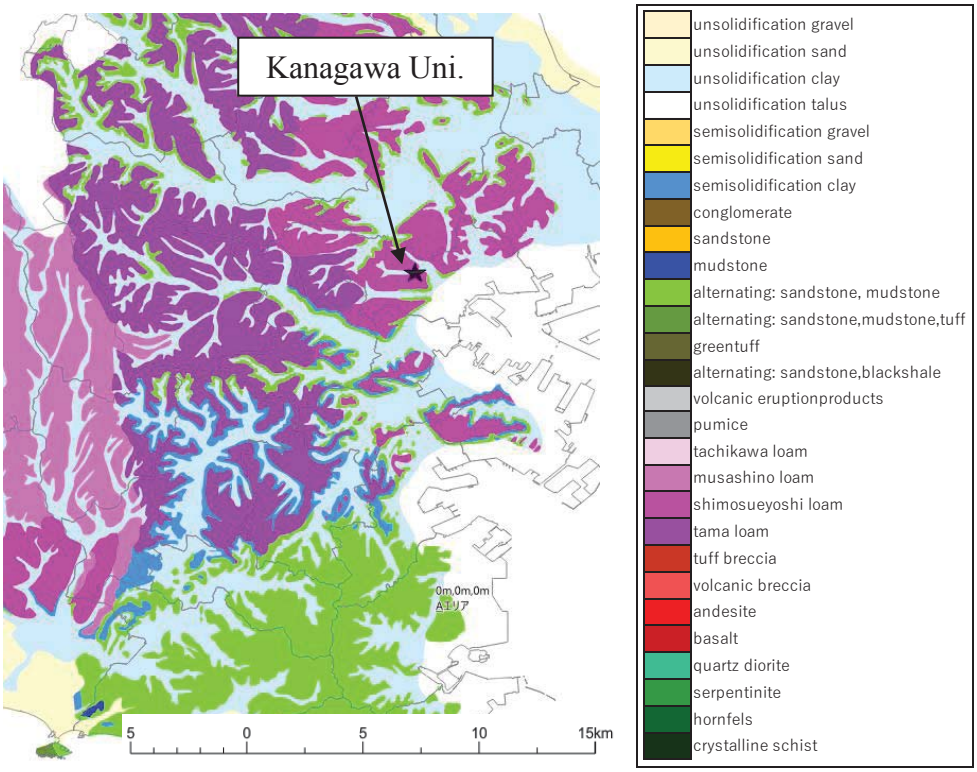

Figure 2: Topography of Kanagawa University and its surroundings [7]

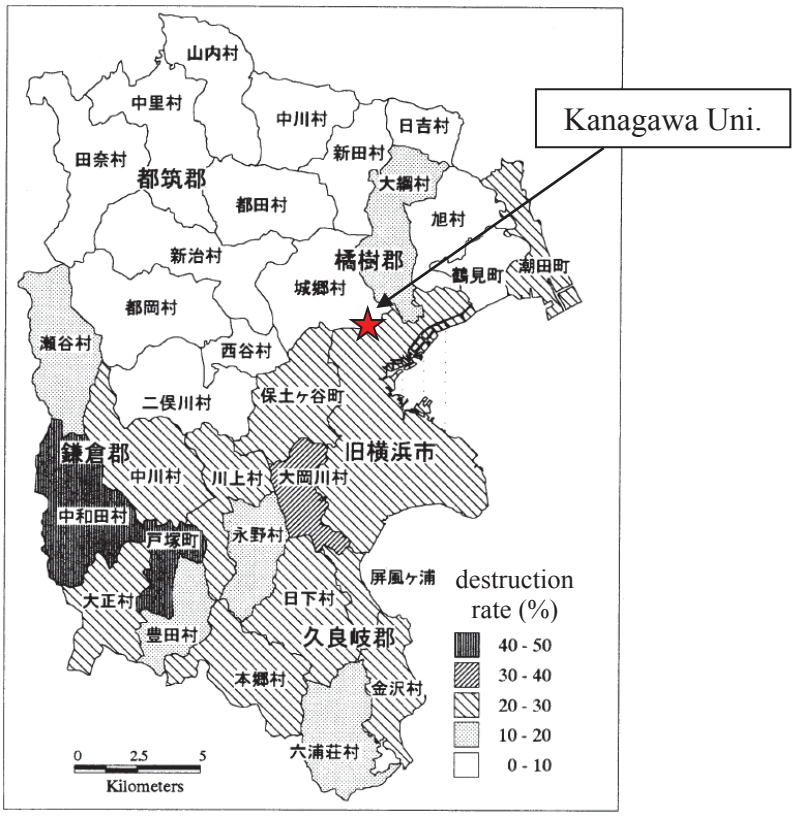

Figure 3: Distribution of the destruction rate of wooden houses during the 1923 Kanto Earthquake [8]. The divisions shown are the administrative divisions at the time.

3 STRUCTURAL MONITORING

3.1 Outline of the building

Building 3 has four floors above ground and two floors below ground. However, for the purposes of structural design, the building is deemed to be situated above ground, with five floors above and one floor below ground level.

Laterally, the structure has atriums on each floor, albeit they are approximately oblong shaped. Vertically, in its top-most section, the structure has pillars erected on beams, again almost oblong shaped. The short side of the building (X) has a span of 2.8 m, while the long side (Y) has a wider span of over 10 m to secure a large lecture room space. Moreover, although the building is a damage-controlled structure that uses buckling-restrained braces, its design is static, so the building is considered to be earthquake-resistant braced [9, 10].

- The main structure is a steel frame with partially reinforced concrete.
- The foundation structure is a spread foundation (the foundation ground is hard and the mudstone layer has an N value of 60 or more).
- There are four floors above ground and two floors below ground (the eave height is 20.45 m).
- The total floor area is 11,480 m2.
- The building area is 2,200 m2.

3.2 Outline of the structural monitoring system

For the structural monitoring, we conducted seismic observations using accelerometers and made displacement observations of the buckling-restrained braces in the building and surrounding ground. In the following, we outline the primarily seismic observations.

The earthquake observation system for this building comprises accelerometers installed in three locations of the building: 4th floor, 1st floor, and B2 floor (see Figure 4) and in two locations in the ground at distances of several tens of meters away from the building (i.e. on the ground surface, excluding the embankment, and at the engineering infrastructure depth). Each accelerometer has three components, two for bi-directional lateral (x, y) operation and one for vertical operation. Records are taken when the trigger level (1 gal) is exceeded at the engineering base position. Observation records are stored on a server and currently collected manually.

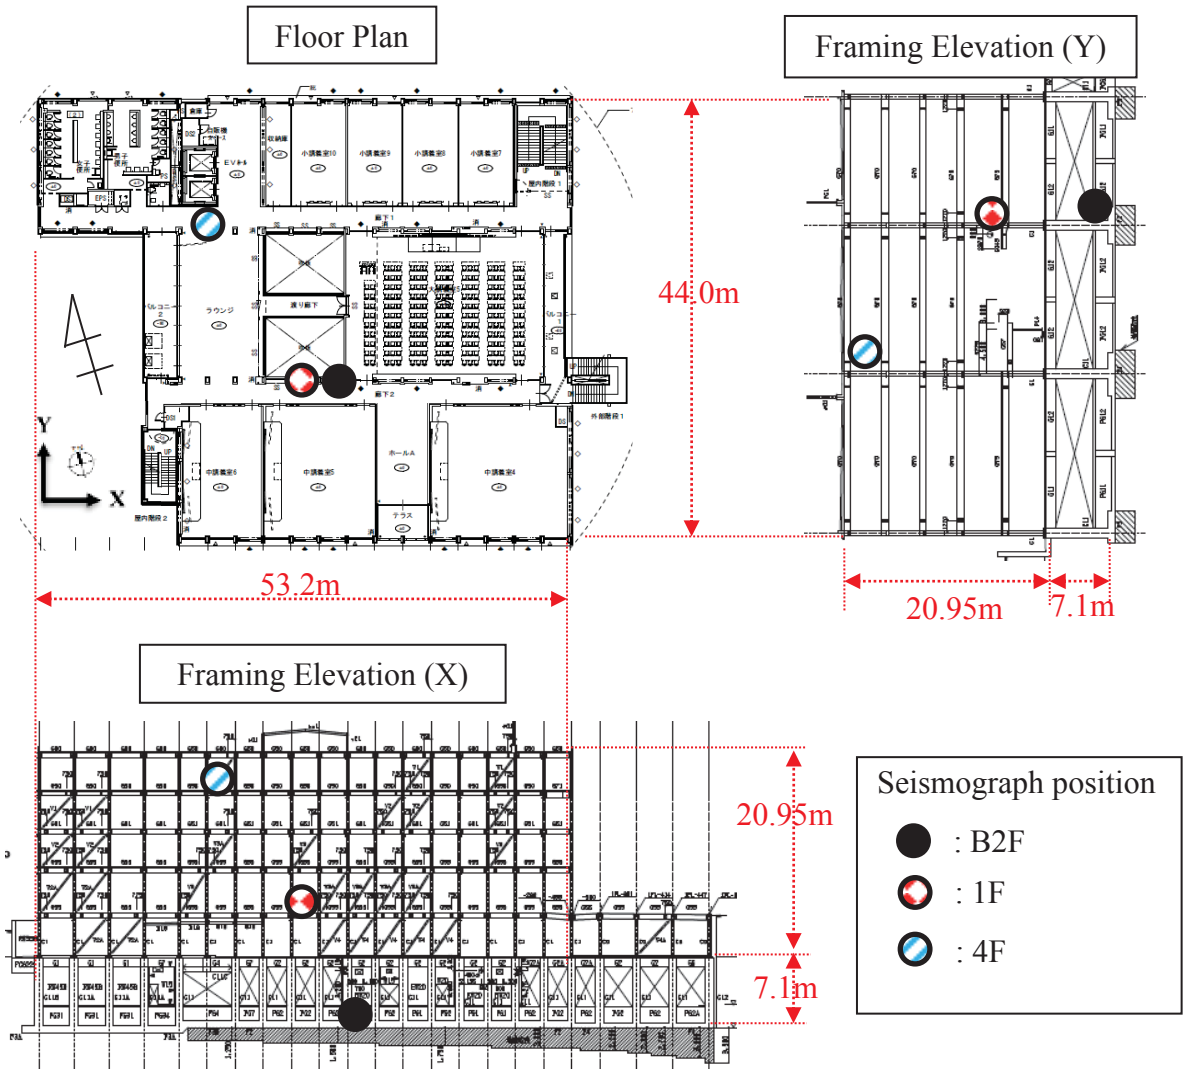

Figure 4: Seismograph positions in the target building (Building 3)

4 MICROTREMOR MEASUREMENT AND SHAKER EXPERIMENTS

4.1 Microtremor measurements

For the microtremor measurements, microtremor meters were installed at the approximate centers of the building's R and B1 floors. The x- and y-direction transfer function (R floor/B1 floor) was calculated from the Fourier spectrum of the measurement records.

The transfer function obtained using the microtremor measurements is shown in Figure 5. The peak frequencies of the transfer function were 2.52 Hz in the x-direction and 2.74 Hz in the y-direction; thus, they were slightly higher in the y-direction. The peak at 3.24 Hz is presumed to be due torsion.

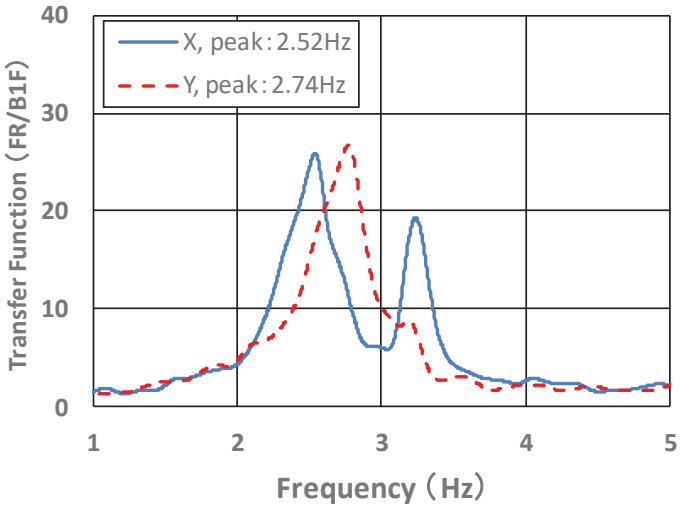

Figure 5: Transfer function from microtremor measurements

4.2 Shaker Experiments

For the shaker experiments, a small shaker with a linear motor was adapted from Aoki et al. [11] and Wen et al. [12]. In the experiments, the shaker was installed almost at the center of gravity on the R floor of the building with one-direction oscillation in each of the x- and y-directions. Measurements were taken at four points on the R floor. Figure 6 shows the resonance curve from the shaker experiment. The peak of the resonance curve was 2.38 Hz in the x-direction and 2.64 Hz in the y-direction; thus, it was slightly higher in the y-direction, as was the microtremor measurement. A peak of more than 3 Hz in the x-direction was conceivably due to a torsional component.

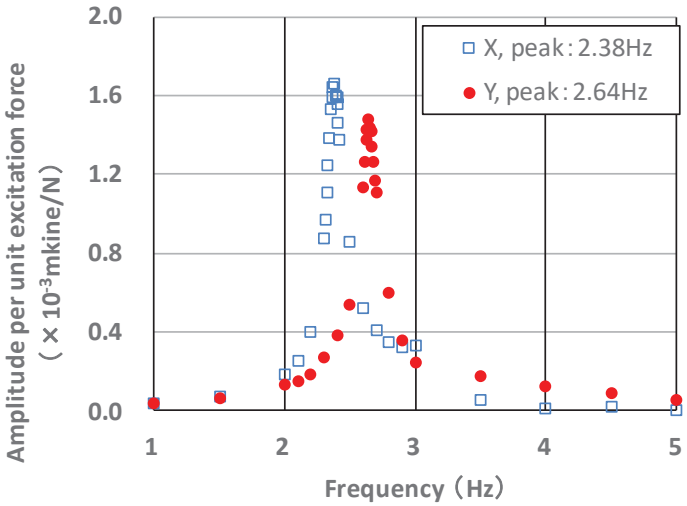

Figure 6: Resonance curve from the shaker experiment

4.3 Transfer function

Using the peak frequency of the transfer function and the peak of the resonance curve as the primary natural frequencies of the building, the primary natural frequencies are shown in Table 1. The results of the microtremor measurements and the shaker experiment were generally consistent. There are several possible causes for the slightly higher frequency in the y-direction. Conceivably, it is because the buildings' overall dimensions are longer in the x-direction (53 m) than in the y-direction (44 m).

Notably, a calculation using the natural period calculation formula of a general S structure (T = 0.02 x H) yields T = 0.409 s (2.44 Hz), which is largely consistent with the measured value.

Table 1: List of transfer functions

	Microtremor Measurement	Shaker Experimentation
X	2.52Hz (0.40s)	2.38Hz (0.42s)
Y	2.74Hz (0.36s)	2.64Hz (0.38s)

5 TARGET EARTHQUAKE

As part of the structural monitoring, Building 3 has been subject to strong earthquake motion and buckling-restrained brace displacement observations. In the following, we focus on the primary natural frequency of the building obtained from the transfer function from strong earthquake motion observation records and consider its secular change.

The target period ran from March 2015 (the start of the observations) to January 2020. The targeted earthquakes comprised 17 earthquakes with a seismic intensity of 2.5 or more

measured at K-NET Yokohama (KNG002), a strong ground motion observation point located relatively close to Kanagawa University. Table 2 lists the targeted earthquake motions and observation records, and Figure 7 shows the epicenter locations.

Of the targeted earthquakes, only the epicenter of the No. 2 earthquake was located off the western coast of the Ogasawara Islands to the south. This earthquake, at a depth of 682 km, somewhat differed from the other earthquakes, which were evenly distributed around the target location, from the north to the south. The majority of the epicenters were located at depths between 10 and 60 km; these earthquakes mainly occurred in shallow strata.

As an example, Figure 8 shows the time history waveform and response spectrum of the ground surface on May 25, 2015.

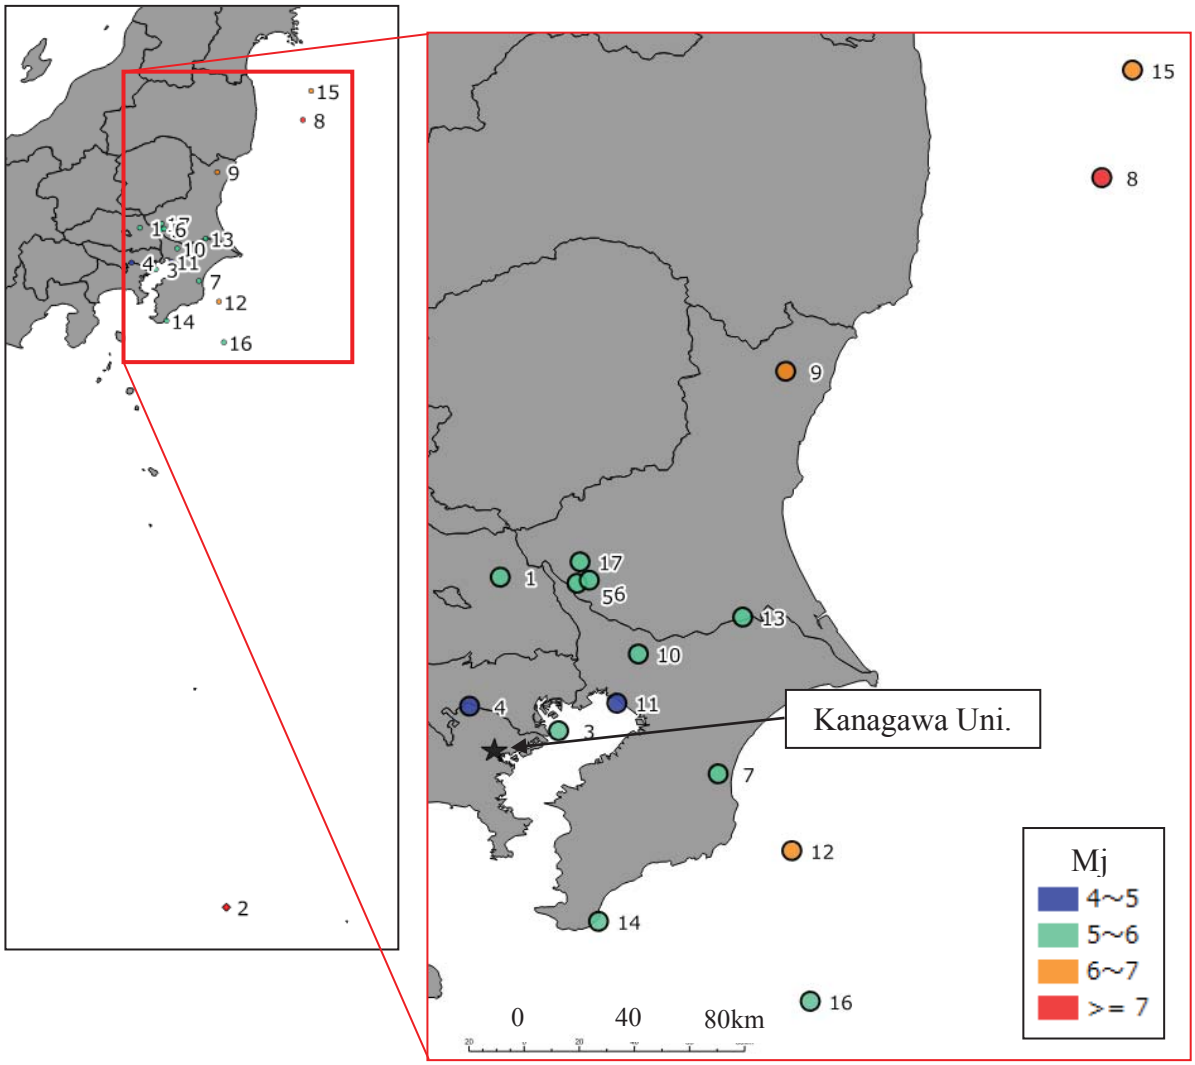

Figure 7: Distribution of the targeted earthquake epicenters

X-direction Y-direction

Figure 8: time history waveform and response spectrum (h = 5%) of the ground surface for the May 25, 2015 earthquake

6 STRUCTURAL HEALTH MONITORING

6.1 Primary natural frequency

Figure 9 presents the superposed transfer functions for each earthquake record. Earthquakes with a maximum acceleration (4F exceeding 20 gal in both directions) are shown in red. In the x-direction, when the maximum acceleration is large, the natural frequency tended to be slightly smaller (cycle prolongation). However, this tendency was not apparent in the y-direction.

Figures 10 shows the relationship between the primary natural frequency and the 4F maximum acceleration. It also presents the approximate curves and correlation coefficients. As described above, when the maximum acceleration was large, the natural frequency tended to be small. Variation in the x-direction was low overall, and the correlation coefficient of 0.84 indicates a relatively strong correlation between the two. As seen in the spectrum, for the y-direction, the overall variation was somewhat higher, and the correlation was weak, with a coefficient of 0.55.

We plan to conduct further analyses of differences in the characteristics of the x- and y-directions.

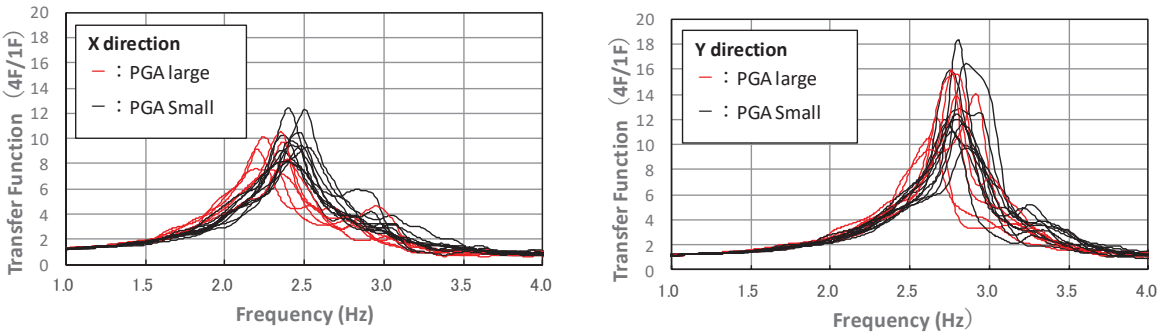

Figure 9: Transfer function (4F/1F)

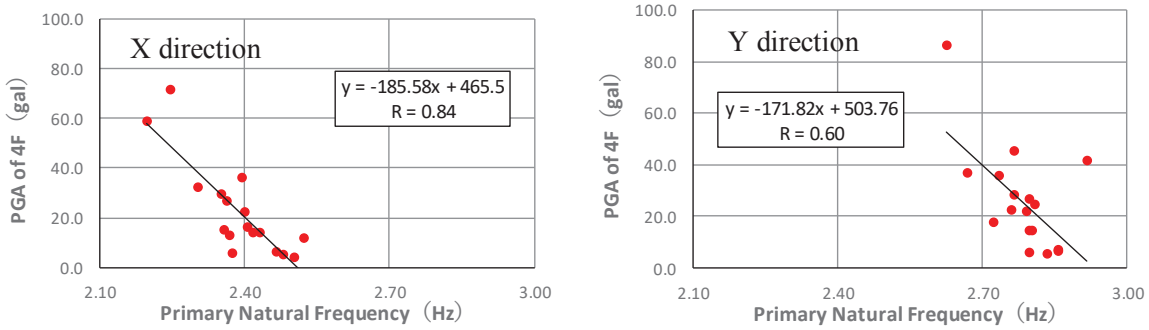

Figure 10: Peak accelerations (4F) and primary natural frequencies

6.2 Changes in primary natural frequency during the duration of an earthquake

Having confirmed the amplitude dependence of the primary natural frequency due to differences in the intensity of ground motion (section 5.1), we then analyzed whether the same tendency could be confirmed during the duration of a single targeted earthquake. The analysis target was the May 25, 2015 earthquake, which resulted in the building's largest acceleration. The earthquake was recorded for 100 seconds. The acceleration amplitude increased from around 20 seconds in both the x- and y- directions and then reduced after 60 seconds, up to about 6 gal at 4F.

Although the time history waveform cut out at 20.48 seconds, by shifting the start time by 2.0 seconds, a transfer function was obtained in the same manner as shown in Figure 9. Figure 11 shows the change in the primary natural frequency during the earthquake with the time history wave. The primary natural frequency in the x-direction for the first half of the 60 seconds, including the main motion, was 2.2 to 2.3 Hz. After 60 seconds, the primary natural frequency gradually increased from 2.3 to 2.6 Hz (micromotion: 2.52 Hz and shaker experimentation: 2.38 Hz). The primary natural frequency for the first 60 seconds in the y-direction was 2.6–2.7 Hz, and the second half was 2.7–2.9 Hz (micromotion: 2.74 Hz and shaker experimentation: 2.64 Hz). These results show that the natural frequency changed with amplitude level during the duration of the earthquake.

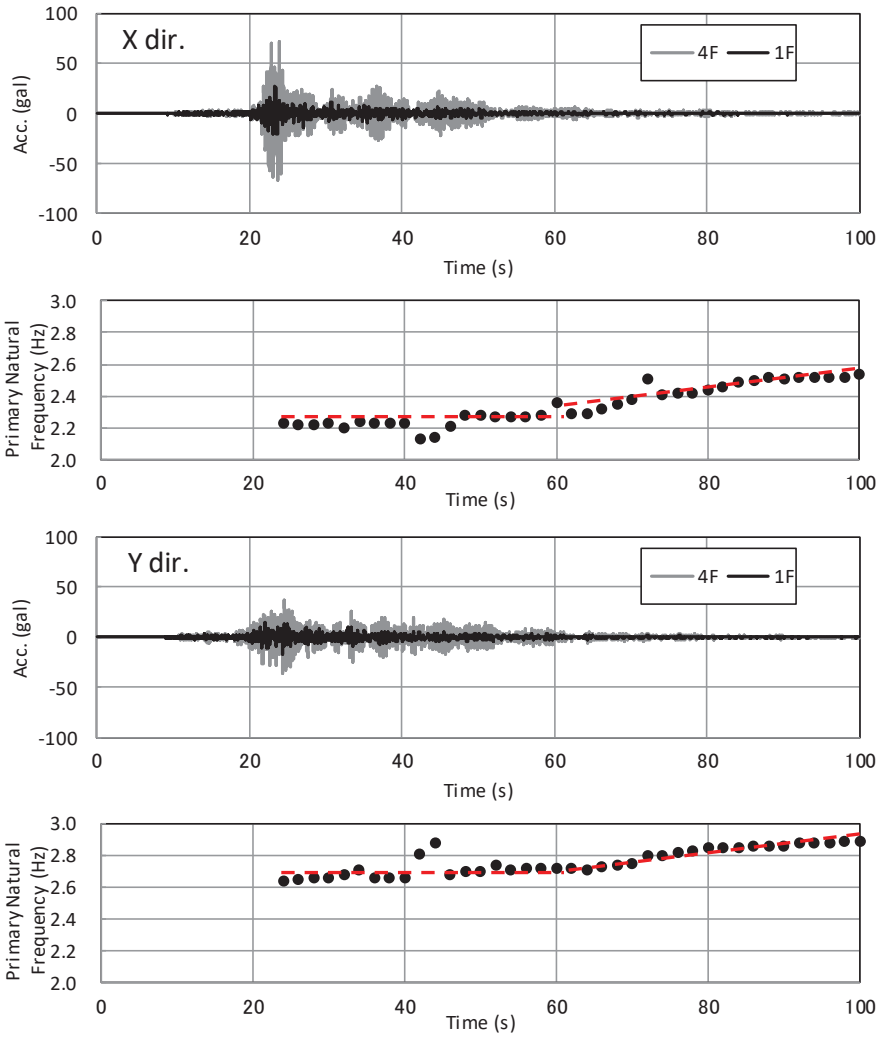

Figure 11: Changes in primary natural frequency during the duration of an earthquake

6.3 Time-dependent change in the primary natural frequency

Figure 12 shows the changes in the primary natural frequency over time, from the start of the observation period until the present. As described above, although there was some variation in the magnitude of the acceleration, the extent of the variation was small overall. Given that there has been almost no change in the natural frequency since immediately after the completion of construction, it was assumed that the soundness of the building has remained intact.

In the future, we plan to continue these observations and proceed with analyses that focus on questions around differences in changes due to external factors, such as seismic motion, and changes due to aging.

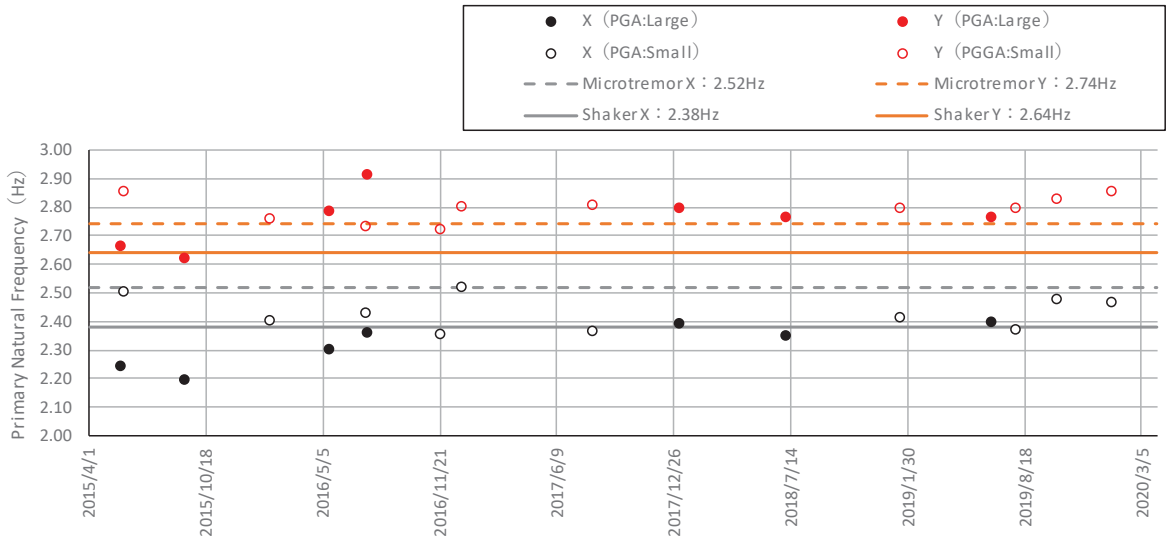

Figure 12: Time-dependent change of the primary natural frequency

7 SUMMARY

We examined the vibration characteristics of Kanagawa University Building 3 using microtremor measurements and a shaker experiment: the primary natural frequency data obtained were largely consistent for both methods.

The transfer function obtained from strong earthquake motion observation records evidenced time-dependent change in the primary natural frequency of the building. In the x-direction, the data showed that the natural frequency decreased when the maximum acceleration was large, and this correlation was strong. However, while a similar tendency was also observed in the y-direction, this correlation was weak. We will continue to analyze differences in vibration characteristics in the x- and y-directions. Currently, five years after the completion of construction, secular change is small, and conceivably, the soundness of the building remains intact.

In the future, based on the results of these analyses, we will focus on extracting indicators that can be used for structural health monitoring.

Notably, while this analysis has only treated primary natural frequency, in the future, we would like to also examine changes in attenuation characteristics.

Abstract. *Wind-induced dynamic excitation is becoming a governing design action determining size and shape of modern Tall Timber Buildings (TTBs). The wind actions generate dynamic loading, causing discomfort or annoyance for occupants due to the perceived horizontal sway – i.e. vibration serviceability failure. Although some TTBs have been instrumented and measured to estimate their key dynamic properties (natural frequencies and damping), no systematic evaluation of dynamic performance pertinent to wind loading has been performed for the new and evolving construction technology used in TTBs. The DynaTTB project, funded by the Forest Value research program, mixes on site measurements on existing buildings excited by heavy shakers, for identification of the structural system, with laboratory identification of building elements mechanical features coupled with numerical modelling of timber structures. The goal is to identify and quantify the causes of vibration energy dissipation in modern TTBs and provide key elements to FE modelers.*

The first building, from a list of 8, was modelled and tested at full scale in December 2019. Some results are presented in this paper. Four other buildings will be modelled and tested in spring 2021.

1 INTRODUCTION

1.1 Background

Due to population expansion and concentration in urban regions, housing shortage is an increasing global issue, necessitating the efficient use of space in urban areas. One solution is an increased supply of tall buildings to optimize the best use of limited space. This has sustainability impacts surrounding the choice of materials and carbon footprint ramifications. Using more wood-based products in building construction, as a renewable raw material, could assist in the transition of society towards a circular based bio-economy, moving away from a dependence on fossil fuels and extractive materials, whilst helping meet the commitments contained within the UN Sustainable Development Goals. The use of tall buildings with timber structures would be an opportunity to create value and impact by encouraging the increased use of forest-based replenishable products. Tall Timber Buildings could provide cost effective, environmentally sustainable developments, maximising the limited space available in urban regions.

Tall Timber Buildings (> 10 storeys) is still a very new concept, some examples are:

- Murray Grove (London, UK (2009)) – 9 storeys,
- Forté (Melbourne, Australia (2012)) – 10 storeys,
- Treet (Bergen, Norway (2015)) – 14 storeys,
- Brook Commons (Vancouver, Canada (2017)) – 18 storeys,
- Origine (Quebec City, Canada (2018)) – 13 storeys and
- Mjøstårnet (Brumunddal, Norway (2019)) – 18 storeys.

The load-bearing system of these buildings are very different giving the buildings different properties. Building tall means several new challenges such as higher loads vertically and horizontally, earthquake loads, fire safety and increased needs regarding technical systems as some examples. One aspect that is of special interest is the dynamic behavior related to wind-loads that leads to a need to limit acceleration levels at the top of buildings. This is a factor that has shown to govern the design of the stabilization system of tall timber buildings from a height of 12-14 storeys and above, see [1] for example. The understanding of the wind-induced dynamic behaviour of Tall Timber Buildings (TTBs) and their components is till poor and results in a lack of confidence by designers in the use of timber as a construction material. A lack of reliable data for modelling is one of the main barriers in the further development of TTBs and wider utilisation of timber within construction.

This lack of reliable data regarding modelling wind-induced vibrations for tall timber buildings was the motivation for starting the ForestValue project "DynaTTB - Dynamic Response of Tall Timber Buildings under Service Loads". The project will be performed by partners from academia, research institutes and companies[2] from five different countries in Europe during 2019-2022. The research hypothesis for this project is that it is possible to create computational models for Tall Timber Buildings, based on system identification and calibration of advanced Finite Element (FE) models. This will be underpinned by data from full-scale tests of a number of representative mid-to-high rise timber buildings in Norway, Sweden, France, Slovenia and the UK. The project plan will utilize unique horizontal electro-dynamic sliding shakers from the University of Exeter (UK) and CSTB (France) to perform vibrational tests and use the data

to estimate Frequency Response Functions (FRFs) for a number of TTBs with different building systems.
The overall objective of the project is to experimentally identify a number of full-scale TTB structures within Europe and, based on these results, develop representative FE-models to predict the vibration response of TTBs exposed to wind-induced dynamic loading.
This paper will present the structure of the project and the first preliminary results from the first two tested buildings.

1.2 State-of-the-art

There are several all timber building systems that can be used for the stabilizing system in TTBs. In principle these systems can be made up of one-dimensional elements in the form of beams and columns, mostly made of glulam, or two-dimensional elements such as cross laminated timber (CLT) or laminated veneer lumber (LVL). The one-dimensional elements can be used in moment-resisting frames or as trusses while the two-dimensional elements are used as shear walls to stabilize the buildings, see Figure 1. It is also possible to use hybrid structures with parts of the building system in steel or concrete to help support the building against especially horizontal loads. CLT elements are typically connected using shear or tension angular steel brackets and self-tapping screws [2]. The glulam members are typically jointed using dowelled connections with slotted-in steel plates - a jointing technique successfully applied in large-span timber bridges and sport arenas.

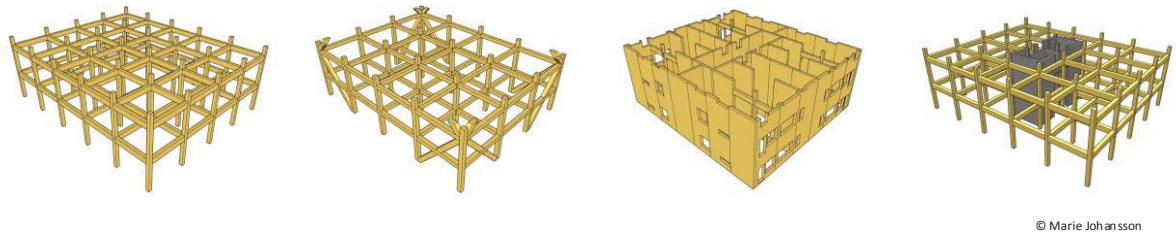

Figure 1: Principal buildings systems for Tall Timber Buildings, a) moment-resisting frames, b) truss-systems, c) shear wall systems and d) hybrid system combining timber with other materials.

TTBs have, in principle, sufficient strength capacity to resist lateral loads (e.g. wind, earthquake) for the ultimate limit state. However, instead the vibration serviceability limit state (SLS) governs the design, leading to the need to restrict wind-induced sway vibrations to within certain limits [4, 5]. The lowest natural frequencies, dependent on mass and stiffness, of the TTB sway motion is in the same frequency range as the wind spectra. The sway is, however, also largely dependent on the damping of the structure. Timber is a light material with only moderate stiffness and hence the fulfilment of the vibration SLS criteria, due to wind, results in restrictions to the total building height [6, 7].

The amount of sway/acceleration depends on the mass and stiffness distribution of TTB structures and the ability to dissipate vibrational energy from the structural system. Currently, the knowledge on structural stiffness and damping in TTBs is limited, particularly regarding the effects of different types of connections used in the load-carrying systems. These connections are crucial generators of stiffness and damping, yet little is known as to their impact on TTB structures. Current modal damping values used in the design of TTBs are based on guess work, with minimal underpinning rational or scientific basis.

Two major contributors to damping are: material damping and structural damping. Material damping arises from the internal friction within the material of a timber element, whilst structural damping is due to friction and energy dissipation in the connections. Non-structural elements and their connections are also assumed to contribute to the total damping. Timber structures are lightly damped systems and, therefore, due to the nature of resonant response calculations, a small change in the damping ratio can lead to significant changes in the vibration response and overall serviceability performance.

Although some TTBs have been instrumented and measured to estimate their key dynamical properties (natural frequencies, mode shapes and damping) [3], no systematic evaluation of dynamic performance pertinent to wind loading, has been performed for the innovative and evolving TTB construction technology. Knowing that the wind response calculations are highly sensitive to the damping values and natural frequencies, indicating that small variations in these uncertain modelling parameters may yield vastly different responses on either side of the acceptable vibration response values.

Full-scale tests on TTBs has been done using Operational Modal Analysis (OMA), also expressed as Ambient Vibration Testing (AVT), where the dynamic response is measured without knowledge of the load, [3, 8] for example). This technique gives relatively good results for natural frequencies and mode shapes but offers considerably less reliable values for damping. Using Forced Vibration Testing (FVT) gives the possibility of controlling the load level and thereby establishing Frequency Response Functions (FRFs) [9]. Using FVT gives the possibility of measuring over a range of frequencies and will result in better understanding of the dynamic response of TTBs as a function of excitation frequency, which is important for stochastic wind loading containing multiple frequencies. The FRFs also give a better base for model calibration of the FE-models of TTBs. The partners at University of Exeter and CSTB have unique equipment enabling measurements of dynamical properties of other types of large civil engineering structures, bridges and floors [10, 11] which will be used for TTBs in this project to provide excellent opportunities to establish unique and vital data.

FE models of full-scale TTBs have numerous uncertainties, for example, whereabouts stiffness and damping occur. Improved knowledge of the dynamic behaviour of TTBs can be developed through dynamic tests on full-scale building structures (in-situ), but these are time consuming and costly. The goal of this project is to limit the required number of tests and develop simulation tools such as reliable FE models.

2 PROJECT PLAN

The main objective of the project is to identify experimentally a number of full-scale TTB structures (existing or currently being built) and, based on these, develop representative FE-models for predicting the vibration response of TTBs exposed to dynamic loading due to wind. Figure 2 includes eight TTBs (plus a timber bridge) that have been identified as potential candidates. In most cases the companies designing and building the structures are involved in the project as industry partners making drawings and calculation models available. Table 1 gives some data for the buildings such as height, width and depth as well as their main building system.

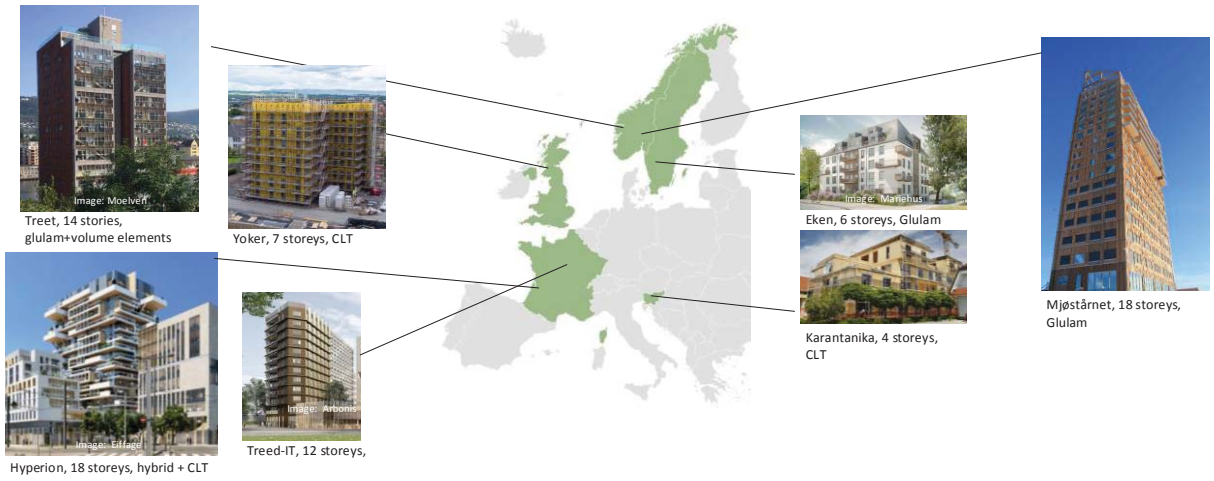

Figure 2: Map of Europe with the buildings that will be measured.

Building name	Country	Building height	Building width	Building depth	Load-bearing system	Stabilising elements
Mjøstårnet	Norway	85.4	36.8	16.3	Glulam	Trusses
Treet	Norway	46			Glulam+ strong concrete floors	Trusses
Timber bridge (Fjell-leet)	Norway	-			Glulam	Trusses
Hyperion	France	57	30.6	19.1	Glulam + CLT	Concrete Core
Treed It	France	36	47.4	18.6	Glulam + Timber Concrete Slab	Concrete Core
FlowerValley	Slovenia	12.7	14.5	21.2	CLT	Shear walls
Kv Eken	Sweden	24.4	27	19	Glulam	Trusses
Yoker	UK	22	31	28	CLT	CLT Shear walls

Table 1: Selected data about the building included measurements and main load-bearing system.

The buildings represent different modern timber building techniques and offer good examples of a variety of building types, providing a range in dynamic response for calibration and reliability in the modelling work. The buildings are dispersed across Europe providing a geographic spread. A bridge is included being an excellent example as to a similar type of glulam structure, including dowel connections, but with less non-structural elements. This will support research into the effect of connections versus non-structural elements.

The work in the project is divided into three interrelated main work-packages (WP2-4) and two supporting work-packages 1 and 5, see Figure 3. Work-packages 2 and 3 are experimentally based, to improve the understanding of the real behaviour of complete buildings measured in-situ (WP3) and parts of the structural system (components, connections and sub-assemblies), known to influence the dynamic response, as measured in the lab (WP2).

Work-package 4 includes the modelling aspects of the project, with a starting point from using best engineering judgement information to develop models of the buildings to predict load levels and initial estimates of the buildings dynamic responses. The data from WP2 will create detailed FE-models of the connections and sub-assemblies simulating the measured behaviour. These models will be simplified and used for model calibration of the FE-model for

the complete buildings, whilst also being calibrated against measurement data for the complete buildings.

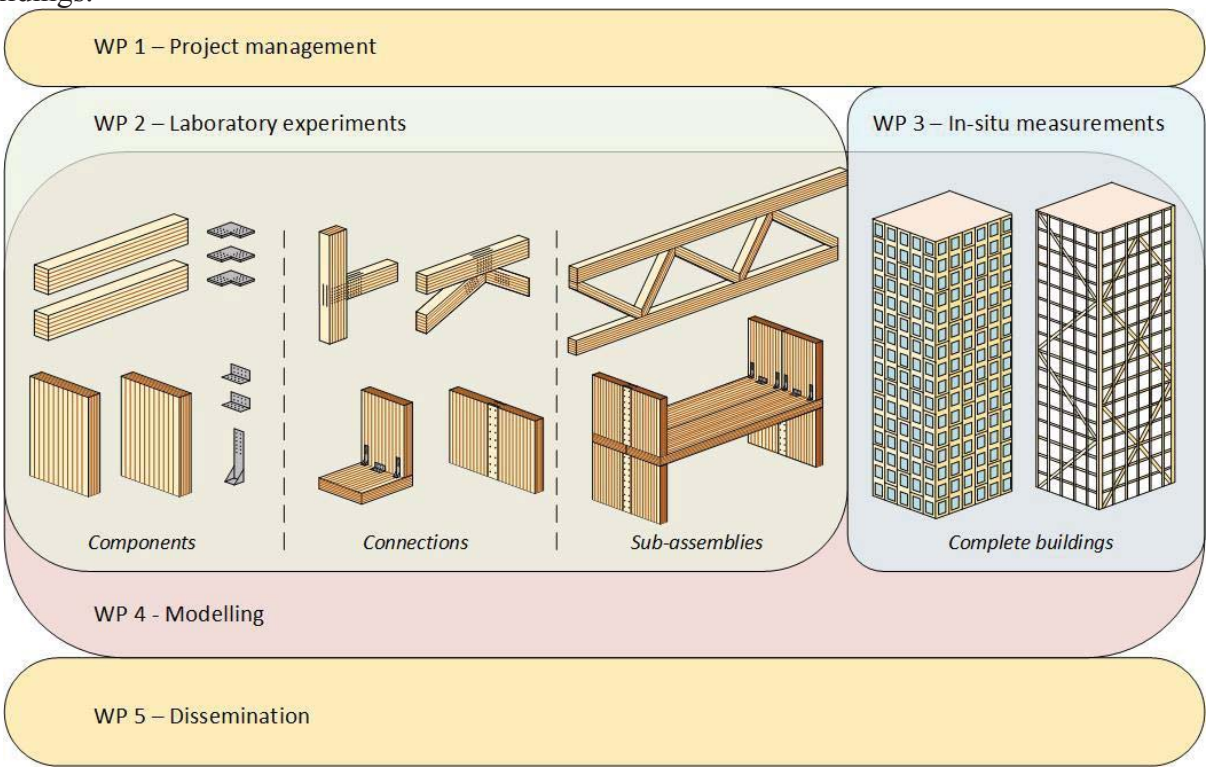

Figure 3: Project structure – WP2 - Laboratory experiments and WP3 - In-situ Measurements will run in parallel whilst WP4 - Modelling supports the measurement WPs and is calibrated with data from measurements. WP1 - Project management and WP5 - Dissemination will run during the whole project time for support and exploitation of the results.

The project is on-going and so far, measurements using forced vibrations have been conducted on two buildings, Treed-It in Paris and Yoker in Glasgow. Preliminary results from the measurements and modelling of these two buildings will be presented in this paper as well as an overview of the measurement techniques and modelling techniques used.

3 EXAMPLES OF BUILDINGS AND RESULTS

3.1 The Treed-It Building - structure

Treed-It is a 12 story building with the first podium story in concrete and then 11 stories with a glulam structure. The building is stabilized against horizontal loads with an elevator shaft in concrete. The building is located in Champs-sur-Marne and is constructed by Vinci Engineering with Arbonis as the main contractor for the timber parts of the structure. The main part of the construction work has been done during 2019 with the timber structure being raised during July to October 2019. The building was finished July 2020.

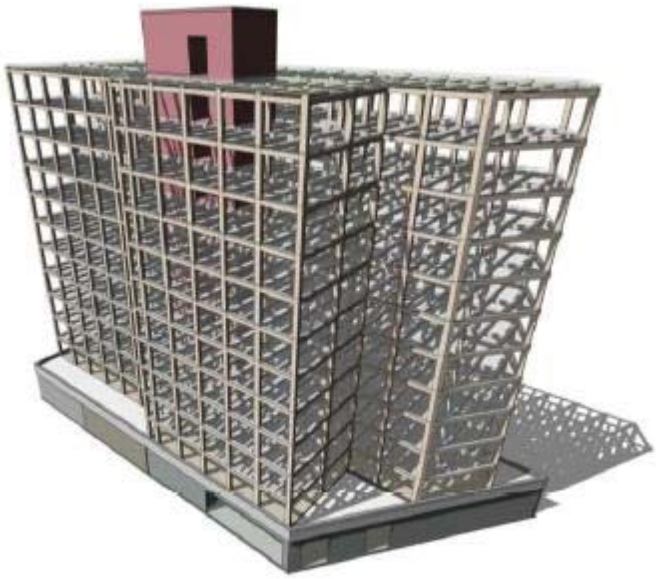

Figure 4: The structure of the Treed-It building with a concrete core and a glulam structure around it and mix timber-concrete floor slabs.

3.2 Modelling of Treed-It

An FE-model of the Treed-It building has been built using Ansys by CSTB. The structure is modelled using beams for the timber part and shells for the concrete and mix parts. As the building was not totally completed at the time of the dynamic measurements, the modelling takes into account the missing dead loads corresponding to inner partition that were not in place when natural frequencies have been measured. Oppositely, the stiffness of the structure was already the same as the final one. Cladding, that was already finished, is considered as bearing only load and no rigidity because façade is not contributing to the horizontal strength.

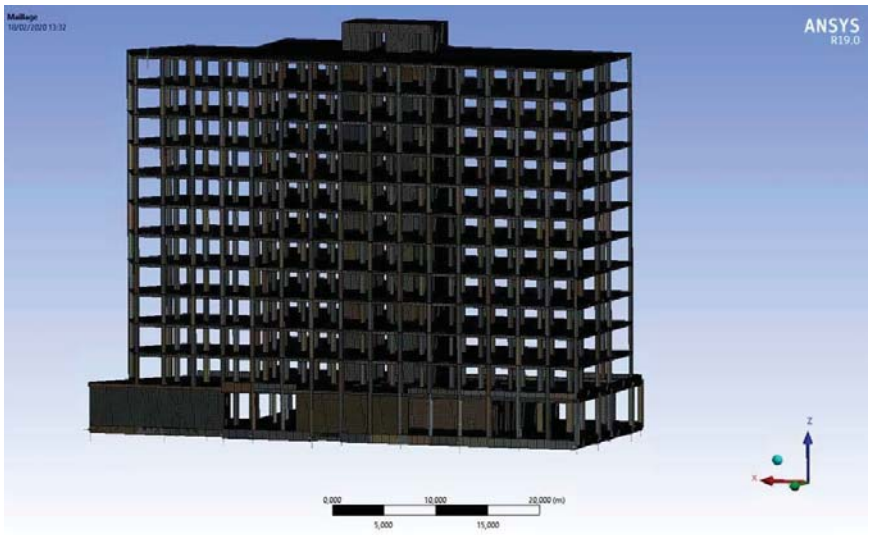

Figure 5: Ansys model of the Treed-It building by CSTB, using beam elements for the columns and beams and shells for the slabs and the concrete core.

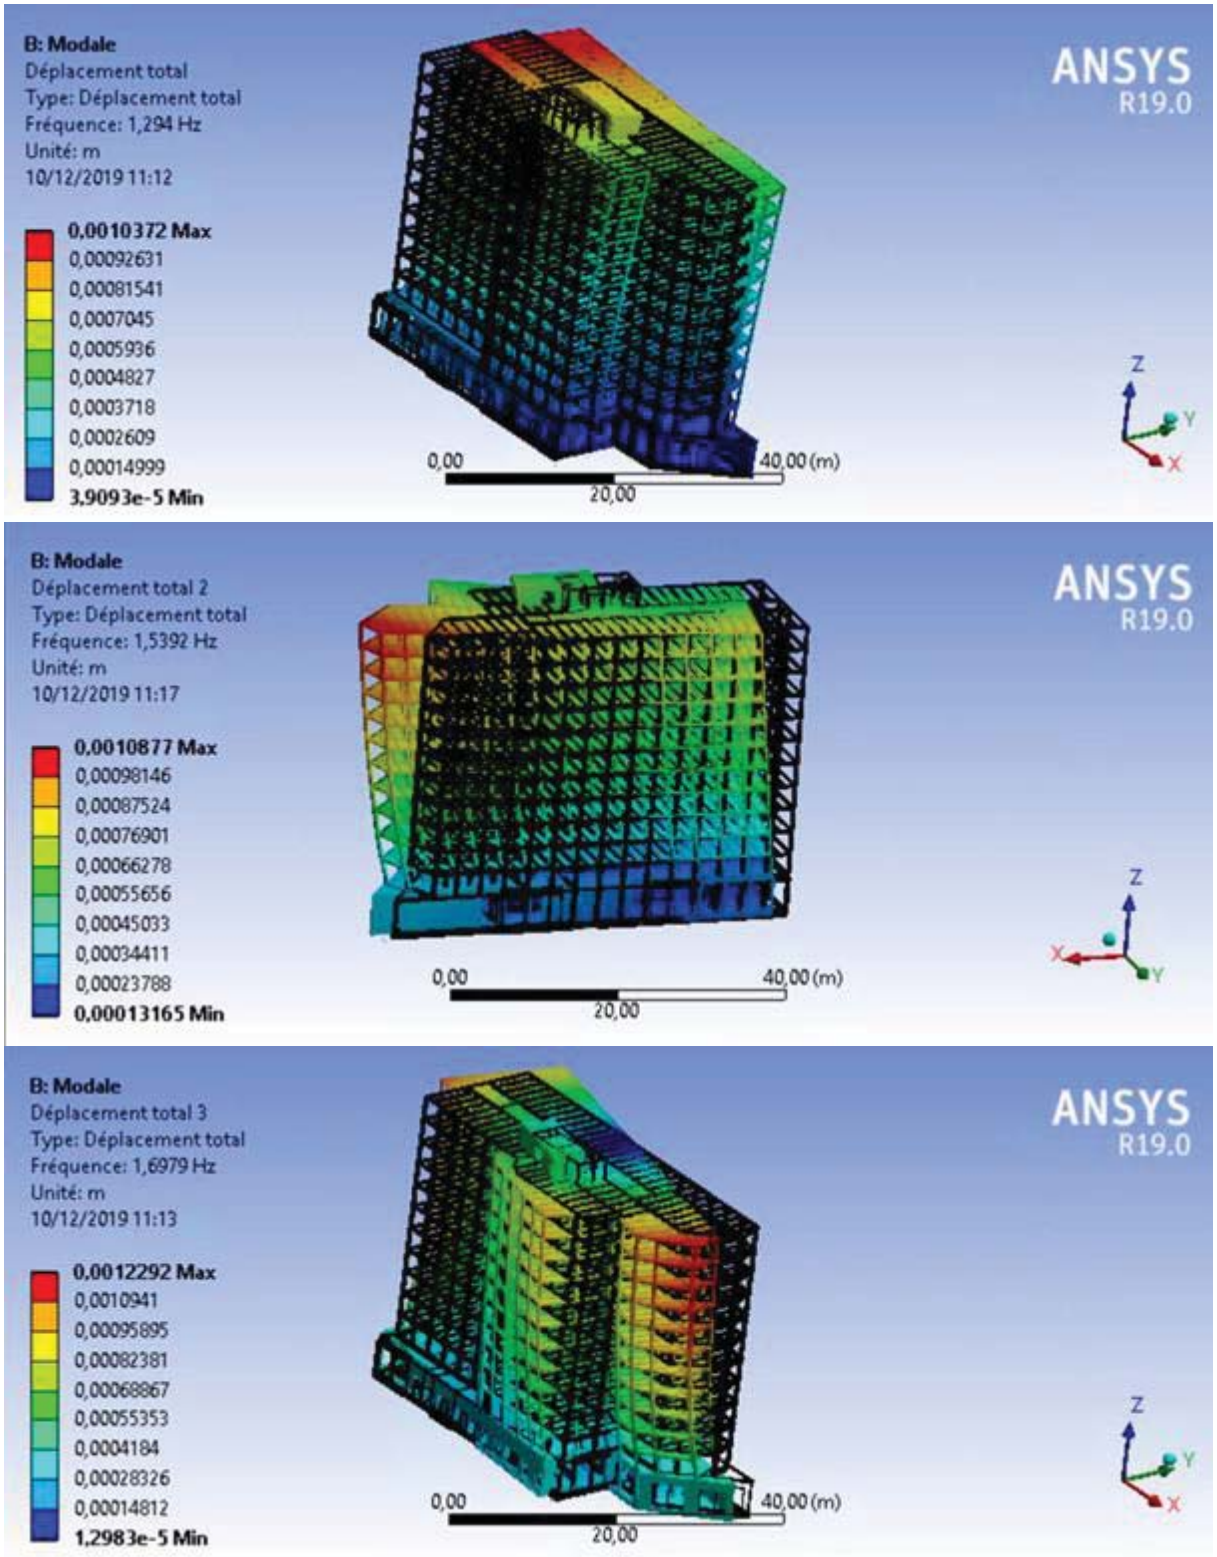

Figure 6: Dynamic analysis of the Treed-It Building performed by CSTB before the real testing.

3.3 Testing of Treed-It

The dynamic properties of the Treed-It Building was measured by CSTB using a horizontal mass shaker with a moving load of 500kg.The shaker was lifted in one piece to the top floor by a tower crane. With a stroke of 240mm the sinusoidal force applied to the building was up to 8000N. This applied force increases with the square of the frequency, as it is an inertial exciter. A first measurement campaign was conducted in December 2019 without internal partition.

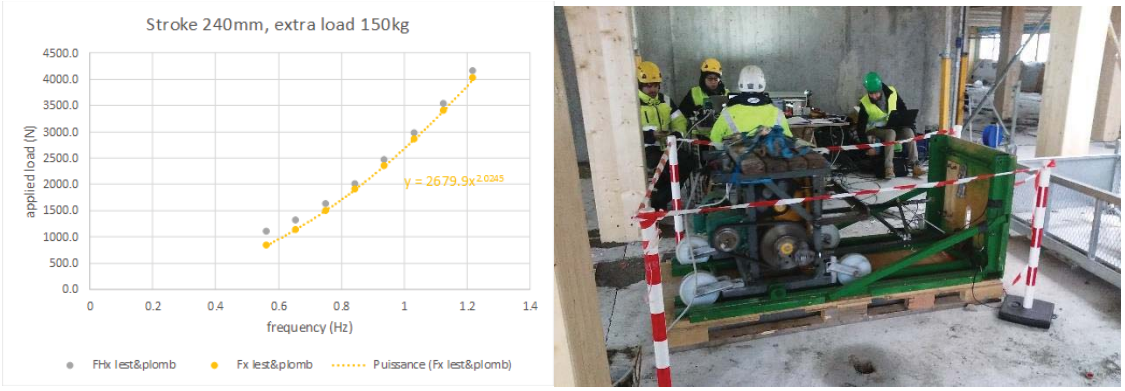

Figure 7: Horizontal force applied by the mass shaker for a given stroke (left) and shaker in operation on the Treed It Building (right)

Three locations of the shaker have been tested. Accelerometers were placed at three levels (11th, 7th and 2nd floor) to measure the amplitude of floor displacements, some displacement sensors (LVDTs) put between timber beam at the 7th level to measure the deformation of the structure. The preliminary analysis of the time domain signal show damping ratio close to 2% of critical, calculated from the decay of the acceleration signals. A more refined analysis shows damping is amplitude dependent. For large amplitudes (0.05m/s² to 0.1m/s²) the structural damping ranges from 2.5% to 3.5% of critical, depending on which mode is excited. For low amplitudes (less than 0.01m/s²) the damping ratio drops down to 1% of critical or less.

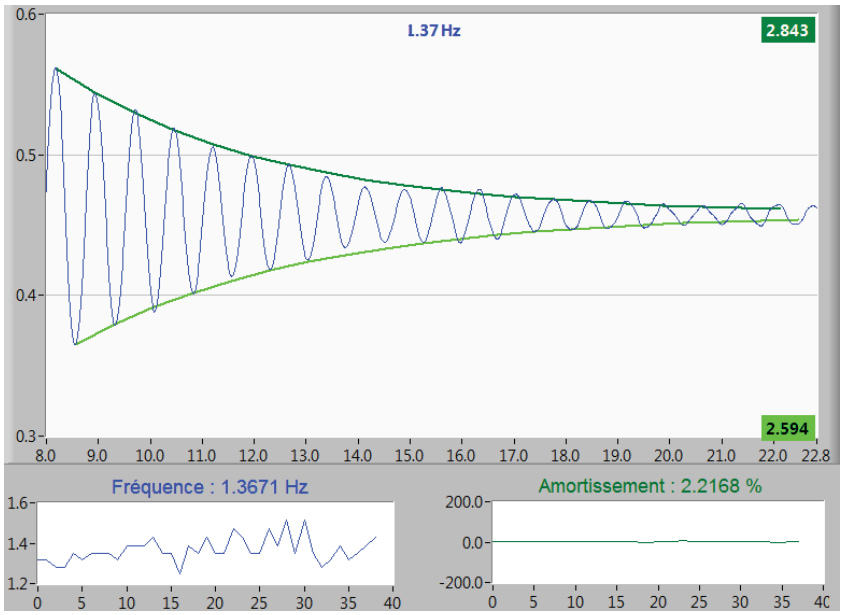

Figure 8: An example of decay of an accelerogram of shutdown test, amplitude in m/s²

A second measurement campaign on Treed It was achieved in June 2020, with all internal partitions done. These partitions added mass and stiffness at the same time : the balance of both gives a slight increase of frequency for the first bending mode, a more marked decrease for the second bending mode and the torsion one.

4 CONCLUSIONS

The DynaTTB research program will provide valuable information concerning the FE modelling of high-rise timber buildings, to be used by designers for assessing the comfort of final users. The modeling of structural damping of such structures is one of the main input of this European research.

5 FURTHER WORK

A FE-model of the Yoker building, which is a 7 storey building in Glasgow designed by Smith and Wallwork Ltd, made using a CLT structure, has been modelled using Ansys by University of Ljubljana. The dynamic properties of the Yoker building was measured Feb 2020 by University of Exeter using horizontal shaker. The Hyperion building in Bordeaux was first tested in July 2020 and will be tested again when completed in March 2021. Data processing is under way.

An extensive measurement campaign in Scandinavia is planned at spring 2021.

6 ACKNOWLEDGEMENT

The research leading to these results has received funding from the ForestValue Research Programme which is a transnational research, development and innovation programme jointly funded by national funding organisations within the framework of the ERA-NET Cofund ‘ForestValue – Innovating forest-based bioeconomy.

Keywords: Slender Structure, Risk assessment, historical buildings, seismic hazard.

Abstract. *In the present paper the risk assessment of the medieval Norman tower of Craco (Matera, Italy) is discussed. Craco is a totally abandoned little town because of the activation of landslide motions of its soil depth. The medieval tower is one of the few buildings still standing as it is built on a fixed stiff foundation ground. Nevertheless, the tower is, indirectly, subjected to the movements of the close landslide.*

The tower is located in the highest and more stable part of the hill where the old town was built in the XII century for protection from enemy attacks. It is 20 m tall and has a (11 x 11) m^2 square plan. The basement has a truncated pyramid shape; originally it had two masonry vaults, one barrel on the first floor, which no longer exists, and a still visible cruise at the second order, connected by a now destroyed internal staircase. In 1949 a reinforced concrete cistern was placed inside the tower.

Craco is classified as a town with a medium level seismic hazard. The main aim of the present study is to evaluate the seismic risk by means of a Finite Element model, calibrated through dynamic tests performed on the tower and considering the historical value of the structure and the context in which it stands. In fact, the structure is characterized by several peculiarities: the presence of a reinforced concrete cistern, the interaction with the surrounding buildings, the closeness to the landslide, the topographical exposition, etc. Moreover, the structure has a great impact on the society due to its touristic interest, as it is an emblem of the, so-called, "ghost town" of the Appennino mountains.

A new approach is proposed to evaluate the effects of all the previously cited features on the evaluation of the seismic risk of the tower, introducing also economical and sociological parameters.

1 INTRODUCTION

In Italy the preservation of architectural heritage towards seismic actions, occupies a prominent place in the social and scientific community priorities. The recent seismic events in Italy underlined the fragility of the historical heritage, which is vulnerable to horizontal forces. Such structures, as well known, were realized only in accordance with the rules of "good practice", which of course were defined considering the ordinary service conditions, i.e. the presence of vertical loads. Thus, in most of these structures a detailed analysis is required to safeguard this heritage, and, consequently, it is necessary to define procedures for evaluating their vulnerability. These procedures can be a tool for the Authorities, which have the responsibility of their maintenance, for judging and scheduling possible interventions. In recent years, the mechanical characteristics of the masonry walls, which make up a historical building, have been a topic of discussion in various studies; in fact, due to the historical value of such structures, the use of traditional tests for the evaluation of the mechanical properties is not allowed. As a consequence, the researchers' attention was devoted to the use of dynamic tests and the results are utilized to obtain the global mechanical characteristics of the structure [1-5].

However, for a complete evaluation of the seismic hazard of a historical structure more considerations/information are needed.

In the report Natural Disasters and Vulnerability Analysis [6], based on the Expert Meeting held in 1979, the scientific community proposed to unify the evaluation of disaster expected damage in any area of interest, through the definition of three parameters:

- *Hazard (H),* consisting in the probability that a disaster can occur;
- *Vulnerability (V),* consisting in the evaluation of the consequences of a disaster;
- *Exposition/Exposed elements (E),* consisting in the socio/economic evaluation of the consequences; this parameter is linked to the context of communities.

On such basis, in [6] the following relationship for the evaluation of the *Risk (R)* was suggested:

$$Risk = Hazard \bullet Vulnerability \bullet Exposition \quad (1)$$

In the last decades, on the basis of this general formulation, several conceptual approaches were developed for the risk assessment related to technological hazards (i.e., nuclear risk) [7, 8] and to natural disaster hazards (i.e., seismic, landslide, blast, flood) [9-13].

In particular, for seismic hazard several models are proposed in [14, 15] to evaluate and estimate the economic losses due to earthquakes for different Italian building typologies.

Recent seismic events highlighted that significant damages were attained in structural and non-structural components of Italian Heritage also under low-to-medium intensity earthquakes. For the purpose of improving the seismic safety of all existing Italian buildings, the Italian "Guidelines for the seismic risk classification of constructions" approved in February 2017 [16] provides technical principles for all seismic risk assessment.

Although several methodologies are available in literature, the evaluation of the risk for a historical building is still under discussion, because for this kind of structures the same procedures of a common building cannot be adopted, due to their peculiarities.

The present work is focused on such topic; in detail, the seismic risk evaluation and the expected damage computation due to a possible seismic event on a historical tower is discussed.

In this paper a new approach is suggested for extending the procedure proposed in [16] to typical buildings of the Mediterranean area, in particular to historic masonry buildings. Since the fragility functions of structural and non-structural components, which are defined for reinforced concrete and residential masonry structures, still need a calibration and validation for

other masonry buildings, in this paper the methodology of Italian legislation [16] is applied to the specific case of the Norman Tower of Craco.

2 PROPOSED APPROACH

The Italian guidelines approach for the evaluation of the seismic risk is described in detail in [17], which reports the fundamental principles and the procedures for determining the seismic risk class of a building and, moreover, for designing reinforcement interventions to reduce the seismic risk. The guidelines introduce several risk classes, from A to G, whose seismic risk increases passing from A^+ to G. To evaluate the risk class of a building, the document refers to a conventional approach and a simplified one. The conventional method, which requires a detailed seismic evaluation of the structural system for different limit states and is principally calibrated for the application to reinforced concrete structures, is the only one that allows improving the building risk class of two or more classes through adequately designed reinforcement interventions. However, the simplified approach, based on the European macro-seismic scale [17], is proposed for masonry buildings. The latter defines the seismic risk class based on the structural type and potential structural deficiencies. In this case, the local strengthening interventions allows to improve the seismic risk of only one class.

Based on the conventional approach and in accordance with eq. (1), the Seismic Risk Assessment (SRA) is identified by three parameters: *H* is the probability that an earthquake occurs considering the seismic zone in which the building is located, *V* is the vulnerability of the structure, in term of load-bearing capacity during the earthquake and *E* is a parameter which takes into account the socio/economic consequences of structural damages. In particular, the SRA of buildings is conducted at different Limit States: Operational Limit State and Damage at Serviceability Limit State; Life Safety and Collapse at Ultimate Limit State, according to the current Italian building code [16-18].

Following this approach, the seismic risk class of a building is defined as the minimum between two classes: one associated with the *Safety Index* of the structure at the Life Safety Limit State (namely *SI-LS*) and the other one related to the expected annual loss, in Italian code [16] namely *Perdita Annuale Media Attesa (PAM*).

In detail, the first index, *SI-LS*, of the structure is defined as the ratio between Peak Ground Acceleration capacity (PGA_C), which determines the achievement of the Life Safety Limit State, and the Peak Ground Acceleration design (PGA_D) referring to the Peak Ground Acceleration (PGA) of the Life Safety Limit State for the specific site where the construction is located, indicated by the Italian code for the design of a new building. Thus, the class associated with this parameter may be evaluated [16], namely $Class_{SI\text{-}LS}$.

The second index, *PAM*, estimates the overall behavior of the construction in terms of economic value (*PAM*) and computes the performance of the structure for different earthquake intensities/return periods T_r. Such index is obtained by plotting the percentage *Reconstruction Costs* (*RC*) vs. the mean annual frequency of exceedance (equal to $\lambda = 1/T_r$) and connecting the points representative of each limit state. The so-obtained broken line is the PAM-curve, the PAM value corresponds to the area under the broken line; the smaller the area subtended by this curve, the lower the expected average annual loss (see Figure 1). *RC* is defined considering the building collapse due to earthquake event and the relevant costs needed to rebuild (according to regional price lists).

Each PGA_C corresponds to a given return period and a mean annual frequency of exceedance, λ. Once the building performance associated with a specific limit state is known in terms of $\lambda = 1/T_r$, a reliable correspondence between each λ and the repair/reconstruction cost of structural and non-structural components expressed as a percentage of RC, is needed.

The return periods, T_{rC}, associated with the peak ground accelerations corresponding to the achievement of the Damage and Life Safety Limit States for the examined building may be evaluated adopting the following relationship:

$$T_{rC} = T_{rD} \, (PGA_C/PGA_D)^{\eta} \tag{2}$$

with η equal to:

$$\begin{aligned} \eta &= 1/0.49 && \text{for } a_g > 0.25g \\ \eta &= 1/0.43 && \text{for } 0.15\ g < a_g \leq 0.25\ g \\ \eta &= 1/0.356 && \text{for } 0.05\ g < a_g \leq 0.15\ g \\ \eta &= 1/0.34 && \text{for } a_g \leq 0.05\ g \end{aligned} \tag{3}$$

where a_g is the maximum acceleration on rigid soil for the considered site.

For each return period T_{rC} the average annual frequency of exceedance is defined by equation (4):

$$\lambda = 1/T_{rC} \tag{4}$$

To estimate the repair/reconstruction cost associated with each limit state, [16] provides conventional repair costs in terms of a percentage of RC for each limit state, properly calibrated to include all the repair actions associated with a specific damage level. Easy formulations to determine the capacity of the structure at Operational Limit State and Collapse Limit State are suggested in [16], once those at Damage Limit State and Life Safety Limit State are known. In particular, the annual frequency of exceedance at Operational Limit State and Collapse Limit State can be computed according to the following simplified formulations:

$$\begin{aligned} \lambda_{OLS} &= 1.67\lambda_{DLS} \\ \lambda_{CLS} &= 0.49\lambda_{LSLS} \end{aligned} \tag{5}$$

where λ_{OLS} is the annual frequency of exceedance at Operational Limit State, λ_{DLS} is the annual frequency of exceedance at Damage Limit State, λ_{CLS} is the annual frequency of exceedance at Collapse Limit State, λ_{LSLS} is the annual frequency of exceedance at Life Safety Limit State.

The percentages of RC were estimated according to the actual repair costs monitored in the reconstruction process of buildings. Based on the costs analysis and taking into account studies based on macro-seismic analyses as well as post-earthquake observational data reported in [3], the percentage of RC associated with Damage Limit State and Life Safety Limit State were set equal to 15% and 50%, respectively; moreover, the percentage of RC for Operational Limit State and Collapse Limit State were set equal to 7% and 80%, respectively. The repair costs associated with the Initial Damage Limit State and total loss or "Reconstruction" Limit States, conventionally related to a fixed λ = 10% and λ = 0%, were assumed equal to 0 and 100%, respectively (see Figure 1 and Table 1).

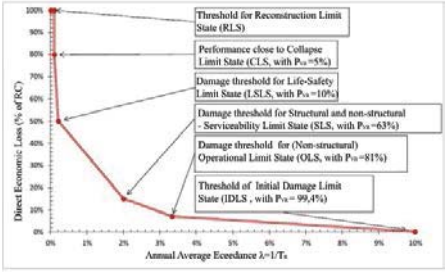

Figure 1: Trend of the curve that identifies PAM referring to a construction with a nominal life of 50 years and belonging to the use class II in according to [18].

Limit State	Percentage of RC [%]
Reconstruction	100
Collapse	80
Life Safety	50
Damage Limitation	15
Operational	7
Initial Damage	0

Table 1: Reconstruction/Repair Costs, expressed as percentage of RC, associated to each Limit State.

To determine the seismic risk class, the approach proposed in [16] requires evaluating PAM, according to the following equation:

$$PAM = \sum_{i=2}^{5} [\lambda(LS_i) - \lambda(LS_{i-1})] * [RC(LS_i) + RC(LS_{i-1})]/2 + \lambda(CLS) * RC(RLS) \quad (6)$$

where index "i" represents the generic limit state (i=5 for Collapse Limit State and i=1 for Initial Damage Limit State). Thus, the class associated with this parameter may be evaluated [16], namely $Class_{PAM}$.

Hence, the seismic risk class of the analyzed building corresponds to the worse risk class between $Class_{SI\text{-}LS}$ and $Class_{PAM}$.

The described procedure allows to simplify the seismic risk assessment and to have a design-oriented approach suitable for common practice applications. It is necessary to specify that the computation of the PAM class relies on the assumption that the repair costs at the different limit states are constant for private residential buildings without any distinction at component level.

This aspect obligates to calibrate the repair cost for different types of Italian construction heritage. In detail, for non-residential buildings the repair cost must be calibrated considering all their characteristics which lead to their proper value. In the following, a new approach is calibrated for the analysis of the case study of the Norman Tower of Craco.

2.1 Case of study

In this research the interest is centered on the Medieval Town of Craco, near Matera (Italy) and in particular on its tower. Today visiting Craco, the scenario is a village completely abandoned due to severe landslide motion, developed in the south-western part between 1959 and 1972, which damaged most part of the existing buildings. The Norman tower, object of the present study, was endowed with a defensive purpose and, for this reason, located on the highest point of the hill. The city has developed over time around it, thus creating the actual historic center (see Figure 2).

The Norman tower is one of the few structures remained unharmed by the effects of the landslide, until today. The defensive character of the tower is underlined by its robust appearance and by a quadrangular structure of 11 m size in compact masonry. The structure consists of an architrave opening on the East side at the first level, which allows access, and arched openings on the second level (12.5 m), one for each side, with the exception of the one facing North. Cracks arranged in three rows at the height of the crown (triangular in the lower rows and quadrangular in the third row) mark the horizontal closure placed at 20 m from the ground level, while the basement has a truncated pyramid shape.

Originally the structure had two masonry vaults, a barrel one (no longer existing) on the first floor and a cruise vault on the second level, connected by an internal staircase which was

destroyed. In relatively recent times, the inside of the tower has been subjected to manipulations, which have affected the general state of conservation. In 1949 the barrel vault and the staircase were demolished, and a municipal reinforced concrete tank of water with a cylindrical shape was realized. The cistern is not connected to the tower, but at some levels it is perfectly adherent to it.

Figure 2: South-East view of Craco with Normand tower.

A geometric survey was performed for evaluating the main characteristics of the structure: the wall thickness varies from 2.15 m at the base of the tower, to 1.70 m at the top. Based on a visual inspection and on the analysis of documents, it is assumed that the wall is realized by rubble masonry with a sand-interposed core. Externally the masonry base consists of a set of irregular river stones and shows conditions of advanced decay; the upper part of the tower, apparently in good conditions, consists of sandstones of varying sizes, with the exception of the cantons where cut stone blocks prevail, used for the double rings of the arched openings.

2.2 A new approach for the Reconstruction Cost calibration

The Reconstruction Cost [16] is the fundamental parameter for the evaluation of the PAM class, $Class_{PAM}$. In the specific case of the Norman Tower, it is not plausible to hypothesize a mere reconstruction cost which cannot take its significant historical and cultural value into account. In fact, even if the reconstruction could be economically estimable, however in no way it could replace the historical and cultural value lost in the event of its collapse and/or serious damage.

For this reason, the approach here proposed envisages the definition of a new *Reconstruction Cost* (*RC**), in accordance with equation (7), which, for the present case, is specified by introducing a new parameter, the *Usability Loss* (C_{UL}). Therefore:

$$RC^* = RC + C_{UL} \tag{7}$$

In the following, the evaluation of such parameter is proposed.

In the last decade, Craco has become a tourist attraction centre for its history, social value and historical and architectural heritage, becoming a symbolic ghost town. For this reason, the "Scenographic Museum of Craco" was realized with the aim of organizing touristic tours in the historic centre of Craco and in particular some visits of its symbolic structures, including the Tower.

It is possible to assume that the collapse of the Tower by seismic events and, therefore, the loss of a symbolic element of the historical centre would cause the non-usability of the latter. Consequently, the non-visitability would produce an economic loss during the whole period, which coincides with the "Recovery Time" of the structure. Such loss is here utilised for the evaluation of the proposed *Usability Loss* (UL) parameter, as a tool to estimate the historical-artistic value of the Tower.

The introduced parameter may be applied to any kind of structure with a historical/architectural value, by adopting a criterion able to describe the specific characteristics of the examined structure.
In this paper, the Usability Loss is quantified by calculating the monthly number of tickets sold (N_T), the time to rebuild the structure (t) and the average ticket price (C_T). In particular, the number of annual users of 2017 has been divided on a 12 months-period, so the monthly number N_T is equal to 1416.

The average ticket price C_T available from the "Parco Scenografico Museale di Craco" web, is equal to €10 [20]**.**

To identify the recovery time *(t)* and the Reconstruction Costs *(RC)* an intervention has been hypothesized, which foresees the faithful reconstruction of the "as it was, where it was" type, in accordance with the costs of [21]. It was therefore estimated that this intervention lasts 12 months, probably the shortest, to try to create the least possible discomfort at the museum.

Thus, *Norman Tower RC** is given in Table 2.

New Parameters	Acronym	Costs (€)
Cost of reconstruction	RC	€ 316,468.00
Loss of usability	C_{UL}	€ 170,000.00
Cost of reconstruction'	**RC***	**€ 486,468.00**

Table 2: New parameters and their economic value.

2.3 Seismic risk class of the Norman Tower

To evaluate the seismic risk class of the Norman Tower of Craco, the conventional method was applied as indicated by [16], adopting the prescription of the current Italian Technical Standards for Construction "NCT 2018" [18, 19].

The analysis of the structure was carried out by means of PROSAP software [22]. The structure was modelled through 12,160 shell elements, 12,470 nodes and a rigid floor. The following mechanical parameters for the masonry walls have been assumed:

- Young's modulus (E_m) equal to 1050 MPa
- Poisson's Modulus (ν_m) equal to 0.2
- Average specific weight of the masonry (w_m) equal to 19 kN/m^3,

while for the reinforced concrete elements the following values have been assumed:

- Young's modulus (E_c) equal to 27460 MPa
- Poisson's Modulus (ν_c) equal to 0.2
- Average specific weight of the masonry (w_c) equal to 24 kN/m^3

All the walls have been considered pinned at the base. The gravitational loads are the ones due to the structural masses, as no servicibility loads are acting on the tower.

In the following, the detailed procedure for the evaluation of the the Norman Tower seismic class is described. In the first part, the PAM graph is evaluted, while in the second part the safety index is discussed, and, finally, the risk class is defined.

The Italian building code [16] gives the design PGA for the Life Safety Limit State ($PGA_{D\text{-}LS\text{-}LS}$) and for the Damage Limit State ($PGA_{D\text{-}DLS}$), by using the Elastic Demand Spectrum for Craco town (Figure 3):

- $PGA_{D\text{-}LS\text{-}LS}$= 0.103g
- $PGA_{D\text{-}DLS}$= 0.048g

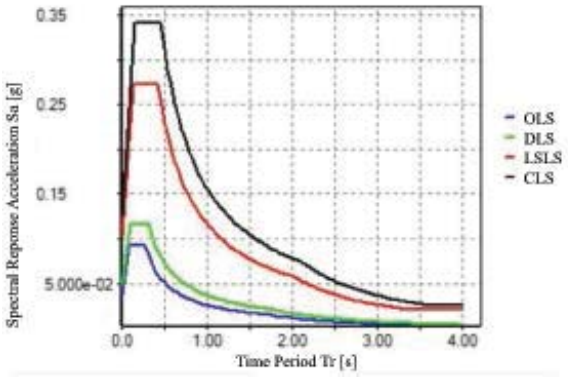

Figure 3: Elastic Demand Spectrum of Craco Town

The FE analysis allows the evaluation of the capacity peak ground acceleration related to the achievement of the Life Safety Limit State ($PGA_{C\text{-}LS\text{-}LS}$) and the Damage Limit State ($PGA_{C\text{-}DLS}$):

- $PGA_{C\text{-}LS\text{-}LS}$= 0.083g
- $PGA_{C\text{-}DLS}$= 0.0336g

The return periods, T_{rC}, associated with the considered limit states (LS-LS and DLS) were then evaluated by using the equation (2), where η was set equal to 1/0.43, in accordance with equation (3) (Craco lays in the seismic zone 2 [23]). In the following, the calculated T_{rC} values are reported:

- $T_{rC\text{-}LS\text{-}LS}$= 287 years
- $T_{rC\text{-}DLS}$= 22 years

Finally, in accordance with the Italian codes, the Annual Average Exceedance (λ) (see equations 4-5) and the minimum/maximum values of the economic loss for the reconstruction of the Tower were evaluated. The procedure adopts the same percentage.

For each considered Limit State, the value of the reconstruction cost percentage and the annual average exceedance values are reported in Table 3, which has been defined adopting the same percentages of Table 1.

Limit State	Percentage RC* [%]	Cost (€)	Annual Average Exceedance (λ)
Restoration	100%	€486,468.00	0
Collapse	80%	€389,174.00	0.0015
Safety Life	50%	€194,587.00	0.003
Damage	15%	€29,188.00	0.046
Operational	7%	€2,043.00	0.076
Initial damage	0%	€0.00	0.1

Table 3: Reconstruction/restoration costs (RC*) and Average annual frequency of exceedance, associated with the achievement of each Limit State for the Tower of Craco.

Finally, $Class_{PAM}$ is identified by means of Table 6 [16] which associates the class to the range of values assumed by PAM.

For the Tower studied in this paper, the *PAM*-value is equal to 2.07%, corresponding to C_{PAM}- class (see [16]).

The second step of the procedure, needs the evaluation of the safety index of the structures, which is defined as the ratio between the peak ground acceleration capacity PGA_C for which

the building reaches the Life Safety Limit State and the peak ground acceleration demand PGA_D of the site where the construction is built, with reference to the same limit state. In the case here examined, the first PGA is equal to *0.083g* while the second to *0.103g*, thus the safety index is equal to 81%.
The risk class associated with the Safety index can be derived through [16] and is equal to $A_{SI\text{-}LS}$.

On the basis of the aforementioned parameters, the Seismic Risk Class of the Tower is ***C***, that coincides with the worst/lowest class between the $Class_{PAM}$ and the $Class_{SI\text{-}LS}$, i.e. the one corresponding to the highest risk. It is useful to point out that the seismic risk class corresponds to the one associated with the PAM class, that is the one modified by the proposed procedure.

In conclusion, for the Norman Tower, being an asset with significant historical and cultural value, hypothesizing a cost of reconstruction alone is not plausible. Its reconstruction, however, economically estimable, can in no way being representative of the historical and cultural value lost in the event of its collapse. The identified approach, therefore, for the estimation of the RC* parameter represents a possible proposal for the determination of an economic value of PAM, associated with types of buildings with high historical and cultural value and accessible to the public.

3 CONCLUSIONS

A new methodology able to evaluate the seismic hazard of the medieval tower of Craco has been proposed, being this construction a historical-monumental building. The current Italian guidelines for seismic risk assessment provide a method based on both the indices PAM and SI-LS. However, this method is proposed for application to residential buildings in reinforced concrete, here such method is extended to the analysis of historical masonry structures.

In detail, the calibration of the *Reconstruction Cost* (RC), necessary to the PAM index calculation for the seismic classification, has been developed. PAM is evaluated by different parameters in the formulation of the new reconstruction cost (RC*). These parameters take into account the socio-economic, architectural, historical and cultural value of the structure. Specifically, in the study case of the Norman Tower, the Usability Loss has been considered as crucial parameter. This choice depends on the museum function of the tower and the *ghost town* of Craco.

From the analysis the tower *PAM*-value was equal to 2.07%, corresponding to C_{PAM}-class.

Further in-depth studies and analyzes are necessary for the validation of the proposed methodology. Additional parameters could be identified in order to take into account several aspects that can condition the value of the building.

ACKNOWLEDGEMENTS

Keywords: Masonry, Pompeii, Restoration, Vulnerability

Abstract. *The archaeological site of Pompeii has been subjected to restoration interventions since the beginning of its excavation. After the second World War concrete structures replaced the old wooden roofs erected in the late XIX. A systematic study of these structures is lacking, despite the number and the significant role they play in the stress state of the ancient masonry. In particular, the structural role of atriums roofing structures in the Pompeii buildings is examined. The impact of the restoration interventions actually present in the archaeological area of Pompeii is analyzed. A dynamic analysis has been performed to assess the seismic vulnerability of the ancient buildings in their actual state. The paper shows that maintenance of the existing interventions is a fundamental topic and substitution of r.c. roofs with timber structures cannot be justified by structural reasons. As a case study the entire Domus of the Tragic Poet is analyzed. A simulation involving a wooden roof is compared with the actual structure of concrete roof building.*

1 INTRODUCTION

Pompeii, since its first excavation campaign, has been profoundly altered by successive mutilations, additions and transformations. In some cases strong interventions have been made in order to rebuild the original construction. This makes archaeological remains the object of complex, interdisciplinary studies involving archaeologists and applied scientists [1]. The balance between the respect of the ancient construction and the exigence of safety is a great challenge for the structural engineer [2, 3, 4]. Several different approaches for the interventions on Cultural heritage have been developed in these last decades [5, 6]. Different restoration materials have been in fact used during the decades, according the scientific approach to the structural technology of the time.

Fig. 1. Concrete Atrium roofs: Villa dei Misteri (left), Fabius Rufus (center) and Tragic Poet (right).

The first structural interventions in many Pompeian *Domus* involved the replacement of old wooden roofs with concrete structures similar to the old ones, especially in the two decades among 1960 and 1980, as the photo archives testify. Several of these roofs realized in particular on the atriums are nowadays visible (Figure 1) and the scientific debate is mainly about opportunity and durability of these interventions [7]. Reinforced concrete and wood are in fact the most diffused materials for the roofing structures of the atriums actually present in the archaeological area of Pompeii (Figure 2). A systematic study of these structures is lacking, despite the number and the significant role they play in the stress state of the ancient masonry.

Fig. 2. Wooden atrium roofs: Vettii Domus (left) and Domus on *Cardo V inferiore*

The use of steel structures in the atriums is limited, being extensively employed for quasi-provisional structures, therefore perhaps a more detailed analysis about the structural performance of both wood and r.c. in the seismic case could be a starting point in the scientific debate about the necessity of substitution of last with the first one [7]. It must be noted that all the upper part of the *Domus* atriums have been rebuilt and the ancient Pompeian masonry represents only the lower part of the walls [8], so that the seismic vulnerability should be regarded only from the point of view of the human safety and protection of original mosaics and paintings

[9]. An eventual collapse without damage to artworks could only bring back the walls to the original ruins state [10].

A Pompeian atrium is only a limited part of the complex structure of the *Domus*, so that the cultural discussion about the quality and scheme of the roof cannot be set apart from the structural analysis of the whole structure of the building and its history [11, 12]. The analysis of part of the structure, as successfully done in some cases [13, 14] cannot be applied to the Roman Domus, that is a complex arrangement of different materials and structures.

This paper deals with this last aspect, analyzing the whole *Tragic Poet Domus* by means of a finite element code. The influence of two distinct materials (wood and reinforced concrete) for the roof of the Tuscanic atrium. The structural behaviour is not significantly affected by the structural material chosen for restoration, so that the actual concrete roof (at present in perfect conditions) do not need an urgent replacement. The structural dynamic analysis of the whole Domus has shown that the atrium is the core structural element of the entire construction and the roofing technique do not significantly influence the vulnerability of the construction**.**

2 STRUCTURAL ANALYSIS

The Tragic Poet Domus in Pompeii, also known as the Domus of the "*Cave canem*" for its splendid black-white mosaic with a dog has been analyzed [15]. The case study is a corner building (Figure 13) with a Tuscanic atrium. The actual roofing structure is composed of r.c. beams, wooden rafters and clay shingles (Figure 1). The Domus has been chosen because it is a typical example of the Pompeian House [16] in which a key structural role is played by the large atrium, with a r.c. roofing structure in good conditions [7].

A finite element analysis has been performed in order to evaluate the role of the roofing structures' technologies in the structural behavior of the Domus (Figure 4).

Fig. 3. The "Cave canem" mosaic (left) and the Tragic Poet Domus (right) [7].

The linear analysis has been considered sufficient [17, 18] and has been carried out by means of a commercial finite element code [19], the whole structure has been modelled with solid tetrahedral elements C3D10 with medium dimensions 0.4 m. Different constitutive parameters have been taken into account, as reported in Table 1.

Mechanical properties	Masonry	R.C.	Wood	Wooden deck
Density, ρ [kg/m^3]	1937	2500	550	400
Elastic modulus, E [N/mm^2]	1140	30000	9800	6000
Poisson's ratio ν	0.2	0.16	0.2	0.2

Table 1. Mechanical properties.

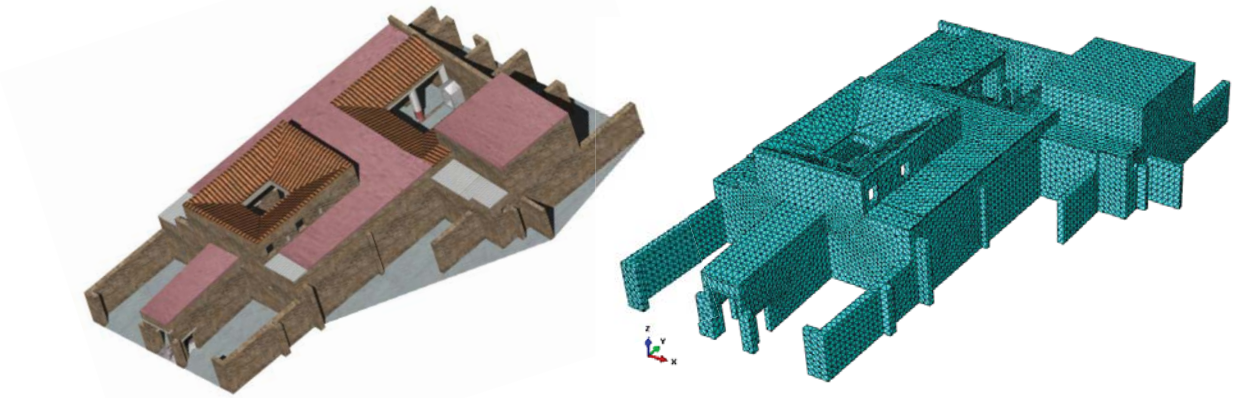

Fig. 4. Picture (left) and 3D mesh for the case study (right)

Two different roofing structures have been considered for the analysis: an ideal wooden structure and the actual r.c. one, leaving unaltered every other element of the Domus (geometry, material characteristics and self weight). The analysis results are reported in the following pictures, so to allow comparison in the two considered structural cases.

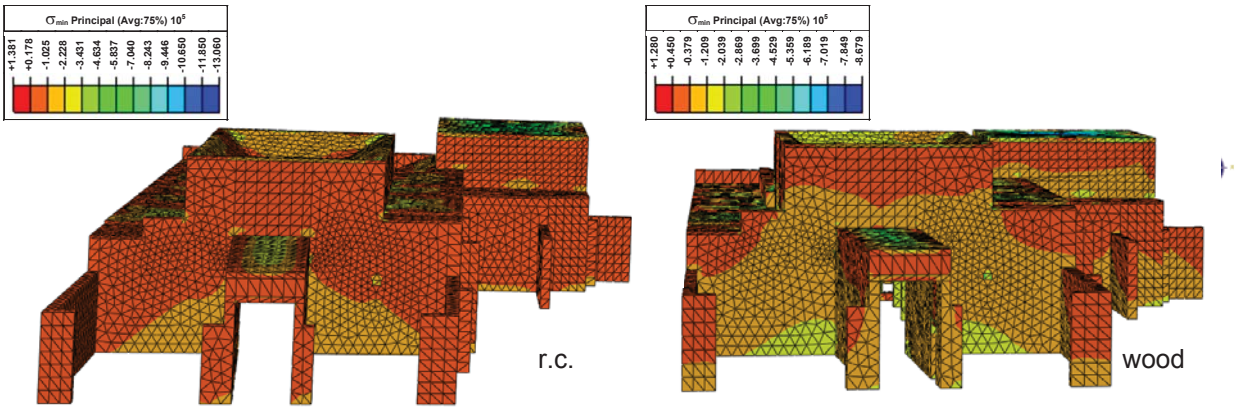

Fig. 5. Principal compressive stresses due to self weight. Detail of the front view

In Figure 5 a detail of the front view with a map of the principal compressive stresses due to the self weight is reported. Considering that the Roman masonry is only the lower part of the walls, its stress state in the two examined cases is similar, and this is true for all the ancient Domus masonry.

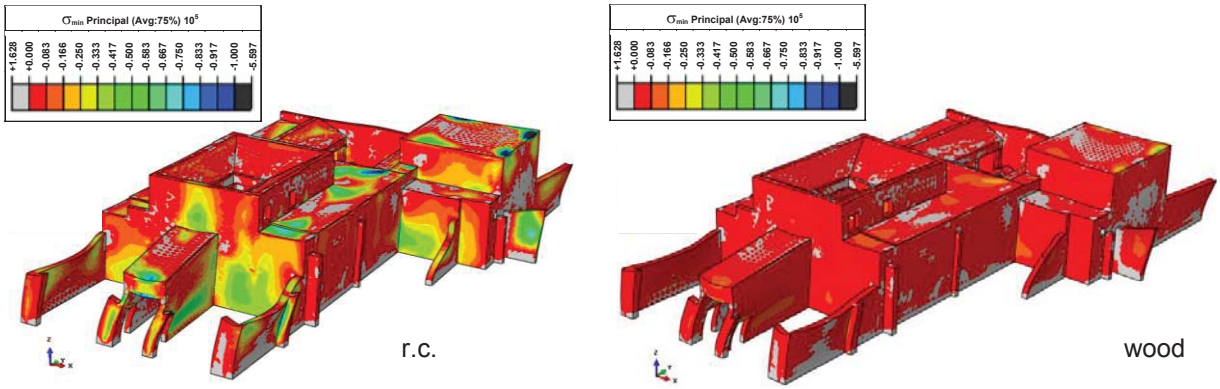

Fig. 6. Distribution of stresses in the case of selfweight and seismic action along x-axis.

Dynamic analyses have been performed considering the seismic action along the two principal axes of the Domus, involving a PGA 0.244 g and masonry tensile and compressive strength equal to 0.1 MPa and 3 MPa respectively [20, 21].

A similar condition can be evaluated in Figure 6 reporting the principal stress maps in the case of the combined actions of selfweight and seismic load along x-axis.

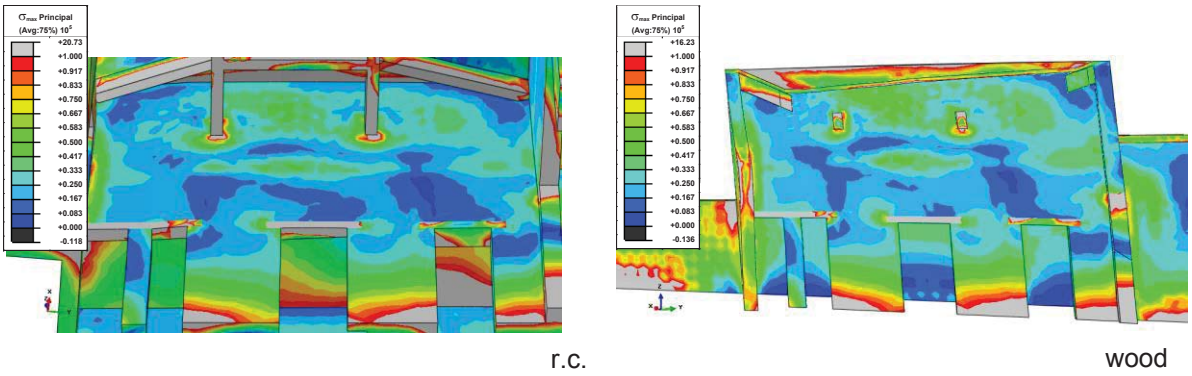

Fig. 7. Atrium distribution of stresses in the case of selfweight and seismic action along x-axis

In Figure 7 the stress state of the atrium is picted. As it can be note, the stress values are of the same order. The seismic analysis according the y-axis, reported in Figure 8, does not give more information, due to the larger inertia of the Domus in this direction.

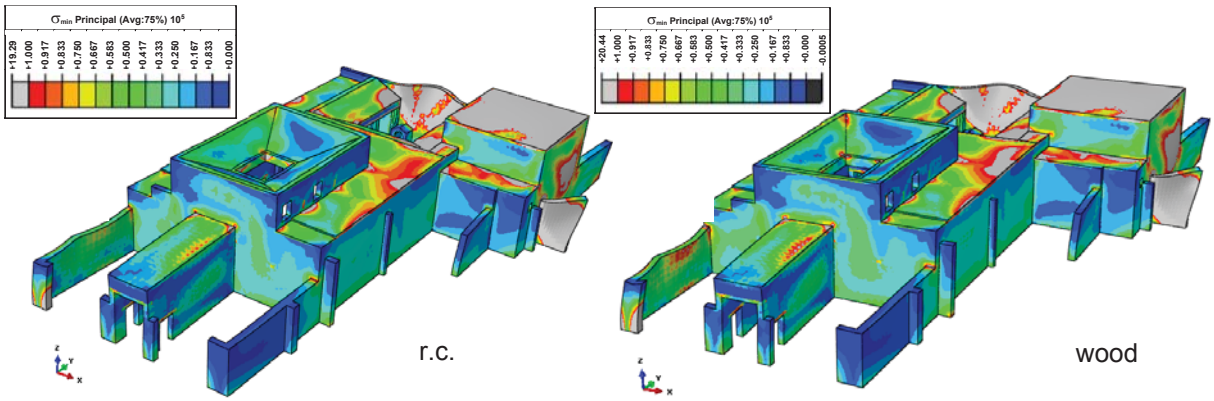

Fig. 8. Distribution of stresses in the case of selfweight and seismic action along y-axis

A dynamic modal analysis has been performed to assess the quality of response to seismic actions. The first 8 modes of vibration involve only limited structural elements: in general, all the masonry walls departing from the central block of rooms and the vestibulum. A representation of the first mode of vibration, where the vestibulum is involved, is reported in Figure 9.

The eventual collapse of the peripheral masonry elements makes the Domus become a more compact structure around the central atrium, since only the ninth mode of vibration involves almost all the domus structure, atrium and peristilium, as it can be seen in Figure 9.

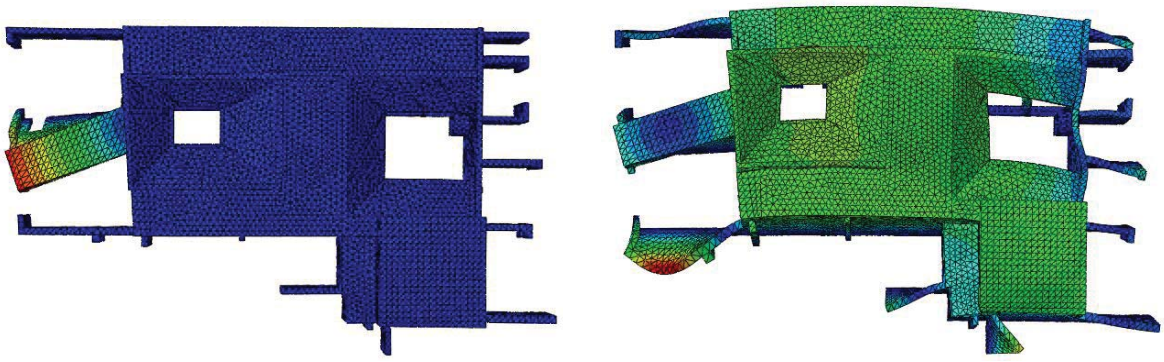

Fig. 9. First (left) and ninth (right) mode of vibration according the x-direction

These last considerations about the modes of vibration underline again the central role of the atrium in the overall behaviour of the Domus.

3 FINAL REMARKS

A Pompeian Domus is a complex arrangement of various structural elements, subjected in their previous life to heavy restoration interventions, in general respecting the original structural geometry only. Different restoration materials have been in fact used during the decades, according the scientific approach to the structural technology of the time. This paper analyzes the roofing interventions actually present in the atriums of the Pompeii archaeological area.

The entire structure of the Tragic Poet Domus (masonry walls and r.c. roof) is analyzed by means of a finite element code to evaluate the influence of structural material. Two cases have been examined: the actual r.c. roof structures, due to a post War intervention, and a geometrically similar timber structure. With regard to stress and strain maps, the two structures affect similarly the lower Roman masonry structures, so that substitution of r.c. roofs with timber structures cannot be justified with structural reasons.

Archaeological, aesthetical and durability considerations together with the restoration yard management, excluded in this approach, are the main aspects to take into account in a restoration program, since the stability and vulnerability questions depending on the roofing material assume limited importance as it has been shown in this paper.

Keywords: Nonlinear dynamics, Plastic shear failure, Modal approximation, Time history

Abstract. *The analysis of structures subjected to earthquake actions can be carried out by means of several methods with different levels of accuracy, among which the nonlinear dynamics is generally recognized as the most reliable one. This paper presents a general treatment to develop approximate solutions for rigid-plastic response of structures subjected to base harmonic pulse, by means of a numerical procedure on purpose developed. The case study is a vertical cantilever beam, with base support, constant mass and inertia distribution, subjected to only ground acceleration. The failure is assumed depending on the formation of a single shear hinge and the results are expressed in general terms. As a result, the motion proceeds through successive spreading and contractions of the plastic front and related elastic returns. Possible applications of the method to real structures can be envisaged.*

1 INTRODUCTION

The strong demand of sustainable energy has today led to build many aeolian park endowed of several wind turbine properly equipped for the production of electric power. A great number of these parks have been realised in seismic areas, and many of them have been established in Irpinia, a region in Southern Italy that was devastated by a strong earthquake in 1980. Observed collapse of several wind towers can be yield by a system of severe actions (see Fig. 1), mainly due to the action of the wind or earthquake. For the earthquake perturbation a nonlinear dynamic model presented in [1, 2, 3] constitutes a reliable tool to analyze this kind of problems.

Fig. 1. Collapsed wind tower [25].

A high level of expertise, high costs, and large amounts of calculation time are required to model the steel towers of these modern windmills. Constitutive and structural models with sufficient accuracy and low numerical complexity are generally adopted when elastic responses can be neglected, so that a rigid-plastic model, usually extensively employed in earthquake engineering, constitutes a simplified procedure [4, 5, 6, 7, 8]. The implementation of rigid-plastic models is a non-conventional stiffness-based computer method, because it exhibits a stiffness jump. Numerous constitutive models for rigid-plastic bending frames are largely widespread, while shear constitutive ones are quite rare. Nevertheless, the latter procedures have the advantage of a low computational complexity and a reduced number of mechanical parameters (yield property) [9, 10]. These advantages are the starting point of the present study because simple relationships between structure strength and parameters that are useful for design purposes can be established [11, 12]. Various authors analysed the dynamic plastic bending responses of structural elements in steel and reinforced-concrete structures and they found that bending hinges are the result of the general response characteristics of several structural elements under transverse loads. A concise number of studies have examined the dynamic of the plastic shear failure. An important issue in bending and shear problems is related to the localization and extension of plastic hinges [13, 14].

The structural dynamics has been largely analysed adopting the single-degree-of-freedom (SDOF) model that provides a first good evaluation of the response mode usually responsible of the collapse state [15]. A rigid-plastic cantilever beam can be an efficient structural scheme to clarify the nonlinear dynamic behavior of highly complex structures [16] and validate the reliability of numerical methods adopted in nonlinear dynamics [17, 18]. Generally, the stiffness of a structure is not uniform when strength and mass vary along the height of the structure. In several cases, such as those involving rigid bodies, efficient schematizations are required to solve complex dynamic problems [19, 20]. Wind turbine towers are structurally assimilable to cantilever beams so that the SDOF model constitutes indeed a powerful tool.

Near-fault ground motions are often characterized by pulse sequences with simple shapes that can be recognized in accelerograms via spectral analysis [21]. Generally, the development of elastic and inelastic response spectra is facilitated when accurate harmonic pulses are utilized to represent ground motions [22]. A sensitive analysis of elastic and inelastic responses induced by different simple pulse shapes has shown that local site effects on structures can be modeled with an appropriate pulse choice [23]. These considerations are the basis of the numerical analysis performed in this work because a harmonic pulse can be a suitable representation of near-fault ground motions [21]. Basically a numerical strategy developing an approximate solution of slender structures with base harmonic pulses is exposed. The fundamental equations are based on the rigid-plastic constitutive model and applied to the structure of a wind turbine tower, assimilated to a cantilever beam, having a harmonic forcing motion at the base support. Failure depend on the formation of shear hinges. The proposed model is an evolution of the SDOF cantilever beam because plastic hinges can form in each beam section.

2 NONLINEAR DYNAMIC MODEL

The validity of simplified constitutive models is limited when these models are applied to structures subjected to short-duration, high-intensity loading, given not extremely large deformations to cause strong geometry change effects and energy disturbance larger than the elastic one. This last consideration justifies the adoption of simplified models and the exclusion of elastic effects caused by large dynamic loads, although the results can also be refined to include the initially neglected aspects. The analysisi of rigid-plastic models is less difficult than that of elastic-plastic ones. In the following, geometry changes are small, and yield stress is assumed to be independent of the strain rate. Reference is made to the elastic-perfectly plastic body in Fig. 2.

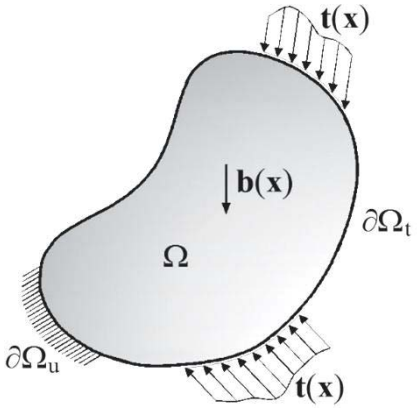

Fig. 2. Elastic-perfectly plastic body

where

$\partial\Omega = \partial\Omega_t \cup \partial\Omega_u$: total boundary of the body Ω and $\partial\Omega_t \cap \partial\Omega_u = \varnothing$,

$\partial\Omega_t$, $\partial\Omega_u$: free and constrained boundary of the body Ω,

$\lambda(t)\ \mathbf{t}(\mathbf{x})$: surface loads on the free boundary $\partial\Omega_t$,

$\lambda(t)\ \mathbf{b}(\mathbf{x})$: body forces in Ω,

$\dot{\boldsymbol{u}}_g(\boldsymbol{x},t)$: assigned velocity vector and $\dot{\mathbf{u}}(\mathbf{x},0) = \mathbf{0}$ on $\partial\Omega_u$,

$\lambda(t)$: time dependent load multiplier function.

The solution of the elastoplastic problem provides the strain rate $\dot{\mathbf{E}}(\mathbf{x},t)$ and velocity fields $\dot{\mathbf{u}}(\mathbf{x},t)$ satisfying the kinematical admissibility conditions and the stress field $\mathbf{T}(\mathbf{x},t)$ equilibrated with the applied loads $\lambda(t)\ \mathbf{t}(\mathbf{x})$, and the inertial forces $-\mu(\mathbf{x})\ddot{\mathbf{u}}^*(\mathbf{x},t)$, where $\mu(\mathbf{x})$ is the mass density function. The approximate response field [4] is assumed to be in the form:

$$\dot{\mathbf{u}}^*(\mathbf{x},t)=\boldsymbol{\Phi}(\mathbf{x})\,L(t) \tag{1}$$

with

$$\dot{\mathbf{u}}^*(\mathbf{x},t)=\dot{\mathbf{u}}_g(\mathbf{x},t) \text{ on } \partial\Omega_u \ ;\ \dot{\mathbf{u}}^*(\mathbf{x},t)=\mathbf{0} \text{ in } \Omega \text{ and } \partial\Omega_t,$$

where the assigned vector $\boldsymbol{\Phi}(\mathbf{x})$ depends on the initial position only and $L(t)$ is an unknown scalar function of the time to be determined.
The difference between the real stress field and the approximate one is in balance with the variation of the associate force fields and reduced to the difference between inertial forces.

The problem solution does not require $\mathbf{T}^*(\mathbf{x},t)$ and $\dot{\mathbf{E}}^*(\mathbf{x},t)$ to be associated by the plastic law. Thus, the stress field is dynamically admissible with respect to the D'Alembert principle. By applying the principle of virtual power, we obtain:

$$\int_\Omega \mu(\ddot{\mathbf{u}}-\ddot{\mathbf{u}}^*)\cdot(\dot{\mathbf{u}}-\dot{\mathbf{u}}^*)\,d\Omega+\int_\Omega(\mathbf{T}-\mathbf{T}^*)\cdot(\dot{\mathbf{E}}-\dot{\mathbf{E}}^*)\,d\Omega=0 \tag{2}$$

given that:

$$\Delta(t)=\frac{1}{2}\int_\Omega \mu(\dot{\mathbf{u}}-\dot{\mathbf{u}}^*)\cdot(\dot{\mathbf{u}}-\dot{\mathbf{u}}^*)\,d\Omega. \tag{3}$$

The first derivative of $\Delta(t)$ is calculated as:

$$\frac{d\Delta}{dt}=\int_\Omega \mu(\ddot{\mathbf{u}}-\ddot{\mathbf{u}}^*)\cdot(\dot{\mathbf{u}}-\dot{\mathbf{u}}^*)\,d\Omega. \tag{4}$$

From equations (4) and (2), we have:

$$\frac{d\Delta}{dt}=-\int_\Omega(\mathbf{T}-\mathbf{T}^*)\cdot(\dot{\mathbf{E}}-\dot{\mathbf{E}}^*)\,d\Omega=0$$

thus,

$$\frac{d\Delta}{dt}=-\int_\Omega\left[(\mathbf{T}-\mathbf{T}^*)\cdot\dot{\mathbf{E}}^*+(\mathbf{T}^*-\mathbf{T})\cdot\dot{\mathbf{E}}^*\right]d\Omega=\int_\Omega\left[(\mathbf{T}^*-\mathbf{T})\cdot\dot{\mathbf{E}}+(\mathbf{T}-\mathbf{T}^*)\cdot\dot{\mathbf{E}}^*\right]d\Omega. \tag{5}$$

Stress field $\mathbf{T}$ and strain rate $\dot{\mathbf{E}}$ are associated through the plastic flow rule, and $\mathbf{T}^*$ satisfies the plasticity condition. Drucker's stability postulate holds that

$$(\mathbf{T}-\mathbf{T}^*)\cdot\dot{\mathbf{E}}\geq 0. \tag{6}$$

In the regions where $\dot{\mathbf{E}}^*(\mathbf{x},t)\neq\mathbf{0}$, the generalized stress field $\mathbf{T}^*_{\dot{\mathbf{E}}^*}$ associated with $\dot{\mathbf{E}}^*$ through the flow rule satisfies the plasticity condition

$$(\mathbf{T}^*_{\dot{\mathbf{E}}^*}-\mathbf{T})\cdot\dot{\mathbf{E}}^*\geq 0. \tag{7}$$

By employing Drucker's stability postulate, relation (5) may be rewritten in the form:

$$\frac{d\Delta}{dt} = \int_{\Omega}\left[(\mathbf{T}^{*}-\mathbf{T})\cdot\dot{\mathbf{E}}+(\mathbf{T}-\mathbf{T}^{*})\cdot\dot{\mathbf{E}}^{*}\right]d\Omega = . \tag{8.a}$$

$$= \int_{\Omega}(\mathbf{T}^{*}-\mathbf{T})\cdot\dot{\mathbf{E}}\,d\Omega+\int_{\Omega}(\mathbf{T}-\mathbf{T}^{*}_{\dot{\mathbf{E}}^{*}})\cdot\dot{\mathbf{E}}^{*}d\Omega+\int_{\Omega}(\mathbf{T}^{*}_{\dot{\mathbf{E}}^{*}}-\mathbf{T}^{*})\cdot\dot{\mathbf{E}}^{*}d\Omega \le . \tag{8.b}$$

$$\le \int_{\Omega}(\mathbf{T}^{*}_{\dot{\mathbf{E}}^{*}}-\mathbf{T}^{*})\cdot\dot{\mathbf{E}}^{*}d\Omega = \Gamma(t) \;\Rightarrow\; \Gamma(t)\ge 0 . \tag{8.c}$$

The first and second integrals in expression 8(b) are less than or equal to zero. Hence, the last term in (8.c) is non-negative, such that:

$$\frac{d\Delta}{dt} \le \Gamma(t) . \tag{9}$$

The integration of the previous relation from 0 to time t provides the approximation measure $\Delta(t)$:

$$\Delta(t) \le \Delta^{+}(t) = \int_{0}^{t}\Gamma(t)\,dt . \tag{10}$$

The maximum value Δ_m of the non-decreasing time function $\Delta^{+}(t)$ is $\Delta^{+}(T)$, with T being the duration of the external forcing function. The function $L(t)$ satisfies the initial conditions:

$$L(0) = 0 . \tag{11}$$

Given the condition $\dot{\mathbf{u}}^{*}(\mathbf{x},0) = 0$, if $\boldsymbol{\Psi}(\mathbf{x})$ is a vector that involves the strain generalized components associated with modal vector $\boldsymbol{\Phi}(\mathbf{x})$, then acceleration $\ddot{\mathbf{u}}^{*}(\mathbf{x},t)$ and strain rate $\dot{\mathbf{E}}^{*}$ are given by:

$$\ddot{\mathbf{u}}^{*}(\mathbf{x},t) = \boldsymbol{\Phi}(\mathbf{x})\,\dot{L}(t) \;;\; \dot{\mathbf{E}}^{*}(\mathbf{x},t) = \boldsymbol{\Psi}(\mathbf{x})\,L(t) . \tag{12}$$

The principle of virtual velocity provides:

$$\int_{S_L}\mathbf{p}(\mathbf{x},t)\cdot\dot{\mathbf{u}}^{*}dS+\int_{\Omega}[\mathbf{F}(\mathbf{x},t)-\mu\ddot{\mathbf{u}}^{*}]\cdot\dot{\mathbf{u}}^{*}d\Omega = \int_{\Omega}\mathbf{T}^{*}(\mathbf{x},t)\cdot\dot{\mathbf{E}}^{*}(\mathbf{x},t)\,d\Omega \tag{13}$$

which can be manipulated with reference to relations (1) and (12):

$$\int_{S_L}\mathbf{p}^{T}(\mathbf{x},t)\,\boldsymbol{\Phi}(\mathbf{x})dS+\int_{\Omega}\mathbf{F}^{T}(\mathbf{x},t)\,\boldsymbol{\Phi}(\mathbf{x})d\Omega =$$

$$= \dot{L}(t)\int_{\Omega}\mu(\mathbf{x})\boldsymbol{\Phi}^{T}(\mathbf{x})\,\boldsymbol{\Phi}(\mathbf{x})d\Omega+\int_{\Omega}\mathbf{T}^{*}(\mathbf{x},t)\,\boldsymbol{\Psi}(\mathbf{x})d\Omega .$$

Hence, function $L(t)$ can be evaluated by the integration of the function:

$$\dot{L}(t) = \frac{\int_{S_L}\mathbf{p}^{T}(\mathbf{x},t)\,\boldsymbol{\Phi}(\mathbf{x})dS+\int_{\Omega}\mathbf{F}^{T}(\mathbf{x},t)\,\boldsymbol{\Phi}(\mathbf{x})d\Omega-\int_{\Omega}\mathbf{T}^{*}(\mathbf{x},t)\,\boldsymbol{\Psi}(\mathbf{x})d\Omega}{\int_{\Omega}\mu(\mathbf{x})\boldsymbol{\Phi}^{T}(\mathbf{x})\,\boldsymbol{\Phi}(\mathbf{x})d\Omega} . \tag{14}$$

This method can be applied to pulse loads with the following conditions: the tractions applied to $\partial\Omega_t$ are null and the initial velocities are prescribed over the entire structure at time $t=0$. Therefore, no external forces act on the structure.

3 SDOF MODEL FOR A WIND TURBINE

The SDOF model provides a good schematization of the dynamic behavior of various structures. Wind turbine towers can be easily represented by a cantilever beam supported at the base. As shown in [1, 2], a rigid-plastic cantilever beam can sufficiently approximate the nonlinear dynamic problem arising from sinusoidal excitation at the tower base. The problem is monodimensional, so that the parameters and relations developed in the previous section are scalar. The reference frame of the model has its origin in the support section and the z axis coincident with the wind tower one (Fig. 3a). The local yield kinematism corresponds to the activation of a shear hinge, in which total shear force $T(z,t)$ attains its bound value. The constitutive model is shown in Figs. 3b and 3c.

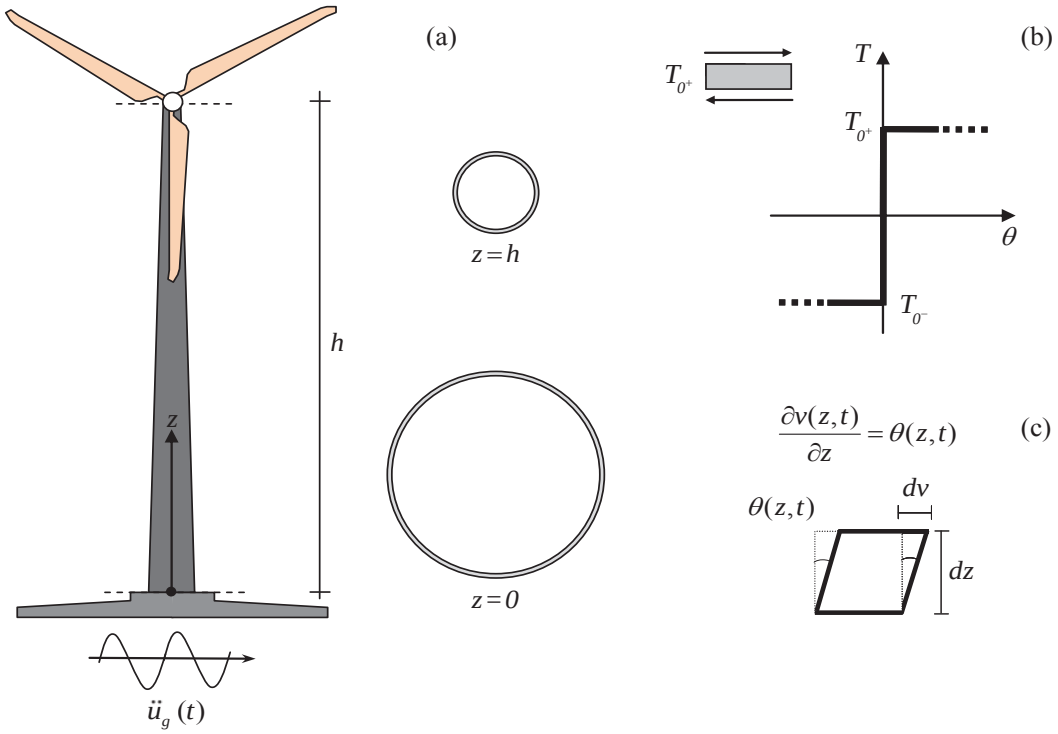

Fig. 3 Wind turbine tower geometry (a), rigid-plastic constitutive law (b), and shear strain representation (c)

where

$\mu(z)$:	linear mass density of the tower,
$u_g(t)$:	horizontal motion of the supported section,
$T(z,t)$:	shear stress whose bounds are $T_{0^+}(z)$ and $T_{0^-}(z)$
$\theta(z,t)$:	shear strain,
h:	total length of the tower.

The shear plastic constitutive relations are expressed as follows:

$$\begin{cases} \left[T(z,t) - T_{0^+}(z)\right]\left[T(z,t) + T_{0^-}(z)\right]\dot{\theta}(z,t) = 0 \\ -T_{0^-}(z) \le T(z,t) \le T_{0^+}(z) \end{cases}. \tag{15}$$

that is,

$$
\begin{aligned}
-T_{0^-} < T < T_{0^+} \quad & \dot{\theta} = 0 \quad \Rightarrow \quad \left[T - T_{0^+}\right]\dot{\theta} = 0 \ \text{ and } \ \left[T + T_{0^-}\right]\dot{\theta} = 0 \\
T = T_{0^+} \quad & \dot{\theta} \neq 0 \quad \Rightarrow \quad \left[T - T_{0^+}\right]\dot{\theta} = 0 \\
T = -T_{0^-} \quad & \dot{\theta} \neq 0 \quad \Rightarrow \quad \left[T + T_{0}\right]\dot{\theta} = 0
\end{aligned}
$$

in which plastic strain rate $\dot{\theta}$ depends on shear stress only. The dynamic equilibrium equation in the cross section at the z level involves inertial forces only:

$$\frac{\partial T(z,t)}{\partial z} = \mu(z)\,\ddot{u}(z,t) = \mu(z)[\ddot{u}_g(t) + \ddot{v}(z,t)]\,. \tag{16}$$

where

$$u(z,t) = u_g(t) + v(z,t)\,. \tag{17}$$

is the absolute displacement, and:

$$v(z,t) = \int_0^z \theta(x,t)dx = \int_0^z \int_0^t \dot{\theta}(x,\tau)d\tau\,dx\,. \tag{18}$$

is the relative one. A plastic shear hinge is formed when the limit value of shear stress is reached. One or more shear hinges can be activated in sections $z_1, z_2, ..., z_n$ during the plastic phase, and their abscissa varies according to time. Kinematic compatibility states that the plastic strain rate is non-null in active hinges only:

$$\dot{\theta}(z,t) = \frac{\partial\,\dot{v}(z,t)}{\partial z} = \dot{v}'(z,t)\,. \tag{19}$$

The relative displacement $v(z,t)$ in (18) can be deduced by integrating equation (19) with respect to z and by introducing the Heaviside function $H(z)$ ($H(z)=0$ for $z<0$, $H(z)=1 \ \ for \ \ z\geq 0$) as follows:

$$v(z,t) = \int_0^z v'(x,t)\,dx = \int_0^z \theta(x,t)\,dx = \int_0^h \theta\left(x,t\right)H(z-x)\,dx\,. \tag{20}$$

Double time derivation provides the relative acceleration $\ddot{v}(z,t)$:

$$\ddot{v}(z,t) = \int_0^z \ddot{\theta}(x,t)\,dx = \int_0^h \ddot{\theta}\left(x,t\right)H(z-x)\,dx\,. \tag{21}$$

When only one shear hinge is active, the time-dependent position is denoted by $z_0(t)$. Thus, the relative displacement velocity and the plastic strain rate have the form:

$$\dot{v}(z,t) = \dot{v}_1(t)\,H[z - z_0(t)],$$
$$\dot{\theta}(z,t) = \dot{v}'(z,t) = \dot{v}_1(t)\ \delta[z - z_0(t)],$$

being $\delta[z - z_0(t)]$ the Dirac function relative to the plastic hinge position. The shear stress becomes:

$$T(z,t) = \ddot{u}_g(t)\int_h^z \mu(x)\,dx + \int_h^z \mu(x)\,\ddot{v}(x,t)dx = \ddot{u}_g(t)\int_h^z \mu(x)\,dx + \ddot{v}_1(t)\int_h^z \mu(x)\,H[x-z_0(t)]dx\,.$$

The mass functions are:

$$m(z) = \int_h^z \mu(x)\,dx \quad ; \quad m_H[z,z_0(t)] = \int_h^z \mu(x)\,H[x-z_0(t)]\,dx\,. \tag{22}$$

The time derivative of (22.b) produces:

$$\frac{\partial m_H[z,z_0(t)]}{\partial t} = -\mu(z)\,\dot{z}_0(t)H[z-z_0(t)] = -\dot{z}_0(t)\frac{\partial m_H[z,z_0(t)]}{\partial z}.$$

Shear stress and its derivatives as functions of masses are:

$$T(z,t) = \ddot{u}_g(t)\,m(z) + \ddot{v}_1(t)\,m_H[z,z_0(t)]$$

$$\frac{\partial T(z,t)}{\partial z} = \mu(z)\,\ddot{u}_g(t) + \ddot{v}_1(t)\frac{\partial m_H[z,z_0(t)]}{\partial z}$$

$$\frac{\partial T(z,t)}{\partial t} = m(z)\,\dddot{u}_g(t) + \dddot{v}_1(t)\,m_H[z,z_0(t)] - \dot{z}_0(t)\,\ddot{v}_1(t)\frac{\partial m_H[z,z_0(t)]}{\partial z}.$$

Approximation by the Taylor series of shear stress proceeds as:

$$\begin{aligned} T(z_0+dz_0,t+dt) = T(z_0,t) &+ \left\{\mu(z_0)\,\ddot{u}_g(t) + \ddot{v}_1(t)\frac{\partial m_H[z,z_0(t)]}{\partial z}\bigg|_{z=z_0}\right\}dz_o + \\ &+ \left\{m(z_0)\,\dddot{u}_g(t) + \dddot{v}_1(t)\,m_H[z_0,z_0(t)] - \ddot{v}_1(t)\,\dot{z}_0(t)\frac{\partial m_H[z,z_0(t)]}{\partial z}\bigg|_{z=z_0}\right\}dt\,. \end{aligned} \tag{23}$$

We consider that shear is equal to the yield value $T(z_0,t) = T_0(z)$ in the plastic hinge. If at the instant $t+dt$ the position of the plastic shear hinge is z_0+dz_0, then $T(z_0+dz_0,t+dt) = T_0(z_0+dz_0)$ and $T(z_0+dz_0,t+dt) = T_0(z_0)+T_0'(z_0)\,dz_0$. Equation (23) in this case can be conveniently rewritten as:

$$\begin{aligned} &\left\{\mu(z_0)\,\ddot{u}_g(t) + \ddot{v}_1(t)\frac{\partial m_H[z,z_0(t)]}{\partial z}\bigg|_{z=z_0}\right\}dz_0 + \\ &+\left\{m(z_0)\,\dddot{u}_g(t) + \dddot{v}_1(t)\,m_H[z_0,z_0(t)] - \ddot{v}_1(t)\,\dot{z}_0(t)\frac{\partial m_H[z,z_0(t)]}{\partial z}\bigg|_{z=z_0}\right\}dt = T_0'(z_0)\,dz_0 \end{aligned} \tag{24}$$

and with $\dot{z}_0 = \dfrac{dz_0}{dt}$, we have:

$$[\mu(z_0)\,\ddot{u}_g(t) - T_0'(z_0)]\;\dot{z}_0(t) + m(z_0)\,\dddot{u}_g(t) + \dddot{v}_1(t)\,m_H[z_0,z_0(t)] = 0\,.$$

According to relations (22) the time evolution of the plastic shear hinge is governed by the relation:

$$\dot{z}_0(t) = -\frac{m(z_0)\ddot{u}_g(t) + \ddot{v}_1(t)\,H(0)\,m[z_0(t)]}{\mu(z_0)\ddot{u}_g(t) - T_0'(z_0)}. \tag{25}$$

When the plastic hinge moves, residual plastic deformations $\theta_r(z_0,t)$ can be detected in the previous position:

$$\theta_r(z_0,t) = \frac{\dot{v}_1(t)}{\dot{z}_0(t)}.$$

Their value do not vary until the plastic hinge forms again at the same position. Hence, the acceleration $\ddot{v}(z,t)$ can be determined as a function of shear:

$$T'(z,t) = T'_{0^+}(z) \Rightarrow \ddot{v}(z,t) = \frac{T'_{0^+}(\bar{z})}{\mu(z)} - \ddot{u}_g(t)$$
$$T'(z,t) = T'_{0^-}(z) \Rightarrow \ddot{v}(z,t) = \frac{T'_{0^-}(\bar{z})}{\mu(z)} - \ddot{u}_g(t).$$

At the abscissa z, the inertial force

$$q(z) = -\mu(z)[\ddot{u}_g(t) + \int_0^z \ddot{\theta}(x,t)\,dx]$$

allows the total shear to be written as:

$$T(z,t) = -\int_h^z q(x)\,dx = \ddot{u}_g(t)\,m(z) + \int_h^z \mu(x)\int_0^x \ddot{\theta}(y,t)\,dy\,dx \tag{26}$$

After some algebraic manipulations [2], the relations (26) can be rewritten in the form:

$$\begin{aligned} &[\ddot{u}_g(t) + \int_0^{z_1} \ddot{\theta}(y,t)\,dy - \frac{T_{0^+}(z_1)}{m(z_1)}][\ddot{u}_g(t) + \int_0^{z_1} \ddot{\theta}(y,t)\,dy - \frac{T_{0^-}(z_1)}{m(z_1)}] = 0 \\ &\frac{T_{0^-}(z)}{m(z)} < \ddot{u}_g(t) + \int_0^{z_1} \ddot{\theta}(y,t)\,dy < \frac{T_{0^+}(z)}{m(z)} \quad , \quad \forall z > z_1 \end{aligned} \tag{27}$$

according to relation (27), the plastic deformations stop at the abscissa z_p and cannot propagate upward. The abscissa z_p can be obtained by solving a minimum problem that is independent of time *t* and ground acceleration $\ddot{u}_g(t)$:

$$\left.\begin{aligned} z_{p1} \rightarrow \frac{T_{0^+}(z_{p1})}{m(z_{p1})} &= \min_{z\in(0,h)}\left[\frac{T_{0^+}(z)}{m(z)}\right] \\ z_{p2} \rightarrow \frac{T_{0^-}(z_{p2})}{m(z_{p2})} &= \min_{z\in(0,h)}\left[\frac{T_{0^-}(z)}{m(z)}\right] \end{aligned}\right\} \quad \Rightarrow \quad z_p = max(z_{p1}, z_{p2}) \tag{28}$$

When relation (28) is satisfied for $z_p = 0$, the beam response involves only one DOF.

4 NUMERICAL OUTCOMES

In general, pulses that occur during earthquakes have qualitative and quantitative characteristics that can adequately be approximated by specific functional expressions obtained by means of wavelet analysis [20]. Several strong ground motions contain in fact an acceleration pulse responsible for most of the inelastic deformations of structures. In the paper by Makris that distinguishable acceleration pulse has been determined with reference to the main world strong earthquakes in the last 50 years. The near fault ground motions are in fact often characterized by pulse sequences with simple shapes that can be recognized in the accelerograms by means of spectral analysis. In general, if accurate harmonic pulses are used to represent the ground motion the development of elastic and inelastic response spectra are facilitated [22]. The sensitive analysis of elastic and inelastic responses due to different simple pulse shapes has shown that local site effects on structures can be modelled with an appropriate choice of the pulse [23]. These considerations are the basis of the analysis performed on the turbine tower of Fig. 3, since the harmonic pulse can be a suitable representation of near-fault ground motion [21].

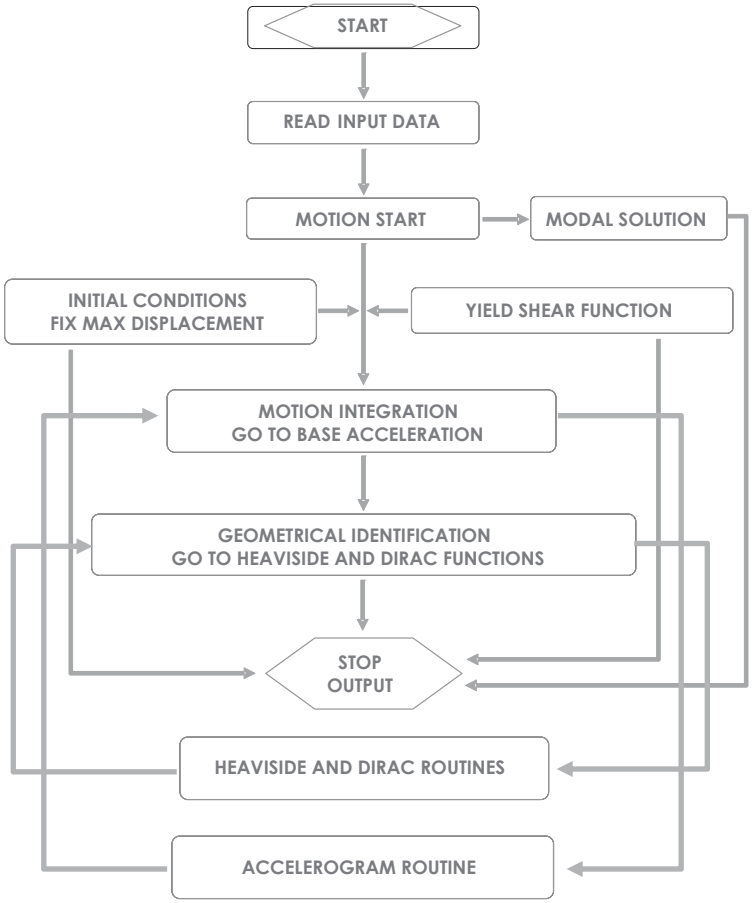

Fig. 4. Flow chart of the numerical procedure

From the numerical analyses (Fig. 4), successive extensions and contractions of the plastic front can be evaluated, according (25) and the forcing time history. In the following figures numerical results are reported: Fig. 5 contains the mechanical characteristics during the reduction of the plastic front, while Fig. 6 reports the situation at the final instant of the plastic process.

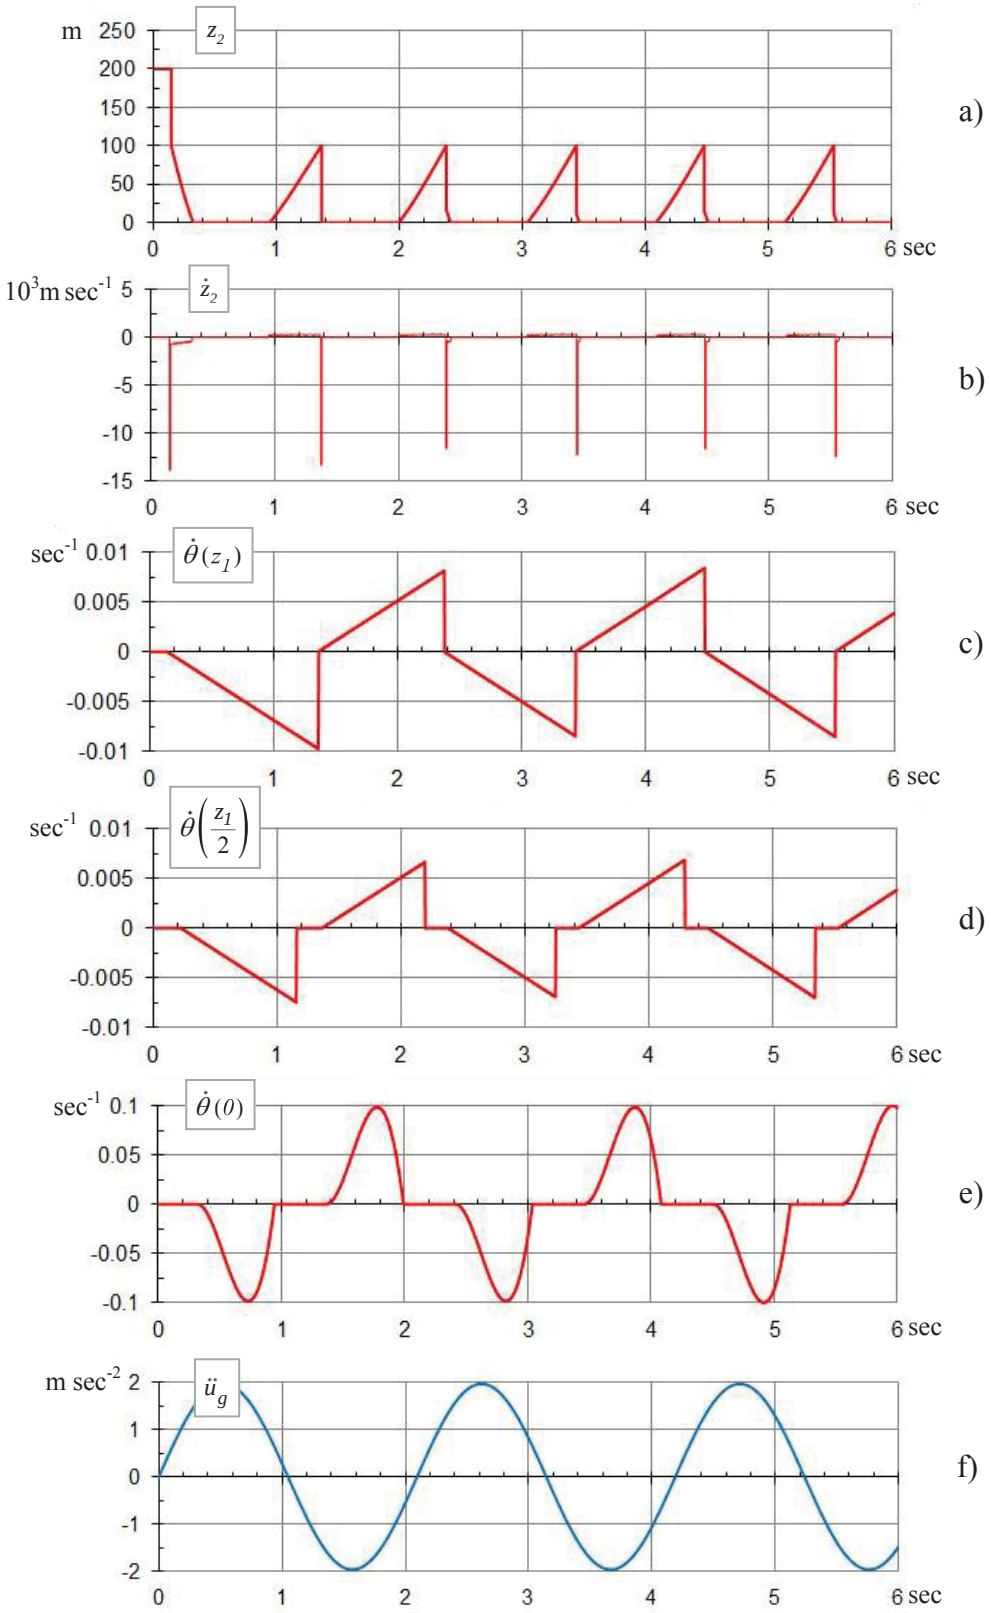

Fig. 5. Time histories of the functions: lower bound (a) and velocity of the plastic front (b); plastic shear rate at the upper bound (c), in the middle (d) and at the base support (e); base accelerogram (f);

The input data are derived with reference to a wind turbine tower with variable annular cross section and this choice implies a quadratic variation of the yield shear and the adopted pulse makes reference to near fault motion of Irpinia earthquake in 1980:

$$
\begin{cases}
h = 200\,m & (\textit{total height of the tower}) \\
\mu(z) = 5\times10^{4}\ kgm^{-1} & (\textit{mass linear density}) \\
\ddot{u}_g(t) = a_0 \sin\omega t & (\textit{base motion}) \\
\text{with} \quad a_0 = 0.2\,g\ ,\ \omega = 3\,\text{sec}^{-1} & \\
D = 6\ sec & (\textit{duration of the time history}) \\
T_0(z) = d\,z^2 + e\,z + f & (\textit{yield shear}) \\
\text{with} \quad d = 2\times10^{3}\ Nm^{-2} & e = -8\times10^{5}\ Nm^{-1},\quad f = 10^{8}\ N
\end{cases}
$$

The extension of the plastic boundary moves starting from the abscissa $z_1 = h/2$ and evolves until the plastic excursion stops, corresponding to the attainment of the plastic threshold. The extension of the elastic range is measured by the distance z_2 of the lower bound of the plastic zone from the base support. The motion proceeds through successive spreading and contractions of the plastic front and related elastic returns [11, 24]. This behaviour is represented in Fig. 5a, where the obscillation of the plastic hinge lower bound is represented. The maximum velocity lower bound corresponds to the attainment of the maximum spreading of the plastic front, as shown in Fig. 6b. The time histories corresponding to the evolution of the shear strain rate in three significant positions are picted respectively in Figs. 5c, 5d and 5e. A detailed analysis of the evolution of shear stress and deformed shape in a single pulse are reported in Fig. 6 together with a schematic picture of the cantilever beam with the actual plastic hinge extension.

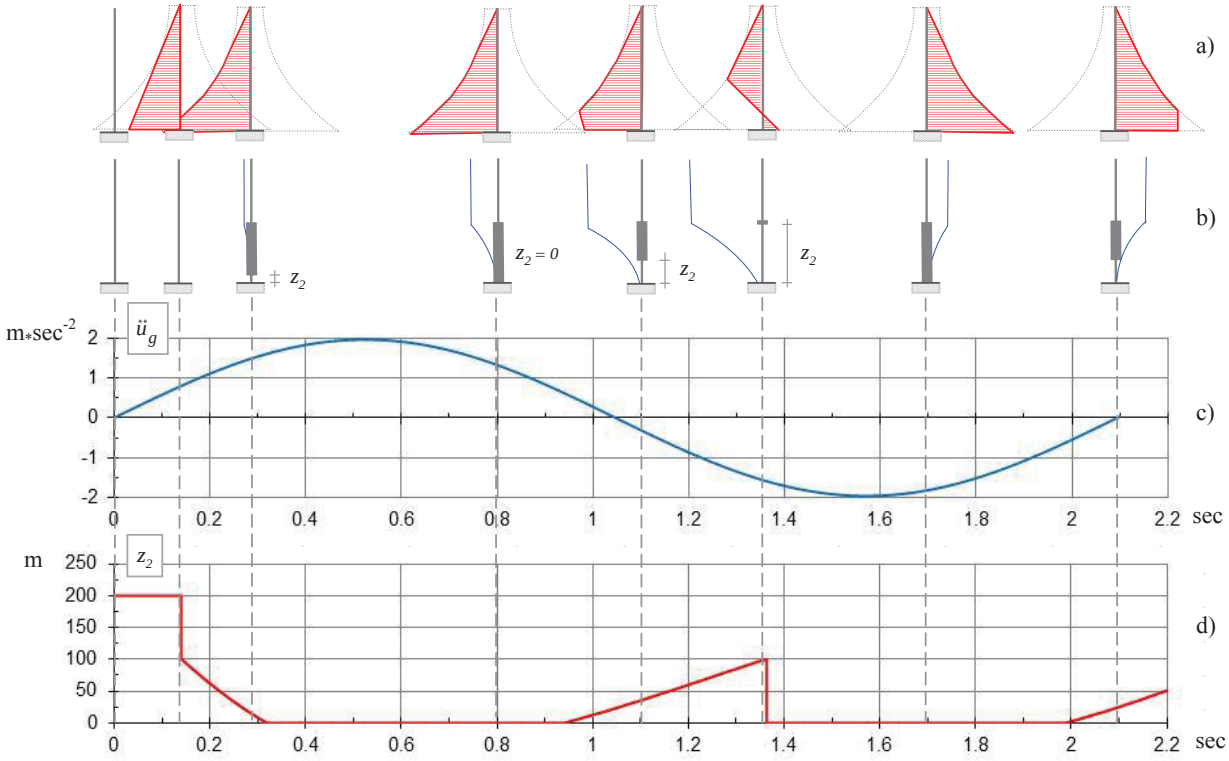

Fig. 6. Variation of the shear stress (a) and deformed shape (b) versus the base accelerogram (c) and the lower bound of the plastic hinge (d)

The inertial effects that cause the delay of the inversion of the displacements with regard to shear diagram are also shown. It is worth noting that both the diagrams have a sudden change of sign due to the inversion of the pulse sign.

5 CONCLUSIONS

The nonlinear dynamic response of rigid-plastic wind tower structures subjected to a base dynamic acceleration has been examined. The collapse mechanism obtained is due to the formation of shear hinges. A step-by-step integration procedure is employed to evaluate the dynamic response of a windmill in the time domain. The numerical analysis gives the plastic hinge patterns and the estimation of the maximum and minimum displacement under different base motions. The exposed method supplies a good interpretation of the tower post-elastic behavior and a realistic representation of fundamental response modes. Moreover, the procedure exhibits also a low computational effort and involves a low number of mechanical parameters. The proposed nonlinear dynamic procedure, with the localization of damage i.e. the extension of the plastic front, allows a designer to recognize the segment of tower that requires special attention. The same procedure can in fact applied to high rise buildings for which a cantilever beam model could represent with suitable accuracy the behavior.

Abstract. *Identification of the tensile force in slender axially-loaded structural elements, such as stay cables, metallic bars and tie-rods, is of paramount importance for health monitoring and safety assessment purposes. Dynamic testing techniques provide the ground for quick and cheap identification strategies, based on the knowledge of: (a) a set of identified natural frequencies, and (b) a structural model that relates natural frequencies to the axial-force value. Within this framework, reliability of the identified axial force values depends, among other factors, on the predictive capabilities of the underlying structural model. Errors may arise, in particular, from the modeling of boundary conditions. The present paper analytically investigates the effect of boundary conditions on the modal properties of axially loaded Euler-Bernoulli beam elements. Starting from theoretical results obtained on this archetypal structural model, a numerical procedure for the identification of the axial force in beam elements with unknown bending stiffness and boundary conditions is then presented. Parametric analyses are carried out to quantitatively assess the accuracy of the proposed identification algorithm in the case of frequencies contaminated by measurement errors.*

1 INTRODUCTION

Dynamic testing techniques are widely used to get estimates of the modal properties of slender axially-loaded one-dimensional structural elements, such as stay cables, diagonal braces, truss elements and tie-rods of vaulted historical masonry structures. Knowledge of a set of measured natural frequencies of the beam, along with a suitable structural model updating strategy, then, can be used to identify the value of the axial force acting on the element, which is of paramount importance for structural health monitoring and safety assessment purposes. Within this framework, reliability of the identified axial force values depends, among the other factors, on the predictive capabilities of the underlying structural model.

Frequency-based axial force identification procedures often rely on the assumption of ideal boundary conditions, in the form of either perfectly hinged or perfectly clamped end sections (see e.g. [1, 7]). A more realistic structural scheme could be defined, however, by considering equivalent translational and rotational springs at the beam end sections to model the flexibility of the restraint devices and of the support structures (e.g. deck and tower for cables in stayed bridges). Proper definition of equivalent springs strongly depends on the particular technology adopted to realize the restraints and is inherently related to several different sources of uncertainties, such as those related to geometric imperfections and aging of the support devices.

The present paper presents an analytical investigation of the effects of the boundary conditions on the modal properties of axially-loaded Euler-Bernoulli beam elements whose end sections are restrained by rotational springs. Starting from theoretical results obtained on this archetypal structural model, a numerical procedure for the identification of the axial force in beam elements with unknown bending stiffness and boundary conditions is then presented. Parametric analyses are carried out to quantitatively assess the accuracy of the proposed identification algorithm in the case of frequencies contaminated by measurement errors.

2 FORMULATION OF THE PROBLEM

2.1 Free-vibrations of the Euler-Bernoulli beam model

Let us consider a straight axially-loaded one-dimensional structural element, with constant bending stiffness (EI) and mass per unit of length (m). Transverse displacements of the centerline are described through the function $v = v(x,t)$, where $x \in [0,l]$ is a coordinate spanning the free length (l) of the element and t is the time. By neglecting sag-extensibility and shear deformability effects, undamped planar transverse vibrations are governed by the partial differential equation (see e.g. [8]):

$$EI\partial_x^4 v - T\partial_x^2 v + m\partial_t^2 v = 0 \tag{1}$$

where $T > 0$ is the axial force (see Fig. 1).

By introducing the characteristic frequency ω_0 and the non-dimensional bending stiffness ε:

$$\omega_0 = \sqrt{\frac{T}{ml^2}},\ \varepsilon = \sqrt{\frac{EI}{Tl^2}}, \tag{2}$$

the Eq. (1) can be re-stated in the following non-dimensional form:

$$\varepsilon^2 \partial_\xi^4 \bar{v} - \partial_\xi^2 \bar{v} + \partial_\tau^2 \bar{v} = 0 \tag{3}$$

where $\xi = \frac{x}{l} \in [0,1]$, $\tau = \omega_0 t$ and $\bar{v}(\xi,\tau) = \frac{v(x(\xi),t(\tau))}{l}$.

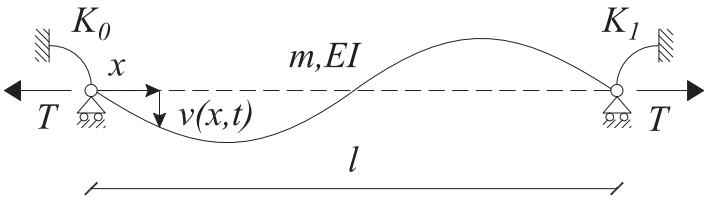

Figure 1: Schematic representation of a straight one-dimensional structural element subject to a tensile load T.

Values of ε typical of slender structural elements, such as stay cables and masts, are lower than 2% (see e.g. [1, 7, 15]). Thicker structural elements such as diagonal braces, truss elements, short cables and tie-rods of vaulted historical masonry structures, instead, can be characterized by values of non-dimensional bending stiffness in the broader range: $0.02 \lesssim \varepsilon \lesssim 1$ (see e.g. [11, 12, 13, 17]). It's worth noting that the governing equation (3) is singularly perturbed for small values of ε, typical of slender elements, hinting the existence of boundary layers in the mode shapes and possible ill-conditioning of numerical solvers (see e.g. [10, 5]).

General solutions of Eq. (3) can be expressed as $\bar{v}(\xi,\tau) = \phi(\xi)\sin(\bar{\omega}\tau - \theta)$, where $\bar{\omega}$ is a non-dimensional vibration frequency, θ is a phase angle depending on initial conditions and $\phi(\xi)$ is a mode shape function. The vibration frequencies $\bar{\omega}$ and shape functions $\phi(\xi)$ are the solutions of a fourth order boundary value problem defined by the ordinary differential equation:

$$\varepsilon^2 \phi^{IV} - \phi^{II} - \omega^2 \phi = 0,\ \xi \in [0,1] \tag{4}$$

along with suitable conditions modeling the cable restraints.

Ideal boundary conditions are often introduced, in the form of either perfectly hinged or perfectly clamped cable end sections. In many practical circumstances, however, this modeling strategy can lead to an oversimplified representation of the structural dynamics, naturally claiming for the adoption of elastically supported beam models (see e.g. [14, 16, 2]). In the present work, two rotational springs with stiffness K_i $(i = 1, 2)$ are assumed to be attached at the end sections of the element (see Fig. 1). The degree of fixity of the rotational restraints is then defined by introducing the non-dimensional parameters:

$$\rho_i = \frac{K_i}{K_i + \varepsilon T l},\ i = 0, 1 \tag{5}$$

It is worth noting that the parameter ρ_i can take values in the unit interval [0,1], being strictly equal to zero for $K_i = 0$, i.e. for a perfectly hinged end section. The upper bound

limit case $\rho_i = 1$, instead, is asymptotically approached as $K_i \to \infty$, i.e. for a perfectly clamped end section.

By accounting for the definitions in Eq. (5), the boundary conditions associated to Eq. (4) read:

$$\begin{cases} \phi(0) = 0 \\ \phi(1) = 0 \\ (1-\rho_0)\,\varepsilon^2\phi''(0) - \rho_0\varepsilon\phi'(0) = 0 \\ (1-\rho_1)\,\varepsilon^2\phi''(1) + \rho_1\varepsilon\phi'(1) = 0 \end{cases} \tag{6}$$

The general solution of Eq. (4) can be expressed as a combination of trigonometric and exponential functions:

$$\phi\left(\xi; z_1, z_2\right) = a_1 \sin\left(z_1\xi\right) + a_2 \cos\left(z_1\xi\right) + a_3 \exp\left(-z_2\xi\right) + a_4 \exp\left(-z_2\left(1-\xi\right)\right) \tag{7}$$

where a_i $(i = 1, ..., 4)$ are real integration constants and the arguments z_k $(k = 1, 2)$ are defined as:

$$z_i\left(\bar{\omega}; \varepsilon\right) = \frac{1}{\varepsilon\sqrt{2}}\sqrt{\left(-1\right)^i + \sqrt{1 + 4\varepsilon^2\bar{\omega}^2}},\ i = 1, 2 \tag{8}$$

Notice that the use of exponential instead of hyperbolic functions in Eq. (7) is more appropriate to highlight the existence of two boundary layers when $\varepsilon << 1$.

Substitution of Eqs. (7) and (8) in (6) yields the algebraic eigenvalue problem:

$$\mathbf{B}\left(\bar{\omega}; \varepsilon, \rho_0, \rho_1\right)\,\mathbf{a} = \mathbf{0} \tag{9}$$

where $\mathbf{a} = \left(A_1, ..., A_4\right)^T$, $\mathbf{0}$ is a null column matrix of size 4×1, and $\mathbf{B}$ is a 4×4 boundary condition matrix whose entries depend on both the non-dimensional bending stiffness ε and the degree of fixity parameters ρ_i $(i = 0, 1)$.

The non-dimensional natural frequencies $\bar{\omega}_k$ $(k \in \mathbb{N}^+)$ coincide with the roots of the characteristic equation $det\left(\mathbf{B}\left(\bar{\omega}; \varepsilon, \rho_0, \rho_1\right)\right) = 0$. Generally speaking, they will be a function of the non-dimensional bending stiffness ε and of the two variables ρ_0 and ρ_1, i.e. $\bar{\omega}_k = \bar{\omega}_k\left(\varepsilon, \rho_0, \rho_1\right)$, $k \in \mathbb{N}^+$. Symmetry, however, allows to conclude that the non-dimensional natural frequencies $\bar{\omega}_k$ should depend on a symmetric transformation of the variables ρ_0 and ρ_1 that can be arbitrarily, but conveniently, defined as:

$$p = \frac{1}{2}\left(\rho_0 + \rho_1\right),\ 0 \le p \le 1 \tag{10}$$

Dependency of the non-dimensional natural frequencies on p, then, can be fully highlighted by writing: $\bar{\omega}_k = \bar{\omega}_k\left(\varepsilon, p\right)$, $k \in \mathbb{N}^+$. It's worth noting that the ideal limit cases of doubly-hinged and doubly-clamped elements correspond, respectively, to set $p = 0$ and $p = 1$.

Exact closed-form solutions of the characteristic equation are only available for the doubly-hinged case (see e.g. [8]). Asymptotic closed-form solutions can also be derived, for small values of the non-dimensional bending stiffness parameters ε typical e.g. of stay cables. By extending the results firstly presented in [6] to deal with a beam element

supported by rotational springs at both end sections, indeed, the following result can be obtained:

$$\bar{\omega}_k = k\pi \left[1 + 2p\varepsilon + \left(\frac{(k\pi)^2}{2} + 4p^2\right)\varepsilon^2\right],\ k \in \mathbb{N}^+ + o(\varepsilon^2) \tag{11}$$

For arbitrary boundary conditions and non-dimensional bending stiffness values, the characteristic equation can be numerically solved e.g. through a sequential application of a root finding algorithm based on the bisection method. Within this context, it is worth noting that, thanks to the scaling of the governing equations adopted in the present work, the determinant of the boundary condition matrix $\mathbf{B}$ is bounded and with leading order terms of order one for vanishingly small values of ε. This makes simple numerical root finding algorithms well suited to find the natural frequencies of the system for over a wide interval of non-dimensional bending stiffness values, ranging from elements characterized by values of ε in the order of $0.5 - 1$ to very slender ones, with ε in the order of few percents or lower.

2.2 Parameter identification algorithm

Once the eigenvalues $\bar{\omega}_k = \bar{\omega}_k(\varepsilon, p)$ are known through an application of the semi-analytic model described in Section (2.1), multiplication by the characteristic frequency $\omega_0 = \omega_0(T, m, l)$ gives the natural frequencies:

$$\omega_k = \omega_0(T, m, l) \cdot \bar{\omega}_k(\varepsilon, p), k \in \mathbb{N}^+ \tag{12}$$

Standard vibration testing techniques (see e.g. [20, 9]) can be applied to obtain the first M natural frequencies of the beam: ω_k^* $(k = 1, ..., M)$. The difference between calculated and measured natural frequencies, then, can be quantitatively assessed by introducing the cost (or objective) function:

$$F_{obj} = \sqrt{\sum_{k=1}^{M}\left(1 - \frac{\omega_k}{\omega_k^*}\right)^2} \tag{13}$$

The unknown model parameters $\boldsymbol{X} = (\omega_0, \varepsilon, p)^T \in \mathbb{R}^3$ can be identified by solving the non-linear optimization problem:

$$\text{Find } \boldsymbol{X}_{opt} \text{ s.t. } F_{obj}(\boldsymbol{X}_{opt}) = \inf\{(\boldsymbol{X})\} \tag{14}$$

with the physical constraints: $\omega_0 > 0$, $\varepsilon > 0$, $0 \leq p \leq 1$. Once the optimal parameters ω_0, ε and p are known from the solution of (14), by assuming that the length (l) and the mass per unit of length (m) are known without uncertainties, the axial-force T can be easily calculated (see Eq. (2)) as $T = ml^2\omega_0^2$.

The non-linear optimization problem defined in Eq. (14) is characterized by several characteristic features that should guide the selection of an appropriate solution algorithm. Due to unavoidable measurement errors affecting the natural frequencies ω_k^* $(k = 1, ..., M)$, the landscape of the cost function (12) is characterized, in general, by many local minima. Moreover, the sensitivity of cost function (12) with respect to the parameter p tends to be substantially negligible for small values of the non-dimensional bending stiffness ε typical of slender elements, as it can be easily inferred by inspecting the asymptotic solution of the eigenvalue problem (Eq. (11)).

Gradient-based optimization algorithms, hence, are not well suited for the particular problem at hand, since they are prone to get trapped in local minima and their iteration operators could potentially be ill-conditioned for small values of ε. Within the class of gradient-free algorithms, the family of Differential Evolution algorithms, firstly proposed by Storn and Price [18, 19], has shown excellent performances in finding the global optimum of non-linear, non-convex, multi-modal and non-differentiable functions (see e.g. the review in [3]). DE is an Evolutionary Algorithm (EA) that iteratively operates on a population of candidate solutions made of NP parameter vectors. The initial population is randomly chosen and offsprings are generated by perturbing trial solutions with scaled differences of randomly selected population elements. As the number of iterations grows, the characteristic size of these differences tend to automatically adapt to the natural scales of the objective landscape [3]. It's worth noting that the peculiar strategy adopted to generate offsprings and evolve the population of candidate solution makes DE algorithms able to deal with objective functions characterized by low or moderately low sensitivity with respect to one ore more variables of the searching space without numerical problems. Selection of the better fitted elements of the population is performed through a one-to-one parent/offspring competition scheme. The physical constraint are enforced through a simple penalty criterion and the iterations are performed until a termination criterion is satisfied.

In the present work, a custom implementation of a well-known variant of the DE algorithm proposed by [4] has been adopted to solve the non-linear optimization problem in Eq. (14). The termination criterion has been defined such that iterations are stopped whenever one of the following conditions is satisfied: (a) the relative difference between the best and worst objective function values $\Delta = \frac{F_{obj}^{worst} - F_{obj}^{best}}{\max\left\{F_{obj}^{worst}, 1\right\}}$ of a population is below a given threshold $Toll$ (cf. the *Diff* termination criterion in [21]), (b) the value of the cost function is lower than a prescribed value V, (c) the number of iterations NIT is equal to the maximum number of iterations $MAXIT$.

3 APPLICATIONS

The performances of the proposed parameter identification strategy have been assessed through extensive numerical testing. Results will be presented in the following for an axially-loaded beam element characterized by $\omega_0 = 5.66$ rad/s and $T = 4000$ kN. Three different values of non-dimensional bending stiffness ($\varepsilon = 0.02, 0.1, 0.5$) have been considered, along with five different boundary conditions: (I) $p = 0$ (doubly-hinged beam), (II) $p = 0.25$, (III) $p = 0.50$, (IV) $p = 0.75$ and (V) $p = 1$ (doubly-clamped beam).

In order to simulate experimental input data, the eigenvalue problem (9) has been numerically solved to get the first five natural frequencies. These frequencies, then, have been corrupted by multiplying the nominal values by a unit-mean and low intensity Gaussian noise, to account for the effects of measurement errors. Different values of noise intensity, ranging from 0 to 2.5%, have been considered. For each noise intensity value, a sample of 10 sets of noisy natural frequencies has been randomly generated. The optimization problem (14) has been solved for each set of numerically generated input natural frequencies by running the DE algorithm ("DEGL/SAW/bin" scheme, with scale factor $F = 0.8$ and crossover parameter $CR = 0.9$, see [4] for further details), starting from a population of $NP = 30$ trial solutions randomly chosen in the initial search space $P \subset \mathbb{R}^3 : 10^{-5} \leq \omega_0 \leq 50,\ 10^{-5} \leq \varepsilon \leq 5,\ 0 \leq p \leq 1$. The parameters of the termination

criterion have been set up as: $V = 10^{-6}$, $Toll = 10^{-7}$ and $MAXIT = 1000$.

Figures (2)-(4) show the results of the proposed identification algorithm as a function of the noise intensity. The results are averaged over the number of runs NR of the algorithm for each different noise intensity level (i.e. $NR = 10$) and expressed in terms of: (a)-(c) the identified values of the parameters $\omega_{0,ave}$, ε_{ave} and p_{ave}; (d) the relative error on the element axial force, $\Delta T = \frac{T_{ave}-T^*}{T^*}$, where T_{ave} is the average identified value of the axial force and T^* is the target value (i.e. $T^* = 4000$ kN); (e) is the average value of the cost function associated to the identified optimal set of parameters (denoted as F_{obj}^{best} in the figures); (f) is the average number of iterations of the DE algorithm.

Figure 2 shows the results for a beam element with target bending stiffness value $\varepsilon = 0.02$ typical of slender elements, such as stay cables. The identification strategy gives fairly accurate results in terms of parameters ω_0 and ε for all values of noise intensity herein considered. As expected from the inspection of the asymptotic solution of the eigenvalue problem (Eq. (11)), the boundary conditions do not affect significantly the cost function of the optimization problem and, as a consequence, the identification algorithm is not able to correctly identifying the parameter p. As already noticed by the authors in [6], the identification procedure tends, for each value of noise intensity, to a mean value of p equal to about 0.5. This latter value coincides with the mean value of p within the randomly generated population members of the DE algorithm. On the overall, in spite of an highly inaccurate identification of the degree of fixity of the beam end sections, the procedure gives a good estimate of the axial force. Errors on the axial force obviously increase at the increase of the noise intensity and are higher for the two boundary conditions corresponding to the limit cases of doubly-hinged (label I, $p = 0$) and doubly-clamped (label V, $p = 1$) beams. Figure 2(e) allows to appreciate how measurements errors, herein associated to non-zero noise intensity values, determines a significant jump in the estimated minimum values of the cost function. Figure 2(f) allows to appreciate how for non-zero noise-intensity values iterations are mostly terminated because the maximum number of iterations ($MAXIT$) is reached. This is mainly due to the already discussed lacking of convergence on the degree of restraint parameter p (see also [6]).

Figure 3 shows the results for a beam element with target bending stiffness value $\varepsilon = 0.1$. The identification algorithm gives very accurate predictions of all parameters ω_0, ε and p for small values of the noise intensity (i.e. lower than 0.5%). By increasing the noise intensity, the accuracy in the predictions of the degree of restraint parameters p rapidly deteriorates, while the errors on both ω_0 and ε remain acceptable with maximum discrepancies from the target values in the order of $\pm 15\%$, depending on the boundary conditions. The maximum relative errors on the identified axial force are in the order of $\pm 15\%$ for small values of the noise intensity (i.e. lower than 0.5%), but rapidly increase up to about $\pm 25\%$ for a noise intensity value equal to 2.5%. Figures 3(a) and 3(d) also allows one to appreciate how, for the non-dimensional bending stiffness value herein considered, the proposed identification algorithm tends to systematically underestimate the axial force for the boundary conditions labeled (I) and (II), i.e. for p respectively equal to 0 (doubly-hinged beam) and 0.25; on the other hand, the axial force is systematically overestimated for the boundary conditions labeled (IV) and (V), i.e. for p respectively equal to 0.75 and 1 (doubly-clamped beam). The opposite trend is remarked for the non-dimensional bending stiffness ε (see Fig. 3(b)). These trends can be easily explained, through an inspection of Fig. 3(d), by noticing that the algorithm tends to: (a) overestimate the degree of fixity of the restraints in cases (I) and (II); and (b) underestimate the degree of

fixity of the restraints in cases (I) and (II).

Figure 4 shows the results for a beam element with target bending stiffness value $\varepsilon = 0.5$, that can be considered as representative e.g. of diagonal braces, truss elements and tie-rods. Differently than in the previous cases, the boundary conditions are identified with good accuracy for all values of noise intensity herein considered, except that for the case labeled as (I), corresponding to $p = 0$ (doubly-hinged beam), which is associated to errors on p in the order of 25%. More in details, the accuracy of the identified values of p decreases with the increasing of the flexibility of the restraints. The identified values of the parameters ω_0 and ε, on the other hand, are affected in general by significant discrepancies with respect to the target values. As a consequence, also the errors affecting the identified axial force are relevant. More in details, it is worth noting that errors on the non-dimensional bending stiffness parameter ε reach the 60%, depending on the boundary conditions and on the noise intensity value. Although difficult to evaluate in slender structural elements such as stay cables (associated to small values of ε), the bending stiffness of thicker structural elements such as diagonal braces, truss elements and tie-rods can often be easily estimated on the basis of available information on the geometric and mechanical properties of the structural element. Whenever the bending stiffness is known, however, the proposed algorithm can be easily re-formulated by assuming that ω_0 and p are the only unknown parameters, leading to a more precise evaluation of the beam axial force.

4 CONCLUSIONS

An analytical model for transverse vibrations of an axially loaded Euler-Bernoulli beam with partially restrained end conditions has been presented and used as the basis to develop a numerical parameter identification strategy. Parametric analyses have been carried out to quantitatively assess the performances of the proposed identification algorithm, for a broad range of structural configurations, characterized by different values of non-dimensional bending stiffness ε and boundary conditions, that cover a wide spectrum of applications, such as stay cables, diagonal braces, truss elements and tie-rods of vaulted historical masonry structures. On the overall, the proposed procedure gives accurate estimates of the beam axial force for small and moderately small values of ε, in the order of $\varepsilon \lesssim 0.1$. For higher values of ε, based on the critical discussion of the results of the proposed identification strategy, a simplified algorithm relying on a preliminary estimation of the bending stiffness of the beam is envisaged to reduce errors on the identified axial force.

Keywords: Vertical Ground Motion, Seismic Vulnerability Assessment, Historical Building, Time History Analysis, Damage Assessment

Abstract. *In the present research work, the effect of ground motion vertical component in case of near-source excitations on masonry buildings has been analysed. To this purpose, an investigation has been made on the Banloc Castle, a historical masonry construction damaged by the Banat-Voiteg earthquake occurred on December 1991 in the Romanian Region of Banloc. A FEM model of the building, setup using DIANA FEA analysis software, has been analysed in the non-linear dynamic field. In particular, the records have been referred to the Banloc site, characterized by a moment magnitude of 5.5 and a focal depth of 9 km. In order to estimate the influence of the vertical seismic motion on the case study building in terms of both displacement and internal forces, two different scenarios have been examined. The first scenario has taken into account the horizontal component only, whereas the second one has studied the simultaneous effects of three components of the seismic action. The comparison between the two scenarios has shown that the vertical ground motion significantly modifies the structural behaviour of the inspected building. Finally, numerical damage patterns have been plotted and compared to the real cracks detected in the case study after the considered seismic event.*

1 INTRODUCTION

Typically, the effect of the vertical component of earthquake ground motion on constructions has been ignored in the current studies of Earthquake Engineering. Gioncu and Mazzonlani have developed an important research activity concerning the influence of ground motion vertical component for the load-bearing masonry structures in the Banat seismic region [1, 2, 3]. In particular, the seismic design and assessment of Unreinforced Masonry (URM) structures is limited to the effects of the horizontal accelerations, neglecting the vertical component of the design ground motion [4, 5, 6]. The damages caused by disastrous earthquakes highlighted the brittle behaviour of several structural systems especially under seismic actions characterised by not negligible vertical components, which produced significant effects in cases of near-field events.

Generally, the ground motion vertical component is mainly associated to the arrival of vertically propagating compressive P-waves and secondary shear S-waves. However, the propagation direction of volume waves (P and S) is not influenced by the site geology, but by the site distance, the fault type and the magnitude. In these circumstances, it is evident that the effects induced by the ground motion vertical component are prominent in areas characterized by high hazard level and that they should be appropriately considered in the seismic behaviour analysis of existing masonry buildings, which have very low tensile resistance [7].

Generally, earthquakes occurring near an active seismogenic source contain pulse-like records (one or more consecutive peaks), characterised by a long period and a short duration [8]. These impulses, caused by the sliding of faults, release a large amount of seismic energy, which is transmitted abruptly to the structures. For this reason, the vertical component of these earthquakes is one of the determining factors to be taken into consideration for the correct safeguarding of buildings and design preventions.

In fact, as reported in [9, 10], it was shown that the ratio between vertical (V) and horizontal (H) components of ground motion in the near-source regions with high hazard earthquakes is considerably different than that expected at a smaller magnitude and greater distances; moreover, it was suggested that the V/H (empirical) limit of 2/3 should be re-evaluated in order to better foresee the effects of ground motion vertical component for design purposes. In particular, it was observed that these ratios near the seismogenic source can exceed the unitary value. The effects produced by the vertical component of the ground motion significantly influence the dynamic response of structures. In fact, as detailed in [11], the vertical component on masonry buildings provokes a reduction of load-bearing capacity of the wall panels and, consequently, an increase of lateral displacements. In particular, during the time history cycle, the vertical component acts alternately with compression and decompression peaks, that lead to a degradation of the stiffness of the masonry under dynamic action with the consequent increase of the local or global vulnerability.

Other studies [12, 13] inspected the behaviour of masonry buildings subjected to vertical seismic actions, asserting that the vertical component of the ground motion in epicentre areas characterized by a *Joyner and Boore* distance (R_{jb} <30 km) causes a variation of the axial stress regime in the walls. Consequentially, the dynamic amplification due to soil stratigraphy leads to a reduction in terms of the shear capacity of structural resistant elements, which show a deficit in terms of resistance, stability and ductility.

In this framework, focusing on the Banat-Voiteg seismic event occurred on December 1991, the Castle of Banloc has been selected as a case study. In order to take into account the influence of vertical accelerations on the seismic capacity of the examined building, nonlinear dynamic analyses have been carried out considering the ground motion records representative of the earthquake occurred in the region of Banat in Romania.

The displacements and foces regime of the investigated castle have been analysed in order to point out the influence of vertical component. Finally, the damages achieved from numerical modelling have been presented, discussed and compared to those really detected under the 1991 earthquake.

2 SEISMICITY OF BANAT REGION

The Western and South-Western part of Romania, well known as the Banat Region, is undoubtedly one of the most seismically active regions of the country, characterized by crustal earthquakes. Due to the presence of multiple vulnerability factors, such as old houses, areas with high population density, unprotected historic buildings, presence of factories, etc., the seismic risk of the region is very high.

The seismic history of this region is characterized by a high dispersion and variability of the epicentres and, therefore, of the events observed. Generally, the earthquakes in the Banat region occurred at the contact between the Carpathian and Pannonian plates (from Timisoara to S-W Jebel and Banloc and north of the Bega canal) and at the contact among irregular structures straddling Sânnicolau Mare, Nădlag-Jimbolia, Arad-Vinga- Calacea and Timis Valley in Faget. Moreover, the distributions of focal mechanisms associated to the earthquakes occurred in the South-West of Romania showed a reverse and strikes faults or the combination of the two. The focal depths of earthquakes in the western areas of Oltenia and Banat-Danube were between 5 and 33 km deep, as indicated in Figure 1 [14].

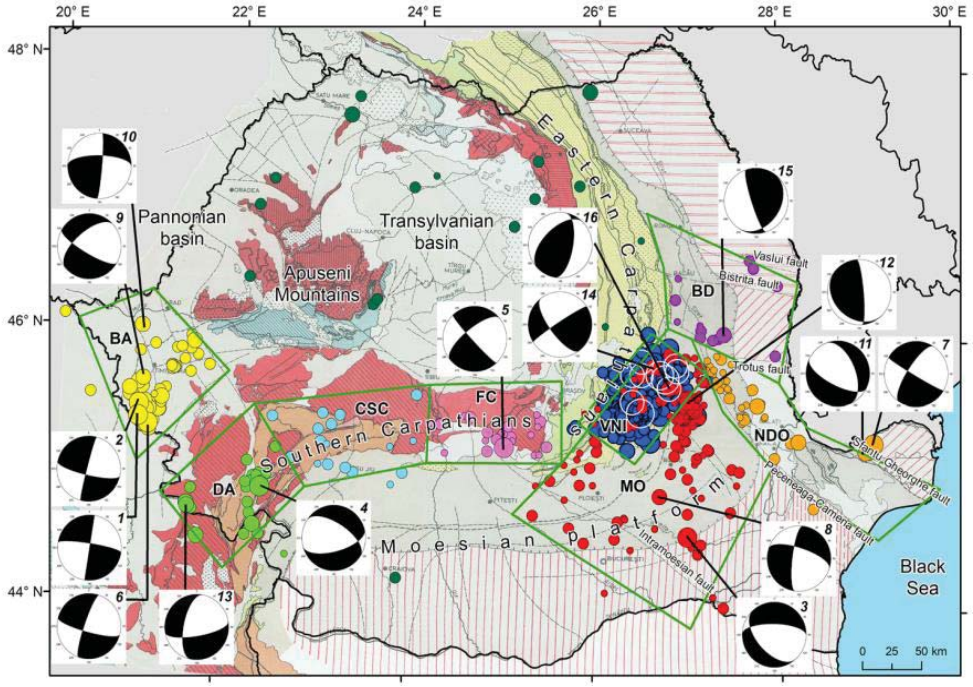

Figure 1: Focal mechanisms occurred in Romania [14].

The most significant earthquakes occurred in the Banat area were the two seismic events detected in Banloc in 1991 and denoted by moment magnitude of 5.5 and 5.6. These main records have been acquired by the INCERC seismic network (Banloc Town-Hall and Timisoara stations). In particular, the accelerometer records taken by INCERC for the cities of Timişoara and Banloc provided earthquakes with the following characteristics: (i) relatively short duration of 9-24 s and (ii) significant spectral values in the range 0.1-0.3 s, which extends up to 0.7 s for the Timişoara record and up to 1.2 s for the Banloc one.

Focusing on the event recorded in the city of Banloc, it is characterized by a reduced site-source distance (7.01 km far from the epicentre), which makes it as a near-source event.

This event showed an impulsive and high vertical peak acceleration of 1.2863 ms^{-2}, a focal depth of 9 km, a moment magnitude, M_w, of 5.5 and an intensity, I, of VIII according to Mercalli Intensity Scale (MCS).

The data provided by the SM-ROM-GL Earthquakes DB [15] related to the 1991 event occurred in the Banat Region are shown in Table 1.

Earthquake	Date	LatN	LongE	Depth - *h* (km)	M_w	Station
Banat-Voiteg	1991/12/02	45.45	21.12	9	5.5	BNL1

Table 1: Reference event occurred in the Banat seismogenic zone in December 1991.

Furthermore, the ShakeMap of the event occurred and the geolocation of the city of Banloc are shown in Figure 2.

3 PRELIMINARY ANALYSIS OF THE CASE STUDY BUILDING

3.1 Historical overview on the Banloc Castle

The municipality of Banloc is attested for the first time in May 1400, when the name "*Byallak*" was reported in a document provided to the clerk of Cenad.

For almost two centuries (1552–1716) Banloc was the summer residence of the Ottoman pasha of Temeşvar Eyalet. In 1716, the Banat region, where Banloc is located, was conquered by the Austrians and, in the census of the year later, the municipality was registered as "*Panloch*" in the district of Ciacova with 85 inhabited houses.

In 1759 the construction of the castle of Banloc was completed.

The castle (Figure 3) is the most important monument of the municipality. It is a massive building with a "U" in-plane shape built in the early nineteenth century. The main façade faces south, while on the opposite side the two wings border a terraced courtyard.

The castle is composed of very heavy perimeter brick and internal walls having thickness of 0.90 m and 0.80 m, respectively at ground level.

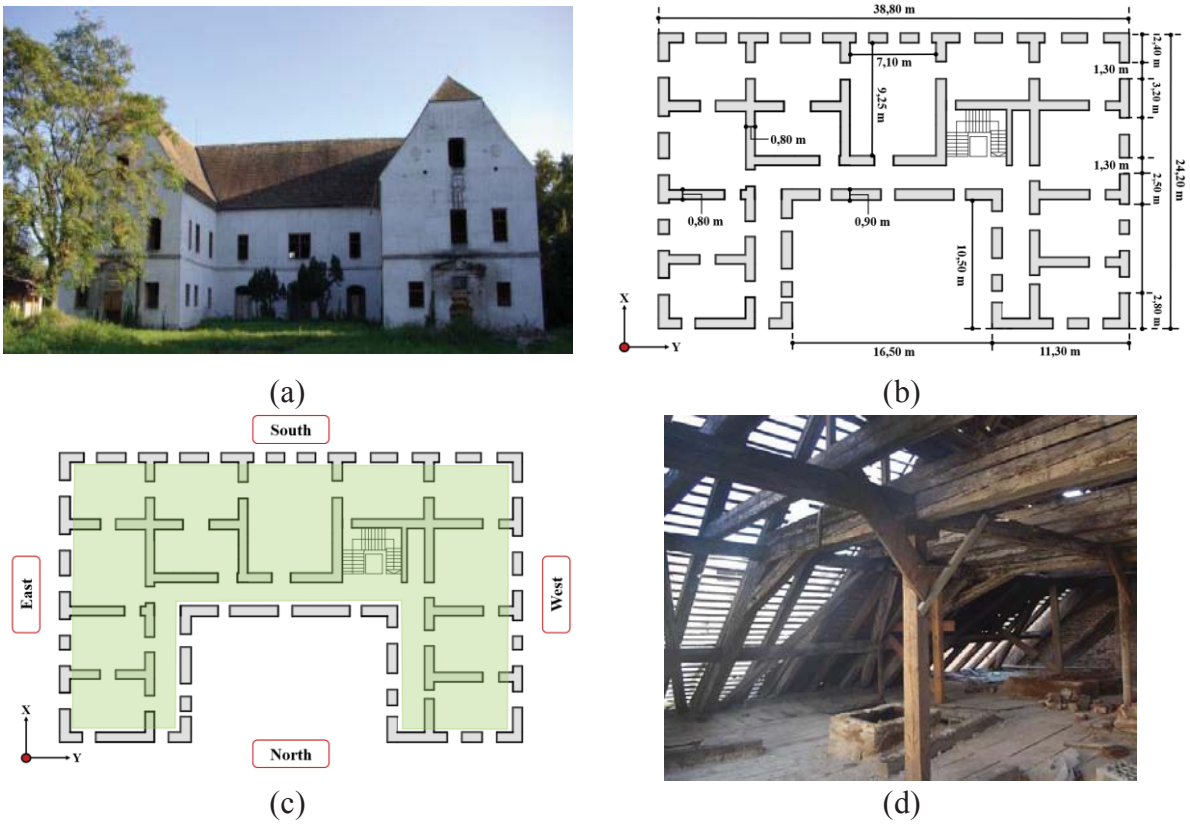

Figure 3: Castle of Banloc: (a) external view, (b) architectural plan layout, (c) geographical orientation and (d) timber roof structure.

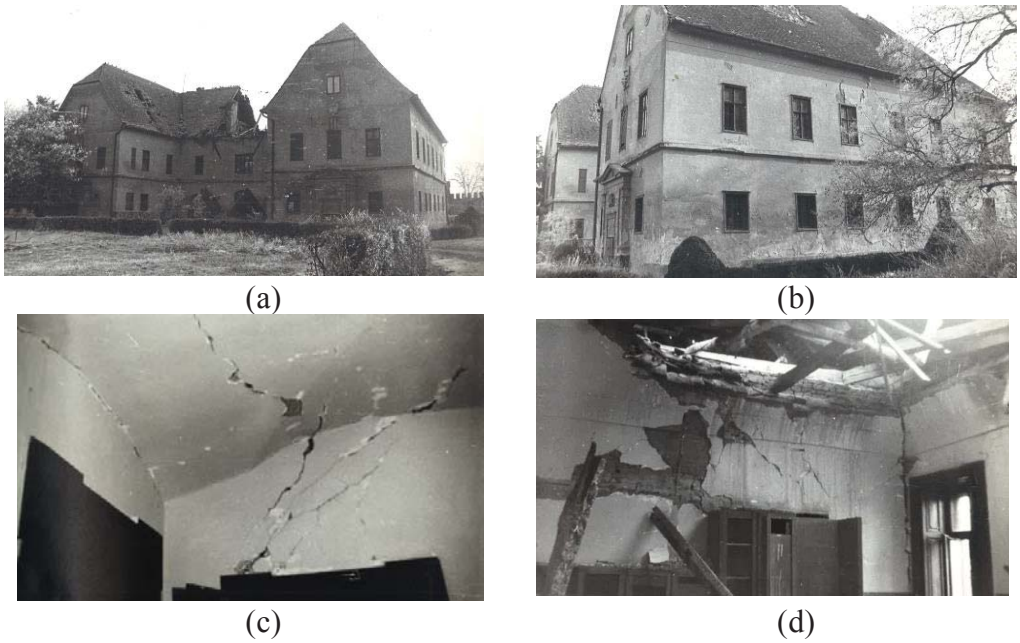
On the top, vaulted ceilings with thickness of 0.25 m are present. The inter-storey heights of first and second floors are 4.00 m and 5.70 m, respectively. The roof is made of a solid timber supporting structure, whose construction technique was frequently used in the Banat region (Figure 3d).

3.2 Field evidence after the Banloc earthquake

The Banloc earthquake, occurred on 1991 December 2nd, was a very significant event in the seismic historicity of the Banat region. It was characterized by a focal depth of 9 km with the epicentre localized in Banloc. The released seismic energy produced a magnitude (M_w) of 5.5 on the Richter scale [15]. This earthquake can be classified as a medium-deep geological event. It caused slight damages to new designed structures, but several masonry buildings in the area were characterized by very serious damages, also with partial collapses. Referring to the case study building, the damage was detected through on-site inspections after the earthquake occurred. The achieved post-earthquake damages are presented in Figure 4 [16].



(a) (b) (c) (d)

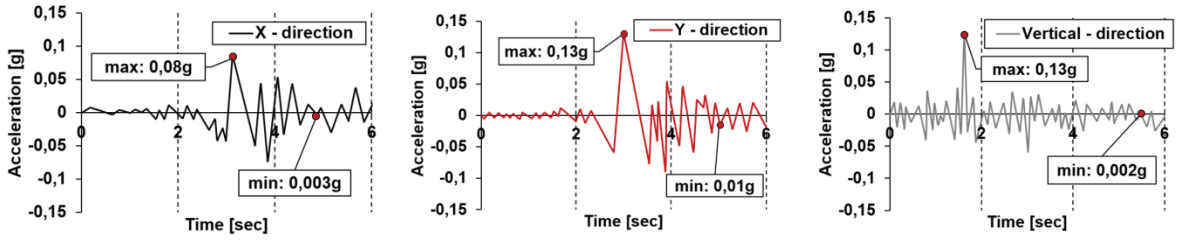
Figure 4: Detected damages on the Banloc Castle after the 1991 earthquake: (a) North façade; (b) West façade; (c) first floor room; (d) second floor room [16]

As it is seen from the previous figures, the highest level of damage was localized in the vaults, which are elements characterized by large spans and resistance lower than that of vertical structures (Figures 4c). In particular, the cracks in the vaults were attributable to the impulsive vertical component, which produced very extensive damages. Contrary, large number of walls were affected by shear mechanisms induced by horizontal seismic components with widespread cracks [16].

4 STRUCTURAL ASSESSMENT

4.1 Analysis of the ground motion records

The accelerograms adopted are representative of the event occurred in Banloc in December 1991 considering the BNL1 seismometric station [15]. The accelerations are characterized by maximum components in X direction of 0,08g, in Y direction of 0,13g and in Z direction of 0,13g (Figure 5). The seismic phenomenon can be defined of near-source type, since the city of Banloc was located approximately 7 km far from the epicentre.



(a) (b) (c)

Figure 5: Accelerograms of the Banat-Voiteg seismic event.

As can be seen from the previous Figure, for numerical analyses, a 6 seconds time history has been considered and elaborated by means of the Seismosignal software [17]. This choice is dictated from the fact that, on one hand, in the first 6 seconds all the seismic energy input deriving from vertical component is manifested and, on the other hand, the analysis elaboration time is short.

The spectral ratios between vertical accelerations, V, and the corresponding horizontal ones, H, for the considered near-source ground motion, have been depicted in Figure 6. These results have shown how the vertical component effects are very important for earthquakes characterized by small site-source distances, where the V/H limit of 2/3 proposed in [9] is exceeded. In particular, Figure 6 shows that for short periods (less or equal than 0,2 seconds), the V/H ratio is greater than 1; this means that the rule imposed in [9] underestimates considerably the vertical component effects for low periods.

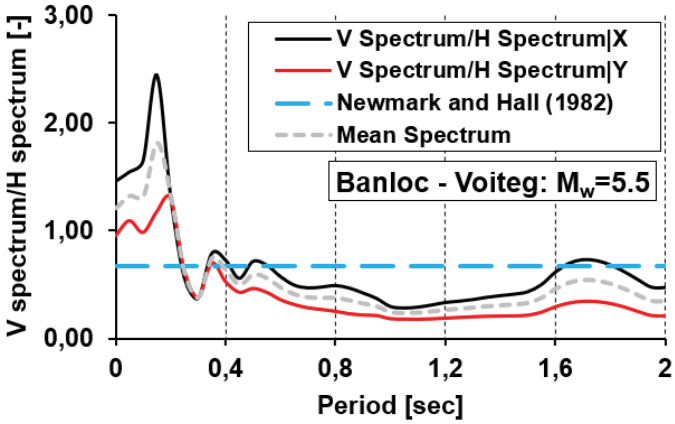


Figure 6: V/H spectral ratios for the Banloc-Voiteg event.

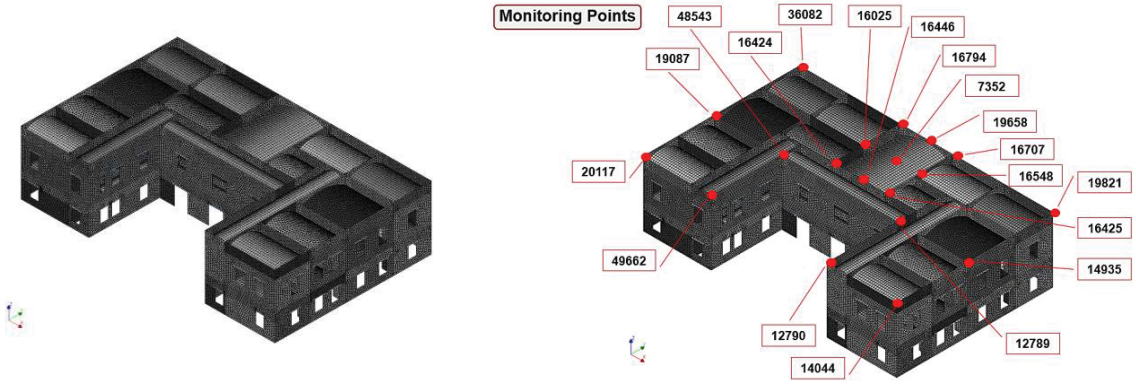
4.2 Non-linear dynamic analysis

Time-history analysis provides a global assessment of the castle dynamic structural response varying specified ground motion accelerograms. The implementation of the model has been set-up using the DIANA FEA software [18], where the structure has been conceived as set of shell elements (Figure 7).



(a) (b)

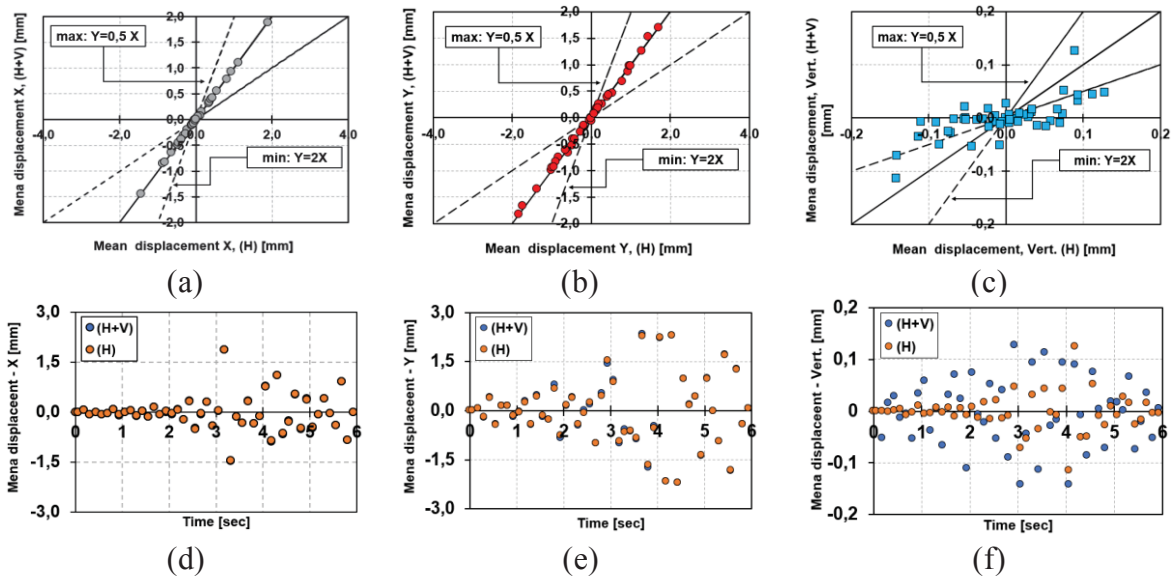
Figure 7: 3D-shell element model of the castle (a) and selected monitoring points (b).

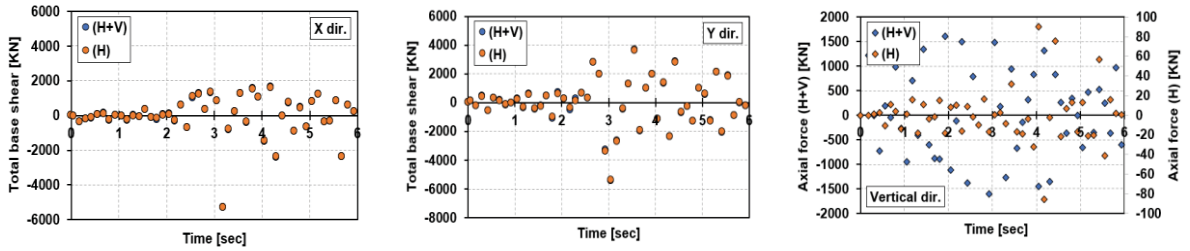
The masonry constitutive law is characterized by a non-linear response with a nonductile post-peak softening behaviour; tensile stresses are assumed to diminish exponentially, while the compression performance combines hardening and softening parabolic phases, as established in [19, 20]. Based on these assumptions, in Table 2 the masonry mechanical properties adopted in the analysis for the case study building have been reported according to NTC18 [21].

Mechanical Properties		
Modulus of elasticity	E [N/mm^2]	1500
Shear modulus	G [N/mm^2]	500
Compressive strength	f_m [N/mm^2]	2.40
Tensile strength	τ_0 [N/mm^2]	0.24
Specific weight	w [KN/m^3]	18
Poisson ratio	ν [-]	0.20
Fracture energy (compression)	G_{fc} [N/mm]	4.64
Fracture energy – Mode I (tensile)	G_{ft} [N/mm]	0.012

Table 2: Mechanical properties of masonry.

The results obtained have been represented, for the two scenarios considered, namely (H) and (H+V), in terms of dispersion of both mean displacements and resistances. They are referred to the monitoring points at the second floor (see Figure 7) and are summarized in Figure 8. Concerning displacements and strengths regime, positive and negative values of the points cloud denote the change of direction induced by the seismic input with respect to the straight line with equation x=y (bisector). Furthermore, in order to better highlight the influence of the vertical component, the upper (y=0,5x) and lower (y=2x) bounds of the dispersion range have been considered. In this way, the greater scatter with respect to the bisector, the larger effect of the ground motion vertical component [11].





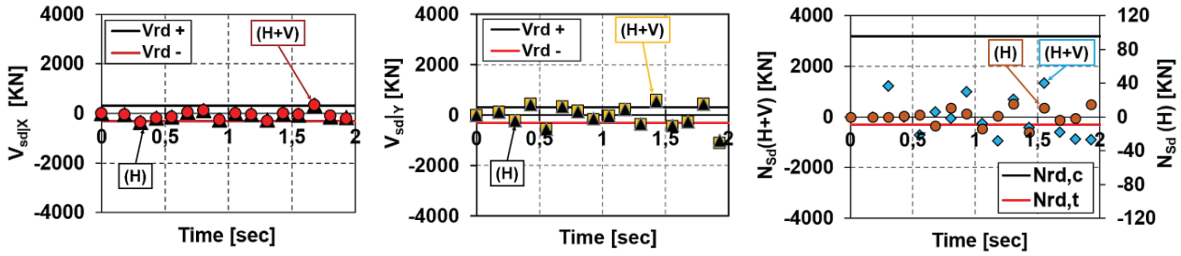
(g) (h) (i)

Figure 8: Scatter results in terms of displacements (a-f) and forces (g-i).

From the gotten results, it is worth noting how the average dispersions associated with the two main directions X and Y, in terms of displacements and base reactions, are not affected by the influence of the vertical component. However, in vertical direction, there is a marked average dispersion (Figures 8c and 8f) with respect to the case in which the vertical component is neglected (H).

It can be seen that in the first two seconds (in which the vertical component reached its maximum acceleration peak), the displacements are increased by about 6 times compared to the case in which the vertical component is neglected (H). Furthermore, in terms of axial stress, the same condition can be found by comparing the two scenarios, (H) and (H+V) mentioned above (Figure 8i).

Consequently, a time step of 2 seconds has been considered in order to consider the effect of ground motion vertical component in terms of both shear [22] and axial demands for one of the most stressed pier of the West façade. So, for the sake of representation, (H) and (H+V) scenarios have been compared and plotted according to the recommendations provided by EC8 [22], as reported in Figure 9.



(a) (b) (c)

Figure 9: Safety checks for shear stresses (a-b) and axial loads (c) in case of (H) and (H+V) scenarios.

Firstly, in Figures 9a and 9b, it is possible to notice how the seismic vertical component in the two main directions, X and Y, does not produce any significant stress variation for both considered scenarios. Secondly, in Figure 9c, it is shown how the vertical component produces a significant increase in terms of axial load. In fact, at time step of 1.55 seconds (which corresponds to the maximum peak vertical acceleration), the difference between (H) and (H+V) is very high (more than two times). Moreover, it is detected that the axial load demands exceed averagely the corresponding tensile capacities ($N_{rd,t}$) of 2 times.

Subsequently, the force reduction factor, q, prescribed in almost all seismic design codes without taking into account the influence of the ground motion vertical component [23, 24], has been predicted for the examined building located in epicentral area of Romania.

The behaviour factor has been assessed both in terms of mean ductility values and areas equivalence criterion between the elastic system and the elasto-plastic one. Based on the energy dissipation criteria, the hysteretic cycles have been defined for the monitoring points

mentioned in Figure 7b, and, thus, the mean capacity curves, representative of the global behaviour of the structure in the two main directions, X and Y, have been considered (Figure 10a and 10b). Furthermore, with the same method, the behaviour factor has been calculated when the vertical component is neglected.

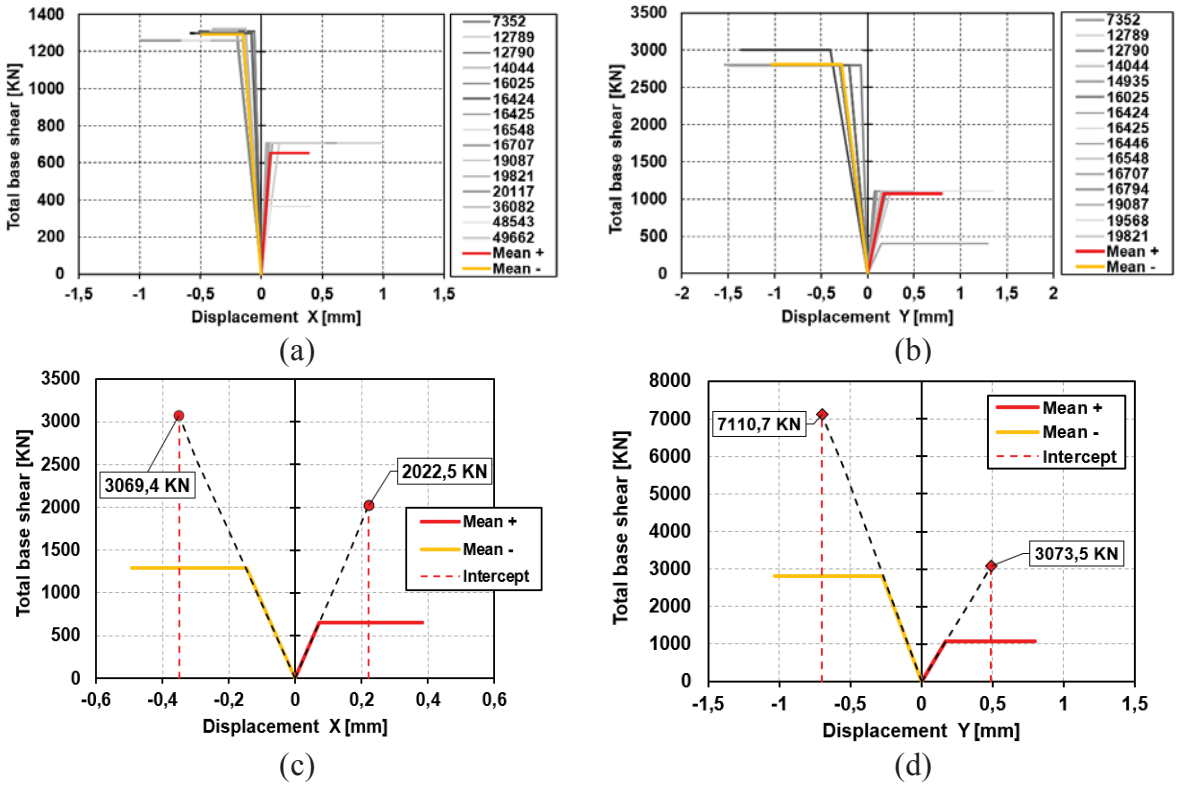


Figure 10: Mean capacity curves for (H+V) scenario in the two main directions X and Y in terms of energetic ductility (a, b) and equivalence criterion of areas (c, d).

From the results obtained, the proposed q-factor is intended as the absolute minimum of the values deriving from the scenarios (H) and (H+V) considered. It has been estimated as equal to 1.94, when the vertical acceleration associated to the case of maximum decompression reached at about 3 seconds in the time history is considered. This choice is based on the fact that, during the decompression phase, the structure presents the highest global vulnerability. Moreover, it is important to observe how the proposed value is contained in the range (1.5-2.5) established by EC8 [22]. Finally, the achieved value shows an increase of about 30% with respect to the value of 1.5 suggested by the Romanian Code [25] for masonry structural systems in case of design spectrum considering vertical acceleration components only.

4.3 Damage assessment

The damages detected in the castle after the Banloc earthquake were represented by a widespread distribution of cracks, that affected the vertical and horizontal structures, producing globally in the time the structure deterioration.

In particular, several failure mechanisms closely related to the seismic event were identified. More specifically, in the first two seconds of the time-history, the maximum vertical peak acceleration produced an extensive damage in the vaults, characterized by a brittle behaviour (Figure 11) [16].

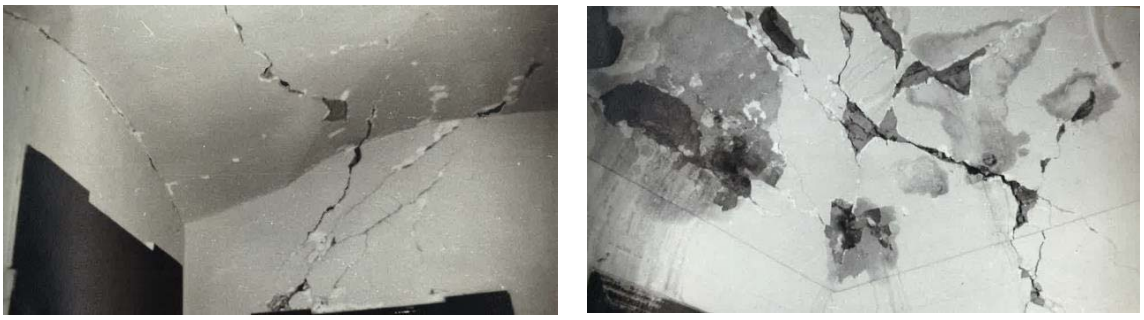

Figure 11: Damages detected in the second-floor vaults mainly due to ground motion vertical component [16].

Successively, following the impulsive action, the arrival of the horizontal components produced damage to the vertical structures, mainly represented by shear cracks in the spandrel beams, as shown in Figure 12 [16].

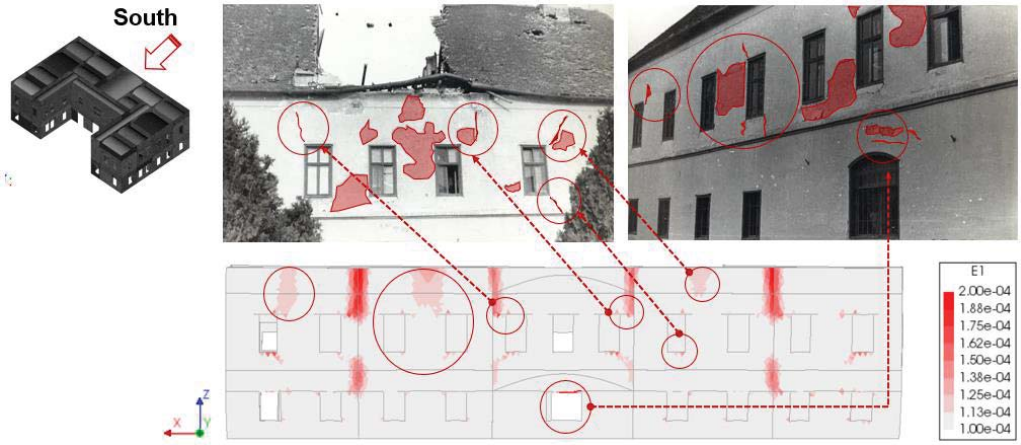
Figure 12: Vertical and diagonal shear cracks detected in the South façade of the case study building [16].

Finally, in the internal court of the building, a partial collapse of the roofing structure was observed. This collapse mechanism was triggered by the impulsive seismic action, as depicted in Figure 13 [16].

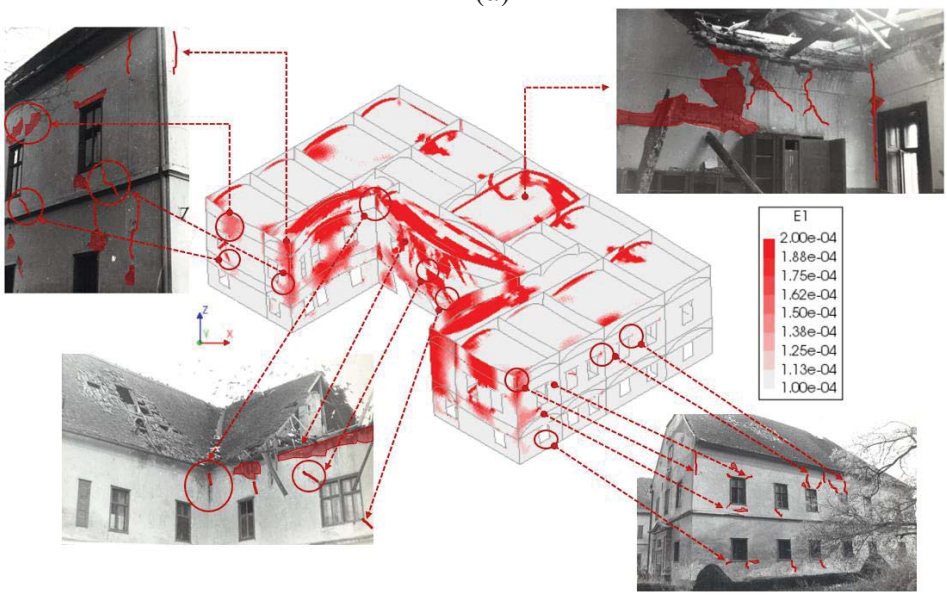
(a) – left view (b) – right view

Figure 13: Failure mechanisms observed in the internal court of the case study building [16].

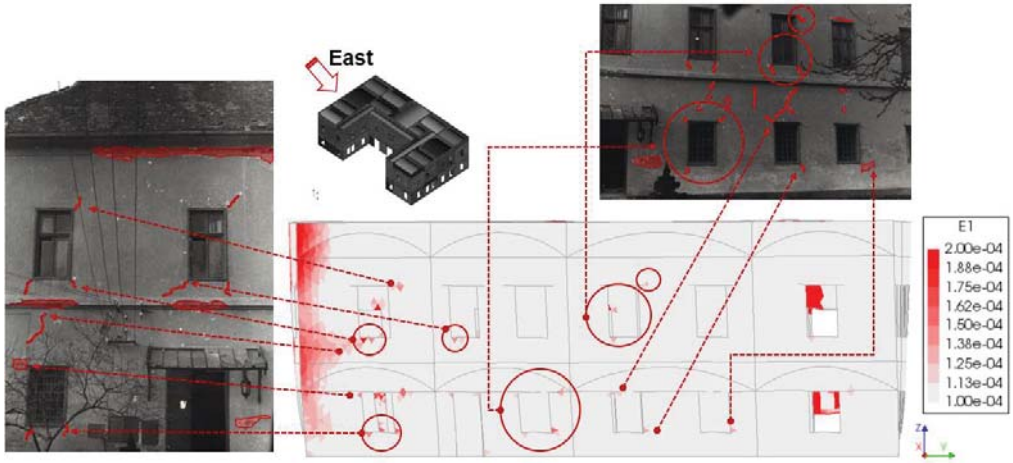
The damages achieved from numerical analyses have been presented and compared to experimental ones in Figure 14.



(a)



(b)



(c)

Figure 14: Numerical damages obtained simulating the Banloc-Voiteg event and comparison with experimental evidences.

From the above comparison, it appears that the non-linear analysis identified local damages very similar to those produced by the Banat-Voiteg earthquake.

The identification parameter used to evaluate the damage state in the numerical analysis is the *tensile fracture energy* (G_f), according to which, when the maximum principal stress reaches the defined cracking criterion, the fracture begins to distribute in the structural element. In particular, the numerical model catches in a satisfactory way the detected local damages and failure mechanisms, providing, as depicted in Figure 14, the right distribution of *Principal Total Strain* (E1).

5 CONCLUSIONS

The proposed work has analysed the effects induced by the vertical earthquake component on a historic masonry building located in the Romanian region of Banloc. The seismic event, occurred in December 1991 with a moment magnitude of 5.5, was characterised by a small (about 7 km) site-source distance. This impulsive event was identified by low frequency content and maximum PGAs comparable in vertical and horizontal directions. The accelerometric records were used to perform non-linear dynamic analyses on the case study building modelled with the DIANA FEA software using shell elements.

The effects of the ground motion vertical component were evaluated considering the comparison between two different scenarios: the first, named H, where only horizontal acceleration components were considered, and the second, called H+V, where also the vertical components were taken into account. The main results are summarized as follows:

- The considered record, due to the combination of medium magnitude and short site-to-source distance, had high energy in terms of vertical component in the first two seconds.
- There was a dispersion of the displacements induced by the vertical component in the first two seconds of the time-history, since the impulsive action releases a high input energy in that time period. The displacements increased about 6 times compared to the scenario in which the vertical component is neglected.
- In the first two seconds of time history, where the maximum vertical energy content of the seismic motion occurred, the comparison of the two scenarios (H and H+V) in terms of stress regime was done. In particular, in terms of shear strength the vertical component did not produce any significant variation of results in the two analysis directions. Conversely, referring to the axial stress regime, the vertical component induces a considerable increase of axial tensile loads, which exceeded averagely the corresponding tensile capacities of about 2 times.
- The q-factor for the study castle was predicted taking into account the influence of the ground motion vertical component. The achieved value was enclosed in the range established by EC8 and it is 30% greater than that provided by the Romanian Code for masonry structures in case of vertical acceleration design spectrum. Moreover, other research activity in this field will be study in future.
- The numerical damage assessment was carried out considering the *Principal Total Strains*, which take into account the overcoming of the tensile fracture energy in the structural elements. The numerical analysis results provided with satisfactory accuracy the same damage mechanisms really detected in the castle, namely cracks in the vaults (produced by vertical components) and vertical structures (mainly caused by horizontal components), as well as the out-of-plane horizontal bending mechanism in the façade facing the courtyard, which was produced by the partial collapse of the roof structures.

VIBRATION MONITORING OF CONSTRUCTION WORK AND INDUSTRIAL ACTIVITIES USING NEW SOLUTIONS OF INSTRUMENTATION

C. Moutinho[1], **and A. Cunha**[1]

[1] CONSTRUCT/ViBest - Faculty of Engineering (FEUP), University of Porto

R. Dr. Roberto Frias S/N, 4200-465 Porto, Portugal

moutinho@fe.up.pt; acunha@fe.up.pt

Keywords: Industrial activities, construction work, new generation of monitoring systems

Abstract. *Over the last years, the Laboratory of Vibrations and Structural Monitoring of the Faculty of Engineering of University of Porto (www.fe.up.pt/vibest) has been monitoring vibrations due to construction work and industrial activities. In these cases, several types of wired and wireless commercial systems were used. When the long term monitoring of vibrations is required, wired solutions are usually demanded because of the need of the continuous power supply to the sensors. However, these systems often present some difficulties such as: a) dependence on external power supply and cables spread throughout to the working area, and; b) difficulty in being physically integrated or attached to structures, especially in construction environment. This has motivated the ViBest research group in contributing to the development of a new generation of measurement systems offering the following advantages: a) cost attractive; b) wireless with high levels of autonomy (may run on batteries for several weeks); c) small size that facilitates the easy integration in the structures; d) possibility of installation of high number of sensors; e) may be easily customized. In this context, the objective of this paper is to share the experience of ViBest in this area by describing the developed instrumentation that may be used in the measurement of vibrations in industrial or construction environment.*

1 INTRODUCTION

In Civil Structures and Infrastructures, the continuous dynamic or static monitoring or certain quantities has lately assumed great importance. In the case of dynamic measurements, the main reason of this interest is related to the subject of Operational Modal Analysis (OMA), which aims to identify the modal parameters of a structure in operating conditions (particularly with regard to natural frequencies, damping ratios and mode shapes) taking into account the measured ambient vibrations at critical points. In these cases, the measurement of vibrations is performed without disturbing the normal functioning of the structures, which may be implemented in buildings, bridges (railway, roadway, highway), dams and offshore structures. Given the importance of this subject, the Laboratory of Vibrations and Structural Monitoring FEUP (CONSTRUCT-ViBest) has carried out consistent work in this area [1], both in the development of numerical tools for identifying modal parameters and in the continuous measurement of vibrations in actual structures (see www.fe.up.pt/vibest).

Parallel to this area, CONSTRUCT-ViBest has also been involved in the monitoring of construction work and industrial activities. In most of the cases, the measurement of dynamic quantities such as acceleration or velocity is requested. This is related to the area of the evaluation of human comfort and structural damage induced by machinery or construction equipment. The continuous monitoring of static variables is also requested in many situations, especially related to the measurement of displacements and slopes in geotechnical works.

In the previous described areas, traditional measurement systems based on commercial equipment from well-known manufacturers have been used for a long time. However, many times these systems present some difficulties, which include: a) high cost; b) excessive dependence on external power supply; c) frequent failures in data acquisition attributed to heavy operating systems; d) difficulty in being physically integrated into structures, taking up too much space and being barely manageable, and; e) when using cables, the number of sensors is limited due to the exponential complexity of the data acquisition system [2]. In contrast, systems based on a new generation of sensors offers the following advantages: a) cost attractive; b) enable wireless solutions; c) autonomous and small size (easily integrated into structures); d) possibility of installation of high number of sensors; e) low power consumption (can run on batteries or solar panels); f) simplicity of functioning and robustness; g) low maintenance, and; h) may be easily adapted and customized [3].

In this context, this paper intends to divulge the alternative measurement systems to the classic ones, which were developed in the scope of the research activities conducted at CONSTRUCT/ViBest in the area of the new data acquisition systems. This includes sensors like accelerometers, geophones, and inclinometers.

2 THE ROLE OF THE NEW GENERATION OF SENSORS

The interest of the research in the area emerged from the technological evolution of the last decades in the topic of sensors and data acquisition systems based on microcontrollers. This was encouraged by the easy access to this technology and by the easy access to information available in the internet. In fact, the quantity of tutorials and blogs around this topic is immense.

At same time, researchers who work in actual structures with data acquisition systems, often face many challenges and problems. The lack of robustness of some traditional instrumentation solutions is one of these difficulties. The failure of these systems when working for long periods is not the only cause of that lack of robustness. Sometimes there also external causes like power failures and adverse weather conditions, beyond to other causes of diverse origin. Some data acquisitions systems are also too complex, involving too many cables and

connections. The high cost of measurement systems is another factor that hinders the widespread use of these systems in common Civil Structures.

In this context, the objective of the research in this area is to develop instrumentation that meets the following characteristics: i) wireless and compact size, for easy integration and installation in structures; b) robust, allowing the functioning of the system for long periods with no crashes; c) long autonomy; d) flexible, by allowing a variety of different sensors in several mounting schemes; e) accurate, and; f) cost attractive.

The role of these systems is not certainly to substitute the traditional systems. However, there are many applications where these instruments have the same effectiveness as the traditional ones, with additional advantages. In fact, they can simplify the process of installation and operation; they can be custom-made, including the use of 3D printing; maintenance and replacement is facilitated, and; more interesting, their attractive cost may allow the generalization of dynamic monitoring systems in Civil Structures. Nevertheless, the implementation of these new data acquisition systems also raises some challenges. Particularly with regard to the following issues: a) power supply; b) data transmission; c) reduced energy consumption; d) miniaturization of the systems, and; e) reliability.

3 DEVELOPED INSTRUMENTATION

3.1 Accelerometers

Acceleration is easy to measure and there are a lot of accelerometers models available in the market. The most updated version of a device using these sensors is composed of a tri-axis MEM accelerometer which is operated by means on an ATmega328P Microcontroller. It includes a Real-Time-Clock (RTC) and a microSD card breakout for saving data. In general, files of a duration of 10 minutes are organized in a folder structure identified according to the date and time of the measurements.

The main issue of these systems (and in all systems as a general problem) is the power supply. If the device can be powered with electrical current, this issue is resolved. However, the need of avoiding electrical cables scattered throughout the structure or construction area makes alternative energy solutions desirable. In this sense, solutions based on solar energy or batteries were developed. Solar energy allows high levels of autonomy. However, it is necessary to bear in mind that solar panels usually take up more space and need to be cleaned frequently. Figure 1a) indicates an accelerometer powered by a solar panel that is being used especially in the dynamic monitoring of bridges [4].

On the other hand, systems based on batteries do not depend on solar exposure and can be used in a more aggressive environments if appropriate enclosures are used. In addition, the size of the sensor may be adapted according to the needed autonomy. Figure 1b) represents a model powered by 3xAAA size batteries, which allows a continuous operation for about 1 week. If more autonomy is required, the model shown in Figure 2a) equipped with 5 li-ion batteries of 18650 type, may guarantee an autonomy of 15 weeks, and the model indicated in Figure 2b), equipped with 9 batteries of the same type, may power the sensor for 6 months.

All previous model may be fixed to structures by mean of 4 screws tightened against the box flange. Figure 3 shows a specific model directed for short period measurements in industrial or construction environment. The weight of this device allows it to simply be placed on the floor for measurement.

Figure 2: Accelerometer module: a) 5x18650 li-ion batteries; b) 9x18650 li-ion batteries.

Figure 3: Accelerometer used for short period measurements in industrial or construction environment.

3.2 Geophones

The measurement of velocity is many times required when evaluating the integrity of structures submitted to dynamic loads. This may happen essentially in construction work, when vibrations originated by construction machinery are propagated to nearby buildings. Standards like DIN 4150-3 [5] may be used for that evaluation in many countries.

In these measurements, the ideal situation is to have wireless solutions allowing data transmission, having at same time high autonomy. For this purpose, an integrated system was developed. It is composed of a set of sensors positioned in critical areas (see Figure 4a), which locally record the time histories of velocities in 3 axis, and periodically send the maximum vibration values via radio transmission to a receiver. In turn, the receiver shows the maximum values in an LCD to be observed by the person in charge (see Figure 4b). The LCD shows the maximum vibration levels in terms of total velocities of the last 10 minutes, of the last hour and of the last day. This way, it is possible to follow the history of the vibrations produced by the ongoing construction works. The maximum values are saved in a microSD located inside the receiver and may be accessed at any time. During the construction activities, if the maximum allowable values are exceeded, the device beeps and an alarm light.

This system is complemented with a device (Raspberry Pi, see Figure 4b) that sends the maximum vibration values to a server via the internet. This way, it is possible to remotely monitor the vibration levels of the construction, and draw graphs representing the history of the vibrations in the several measurement points.

One of the most important issue to be considered in this integrated solution, is the guarantee of the robustness of the system, as in this process some things may fail, especially with regard to the data transmission chain. Therefore, the recording of the original data inside the sensors is indispensable. In fact, data is recorded on a local microSD in each sensor, which may be accessed later to create a database of the signals.

The autonomy achieved with these sensors is about 1 month when using 6 li-ion batteries of 18650 type, which is considered a very good performance take into account that the signals are acquired continuously, with the exception of night and weekend periods.

At last, it must be mentioned that signals are primarily acquired in acceleration at a sampling frequency of 500Hz and integrated to velocity after applying the appropriate filters. The error in signals is less than 0.1 mm/s, which seams adequate for accessing vibrations admissibility.

a)  b) 

Figure 4: Measurement of velocities: a) Sensor unit; b) equipment for receiving and transmitting data.

3.3 Inclinometer

This sensor was developed for measuring the displacements profiles in the construction of pile walls. During the excavation process, it is often required to control the horizontal displacements of the wall in orthogonal directions. In this case, the topographic measurement of displacements is complemented with the measurement of displacements in tilt tubes placed on the back of the walls. The developed device is shown in Figure 5a). It consists of a probe that measures the inclination of the tube in 0.5-meter sections. The displacement profile of the wall is obtained by adding the contribution of each section from the base to the height of the tube. The measurement of the inclination is obtained by using a very precise 3 axis MEM accelerometer inside the probe, which enable the evaluation of the tilt by measuring the gravity acceleration in the 3 directions. It allows a resolution of the horizontal displacement 0.004mm/m and a maximum error of 0.02mm/m. The internal sampling rate of the accelerometer is 500 Hz, being each measurement of the slope obtained from the average of samples taken for 5 seconds.

The solution found for the data acquisition and storage module differs from commercial solutions, being able to be coupled directly to the tilt tube. This means that the device can only be operated by one technician, instead of the need of 2 persons, as is normally required (see Figure 5b). This module has an LCD for viewing records and internally contains a microSD card for saving the readings validated by the technician.

4 CONCLUSIONS

This paper describes the work developed at CONSTRUCT – ViBest research group located in FEUP, on the topic of a new generation of monitoring systems applied to Civil Structures, particularly related to dynamic and static measurements in industrial and construction environment.

It was pointed out that some traditional systems have some drawbacks, particularly related to the lack of robustness, complexity, and high cost. In the other hand, simpler systems based on new sensors may substitute that classical systems in certain applications, offering some advantages like the ease of installation and operation, less maintenance and attractive cost.

In this context, this document describes several measurement systems developed for the previously mentioned applications, which are shown to be sufficiently accurate when compared to commercial systems, which makes these systems a possible alternative solution to traditional systems in many practical cases.
